(Dated: February 3, 2009)

We measured the effects of periodic surface holes, created using a focused ion beam, on the phase diagram of the vortex matter in high-$T_c$ Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ crystals. Differential magneto-optical measurements show that the irreversibility line is shifted to higher fields and temperatures, with respect to the pristine melting line. The irreversibility line displays weak field dependence between integer matching fields indicating multiple-flux-quantum pinning at holes. We find reduced equilibrium compressibility of the vortex matter at integer matching fields, which is strong evidence for the existence of thermodynamic Mott insulator phases. Shaking with a transverse ac field surprisingly reveals first-order melting that is not shifted with respect to the pristine melting line and that seems to occur within the Mott insulator regions. This melting is understood to be the first-order transition in the bulk of the crystal beneath the surface holes. The transition is visible at the surface, despite the reduced vortex compressibility in the top layer.

I. INTRODUCTION

Experimental and theoretical studies of high-$T_c$ materials with correlated pinning centers have led to the discovery of many novel phases of vortex matter, non-existent in the pristine materials. These new phases arise from the complex interplay between intrinsic point disorder, correlated disorder, vortex-vortex interaction, and temperature. Correlated disorder in high-$T_c$ crystals is often introduced by heavy ion irradiation along the crystallographic c-axis, which leads to a random distribution in the a-b plane.$^{12}$ The effects of such random correlated disorder on the high-$T_c$ phase diagram are relatively well-understood, both theoretically$^{1,11,12,13}$ and experimentally.$^{11,12}$ Measurements of crystals with periodic correlated disorder are limited, since it is not yet known how to physically realize periodic correlated disorder in thick samples. Experimental studies of periodic disorder must therefore choose between two options: study of thin samples, or study of artificial pins located at the sample surface. Efforts have focused mainly on the study of thin superconducting films with periodic pinning centers.$^{13,14,15,16,17,18,19,20,21,22,23}$ However, thin films do not necessarily retain the thermodynamic properties of the bulk crystal, due to enhanced point disorder. Comparison of the resulting vortex phases to the thermodynamic phases of the pristine material is thus usually not possible.

Theoretically, the thermodynamics of vortices in the presence of random correlated disorder have been studied extensively. Nelson and Vinokur$^1$ mapped the pinned vortex matter onto a system of quantum 2D bosons. They predicted the Bose glass transition from the low-temperature Bose glass phase, in which vortices are localized, to a higher-temperature delocalized vortex phase. They also discussed the possibility of an incompressible Mott insulator (MI) phase, when the magnetic induction of the sample $B$ exactly equals the matching field $B_\phi = \rho \phi_0$, where $\rho$ is the density of the columnar defects. Radzihovsky$^5$ extended this model to include additional phases for $B > B_\phi$: a low-temperature weak Bose glass phase, in which both vortices residing at pins and those at interstitial sites are localized, an interstitial liquid phase at intermediate temperature, in which interstitial vortices are free to move but those at pinning sites are still pinned, and a homogenous liquid phase at higher temperature, in which all vortices are delocalized. For periodic pinning centers, the various Bose glass phases may be modified.$^{22}$ For periodic surface holes, even such a modified description is expected to be valid only within some finite depth from the surface of the superconductor.

Simulations of two-dimensional systems containing periodic pinning centers that allow only single-vortex occupancy demonstrate commensurate states at integer matching fields $nB_\phi$, with permitted values of $n$ depending on the geometry of the pinning centers.$^{22}$ Solutions of Ginzburg-Landau theory reveal additional commensurate states with multi-quantum vortices$^{20,27}$ for more general sample and pinning center parameters. Different melting scenarios have been demonstrated for triangular and kagomé arrays at low matching fields$^{22}$, and for square pinning arrays both at and in-between matching fields.$^{25}$ The square pinning array at the first matching field displays three phases: a low-temperature pinned solid with square geometry, an unpinned (“floating”) solid with triangular geometry, and a high-temperature liquid that lacks long-range order. At higher commensurate matching fields, the floating solid phase is not found, but an intermediate phase with mobile interstitial vortices similar to the liquid is observed. Incommensurate
fields display a pinned phase at low temperatures with extra vortices located at interstitial positions, a phase at intermediate temperatures in which some vortex motion is present with both interstitials and pinned vortices participating, and a phase at higher temperatures, in which all vortices are mobile. The temperature at which mobility is observed for incommensurate fields is lower than the melting temperature at the commensurate matching fields. For the triangular and kagomé geometries, melting at the first matching field involves a low-temperature pinned solid and a high-temperature liquid only. Intermediate-temperature phases, in which some or all of the interstitial vortices are mobile, are observed at higher matching fields. These melting transitions are expected to be most relevant to high-$T_c$ superconductors.

