Persistence and viability of SARS-CoV-2 in primary infection and reinfections

ABSTRACT

Since the beginning of the SARS-CoV-2 epidemic, virus isolation in the infected patient was only possible for a short period of time and it was striking that this occurred constantly and did not provide guidance on the clinical course. This fact led to confusion about the efficacy of some of the drugs initially used, which seemed to have a high efficiency in viral clearance and proved ineffective in modifying the course of the disease. The immune response also did not prove to be definitive in terms of evolution, although most of the patients with very mild disease had a weak or no antibody response, and the opposite was true for the most severe patients.

With whatever the antibody response, few cases have been re-infected after a first infection and generally, those that have, have not reproduced a spectrum of disease similar to the first infection. Among those re-infected, a large number have been asymptomatic or with very few symptoms, others have had a moderate picture and very few have had a poor evolution.

Despite this dynamic of rapid viral clearance, laboratory tests were still able to generate positive results in the recovery of genomic sequences and this occurred in patients who were already symptom-free, in others who were still ill and in those who were very seriously ill. There was also no good correlate.

For this reason and with the perspective of this year and the half of pandemic, we compiled what the literature leaves us in these aspects and anticipating that, as always in biology, there are cases that jump the limits of the general behavior of the dynamics of infection in general.

RESUMEN

Desde el inicio de la epidemia por SARS-CoV-2, el aislaniento del virus en el paciente infectado era posible solo durante un periodo corto de tiempo y llamaba la atención que esto ocurriera de una manera constante y no orientaba sobre la evolución clínica. Este hecho, indujo a confusión sobre la eficacia de algunos de los fármacos utilizados inicialmente que parecían tener una gran eficiencia en el aclarado viral y que resultaron ineficaces para modificar el curso de la enfermedad. La respuesta inmune tampoco se mostraba definitiva para aventurar la evolución aunque la mayoría de los pacientes que tenían una enfermedad muy leve, tenían una débil o nula respuesta de anticuerpos y en los más graves pasaba lo contrario.

Con cualquiera que haya sido la respuesta de anticuerpos, pocos casos han vuelto a infectarse tras una primo-infección y generalmente, los que lo han hecho, no han reproducido un espectro de enfermedad similar a la primera infección. Entre los re-infetados, gran parte han sido asintomáticos o con
muy pocos síntomas, otros han tenido un cuadro moderado y muy pocos han tenido mala evolución.

Pese a esa dinámica de rápido aclaramiento viral, las pruebas de laboratorio podían seguir siendo capaces de generar positivos en la recuperación de secuencias genómicas y esto ocurría en pacientes libres ya de síntomas, en otros que seguían enfermos y en los muy graves. Tampoco había un buen correlato.

Por eso y con la perspectiva de este año y medio de pandemia recopilamos lo que nos deja la literatura en estos aspectos adelantando que, como siempre en biología, existen casos que saltan los límites del comportamiento general de la dinámica de la infección en general.

INTRODUCTION

Since the beginning of the SARS CoV2 infection pandemic, the scientific world has wondered about the pathogenesis of the disease, the persistence of viable viruses, the duration of transmissibility, and the risk of reinfection. Diagnostic tests based on the presence of nucleic acids persisted positive in some patients for weeks and even months and it took a certain period of time to demonstrate their dissociation with viral viability.

Over time, some unknowns such as those mentioned have been cleared up, but others such as the duration of immunity, vaccine efficacy, the risk of longer-term reinfections and the clinical forms of second infections appear.

The Committee on COVID of the Illustrious College of Physicians of Madrid, has received questions both about the persistence of the viral presence during primary infection and about reinfections that it has tried to answer after multidisciplinary discussions.

This document collects the questions received and the answers that in the current state of knowledge we have been able to offer.

WHAT ARE THE VIRAL DYNAMICS IN PRIMARY SARS-CoV-2 INFECTION AND THE SIGNIFICANCE OF MICROBIOLOGICAL TESTS DURING THE CLINICAL COURSE?

It is very well documented that, after the acquisition of the virus, the replicative curve and the consequent viral load has a great rise between the second and third day before the onset of symptoms, reaching their zenith immediately before and in the first week of the disease, to decrease in the following days [1-4].