Direct imaging experiments of low-$T_c$ thin films with artificial periodic disorder have shown that highly ordered vortex states exist at integer $nB_\phi$ and fractional $(p/q)B_\phi$ matching fields, with $n, q$ and $p$ integers. Due to these ordered vortex states, such films have demonstrated commensurate effects in critical currents, magnetization, magneto-resistance and magnetic susceptibility measurements. Possible phases and phase transitions of the vortex matter have been inferred from these measurements. Enhanced flux creep rate for $B > B_\phi$ was thought to be evidence of a transition from an incompressible MI state to an interstitial liquid state. Shapiro steps in transport measurements were understood to be the result of the coexistence of vortices pinned to artificial pinning sites and mobile interstitial vortices. The behavior of the critical current was interpreted as evidence of two pinning mechanisms, corresponding to the upper boundaries of the weak Bose glass and interstitial liquid phases. Onsets of nonzero real and imaginary parts of the magnetic susceptibility were tentatively identified as the lower and upper phase boundaries of an interstitial liquid phase. In addition to these states, the possibility of a saturation number $n_s > 1$, corresponding to $n_s$ vortices at each pinning site, leads to multiple-quanta pinned vortex states, which have been observed in many samples.

There are fewer experimental data regarding the thermodynamic phases of high-$T_c$ superconductors with periodic artificial pinning centers. The critical current in YBa$_2$Cu$_3$O$_7$ (YBCO) thin films exhibited integer commensurate effects over a large temperature range. Scanning Hall probe measurements indicated that trapping of ~ 15 flux quanta is possible for 2.5 μm-diameter holes close to $T_c$ in YBCO. Thin crystalline Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ (BSCCO) samples with fully-penetrating periodic holes exhibited integer and rational matching effects, in magneto-resistance and transport measurements, respectively. Similar samples with surface holes also displayed matching effects in magneto-resistance and critical current. A single study using thick BSCCO samples with surface holes displayed integer matching in local magnetization. In these studies of BSCCO, the matching effects were visible in the field and temperature ranges at which the vortex matter is known to be in a liquid state in pristine crystals. No first-order melting step was measured in these samples, and a full description of thermodynamic phases and transitions is lacking.

In this work, we present an investigation of a thick BSCCO crystal, partially patterned with periodic surface holes created by a focused ion beam, measured using differential magneto-optics (DMO) accompanied by shaking with transverse ac field. We observe step-like behavior of the irreversibility line (IL), which may be a result of multi-quanta pinning to holes. We see a reduction in the DMO signal at integer matching fields, evidence of MI phases. We find a first-order melting transition (FOT) in the patterned regions that is not shifted with respect to the pristine melting line. This FOT is observed even at integer matching fields, where the vortex matter in the surface layer is essentially incompressible. We believe this FOT to be the melting transition of the bulk of the crystal beneath the patterned surface.

II. EXPERIMENTAL DETAILS

Several samples were prepared and studied. Here we present a detailed investigation of a ~ 2750 × 740 × 30 μm$^3$ BSCCO crystal ($T_c$ ~ 90.5 K), with two triangular arrays of periodic holes patterned on the top surface using an FEI Strata 400 focused ion beam system. Figures (a) and (b) show SEM images of the hole profile and period-

![Figure 1: (a) SEM image of the cross section of the surface holes. Hole depth is ~ 1.4 μm. (b) Part of one of the two arrays patterned on the sample, imaged by SEM. The distance between holes is 0.9 μm. (c) A DMO image of the sample at $T = 80$ K and $H = 21$ Oe. The sample's edge is the vertical border indicated by the arrow. The two $B_\phi = 29.5$ G arrays, M1 and M2 of 170 × 170 μm$^2$, appear as darker regions, due to their enhanced irreversibility. The irregular shape of M1 is a result of surface damage that occurred after writing the holes.](image-url)
ricity, respectively. The measured hole depth was approximately 1.4 µm. Hole diameter decreases from ~0.6 µm at the sample surface to ~0.3 µm at a depth of 0.7 µm. The lattice constant of both arrays was 0.9 µm, corresponding to a matching field of $B_\phi = 29.5$ G. The dimensions of each array were approximately $170 \times 170$ µm$^2$.

DMO measurements were performed by modulating the applied field $H$ by a constant field $\Delta H = 1$ Oe while sweeping temperature $T$ at constant $H$ or scanning $H$ at constant $T$. Each measurement point required averaging over $k$ CCD camera exposures, first at $H + \Delta H/2$ and then at $H - \Delta H/2$, and calculating a difference image. Each DMO image is the average of $m$ such difference images. Using $k, m \sim 10$ with a typical exposure time of 0.3 sec yielded a typical modulation frequency of $\sim 0.33$ Hz. Values of $dB/dH$