The microbiological data on virus recovery, RNA quantification and pathogenic viability in cell line cultures reflect and are consistent with the transmission capacity and infectivity collected in epidemiological and observational studies during the pandemic [5, 6].

The recovery of viable viruses is estimated in 8 days after the onset of symptoms and the rate of RT-PCR cycles that suggest viral viability is estimated in equal or less than 28.

Immunosuppression is a conditioning factor that may prolong this time window, being exceptional in these cases a lapse of more than 20 days [3,7]. On the other hand, the clinical severity of the disease conditions the immune response and it is not clear if conditions also the viral dynamics [8].

Forty-four per cent of infections occur before the onset of symptoms [5] and in general, there is no transmission capacity from the tenth day of the onset of the disease. In fact, quarantine recommendations have been made for those infected with this criterion [9]. This does not mean that viral RNA cannot be recovered from organic samples beyond this period.

There are many studies that establish the re-positivity of RT-PCR in recovered patients, even those who had previously made the test negative. In a review of these series [10], figures ranging from 2.4% to the highest of 69.2% are given and with intervals from discharge from 1 to 38 days and up to 82 days after the onset of symptoms. The vast majority of patients are asymptomatic, but in some of these studies, up to 44.7% have some mild symptoms of those related to acute COVID; few have a worse course of the disease and some die [10-12].

The factors that determine this re-positivization (viral genetic material, viable or not), and its meaning (genome remains; viral persistence or even reactivation and finally reinfection) is determined by multiple factors, some of which are independent of the disease proper biology, such as technical errors (false negatives, false positives) and cross reactions with other coronaviruses.

Others depend on the biology of the virus itself, such as the initial viral load [13,14], the possible intermittent excretion or the different persistence time of the new variants [15]. Also, on the type of organic samples analyzed (high or low respiratory secretions, blood, feces) [4,16].

Finally, determining factors of the patient. The immune status is shown as a very determining factor, as well as the medications received and age.

Improving knowledge of the viral dynamics and its modifications with the different variants and with the immune response is essential to be able to speak with greater conviction about persistence, reactivation or recurrence and reinfection and to be able to sustain the quarantine recommendations for patients on recovery of the primary infection in the successive phases of the epidemic.

HOW MUCH AND WHAT DOES REINFECTION WITH SARS-CoV-2 INVOLVE?

Reinfection, defined as the positivization of the RT-PCR, beyond three months after the primary infection, (definition accepted in the literature) whether with clinical symptoms or not, is another face of the SARS-CoV-2 disease, well documented.

Considering reinfection with a criterion of microbiological as well as clinical certainty, goes beyond simply re-positivizing...
the RT-PCR. It requires demonstrating by genetic sequencing that the first and second episode viruses have a sufficiently different structure from what might be expected based on the mutation rate of the original inoculum. That is, to confirm that we are dealing with a differentiated clone or a phylogenetically different virus. Unviable demonstration in the day-to-day of most healthcare structures [17-20].

We know that with SARS-CoV-2 there is an early drop in antibodies titer, including low or no generation in mild clinical conditions [13, 22], although there are more and more studies that measure neutralizing antibodies (anti-S) and provide data on longer duration of these than ordinarily we titrate them in the standard clinical follow-up tests, suggesting that there may be a more durable protection than we initially intuited and more consistent with the reality of the observations [23, 24].

Added to this is the large number of patients who passed the primary infection asymptomatic and unnoticed (figures up to 10 times the clinically documented according to serological prevalence studies). Likewise, the casual observation in asymptomatic samples of RT-PCR positivity in subjects who have already passed the disease and are outside the known time frame for viral persistence or its genomic fragments.

In addition to the drip of communication of cases with the certainty of being faced with a different virus, and therefore defining reinfection [25-32], studies are appearing that focus the estimates of reinfection.

There is a Danish series of observational follow-up of a long court of infected with positive RT-PCR in the first months of the pandemic (until June 20), and measure how many of these are re-infected (September to December 20), 0.65% of them did.

A parallel cohort of not infected in the first wave, positivized up to 3.25%. The work shows that the primary infection generates an important but not total protection [33].

Austria has a retrospective observational epidemiological study along the same lines and, taking into account the weaknesses of these measurements, it gives equivalent figures in a proportion of 0.27% of reinfections and 2.85 of new infections in the second wave [34].

The British SIREN study performs clinical, serological and microbiological monitoring of two large cohorts of health personnel (younger and with greater exposure). One cohort with proven primary infection and another virgin to the infection. They once again demonstrate accumulated incidences of new infections in similar ratios (0.5% and 2.2% respectively). Again, significant protection is evidenced after natural infection, at least up to 5 months, but not complete. The study makes a comparison with what is known about vaccines and equates their protection to that of natural infection [35].

The new variants enter fully into reinfections and their clinical behavior and do so fundamentally due to their higher prevalence in a geographical location and at a specific time. The Marseille series is very demonstrative in this sense, confirming the British variant in reinfection and the initial Wuhan variant in the primary infection of its cases [39].

The United States provides another interstate series, based on a database of 3,257,478 persons with conventional serology performed (11.6% positive and 88.6% negative and 0.1% doubtful) and studies the number of PCR positives at an average follow-up time of 390 days per person and again shows infection rates of 0.3% for those initially serologically positive and 3% for those negative [37].

These repeatedly similar figures confirm, with different methodologies, a significant protection at least one year after immunization.

Reinfection considered only from a clinical point of view is a fact that is attended on time and with many probabilities that the frequency with which we see it is much lower than what happens in reality due to considerations of inadvertent disease, both for the first as for the second episode and the demonstrative figures from these observational studies.

The literature recognizes this and there are proposals to diagnose reinfection with clinical criteria [38].

Now we cannot even ensure that natural infection conditions a greater defense than vaccines for reinfection.

WHAT DOES REINFECTION LOOK LIKE CLINICALLY AND HOW IS THE IMMUNITY?

There are asymptomatic (most), some mild cases and others more severe than the first episode, even with a fatal evolution [28,29].

The biological advantages of infectivity and the possibility of escape from the previous immune response are determining factors, although at the moment the conjecture of laboratory studies of the neutralizing capacity of the sera of convalescent or post-vaccination patients is more than the real epidemiological evidence [35, 40-45].

We are already in a time of epidemic, in which it should become mandatory, at least in healthcare environments of medium complexity, to have, together with the RT-PCR positivity, more information on the strains found and the viral load or the cycle threshold obtained. We should process more samples and make a greater clinical, laboratory and immuno-microbial follow-up of those infected. Naturally in controlled and not indiscriminate studies.

Only then, when we accumulate series with more documentation after the disease produced by the different variants, the immune response to these and after the administration of the different vaccines, can solid conclusions be drawn about the natural history of COVID-19 and the effectiveness of protection.

Now we cannot even ensure that natural infection conditions a greater defense than vaccines for reinfection.
munsuppression is once again an evolutionary risk in reinfection [29, 43].

Regarding what we know about the immune status of the reinfected people, in most cases, serologies were not available after the first episode, in others it had become negative even though they had responded. Others had an adequate immune response even with neutralizing antibodies. Not enough information is available regarding specifically this type of anti-S antibodies and their protective quantification criteria.

What seems clear is that practically everyone makes an adequate antibody response in the first week of reinfection and this suggests that there is a cell population with memory that facilitates the rapid response.

In some cases, neutralizing antibodies are measured in the nasopharyngeal mucosa in the first week after reinfection [31].

Epidemiologically, it seems that there is a greater risk of greater exposure, as is the case with health-care workers.

Regarding the transmission capacity of the reinfeeted people, there is also little epidemiological data that they behave as index cases, although some reappear in small outbreaks.

Therefore, for the purposes of clinical care and protection against transmission, reinfection should be treated in the same way as primary infection.

WHAT CAN BE THE FUTURE OF REINFECIONS?

It is possible to speculate on the future evolution of re-infections, but in the light of our current knowledge, we can only assure that in the last months the work on reinfection remains in similar figures to those mentioned and the difference is the time lapse between the first and the second infection. It must be taken into account that there will be a very determining factor and it is the prevalence of the virus in the following months. If it continues to fall, both primary and re-infection will be lower. Vaccines are proving to be effective in the first week of reinfection.
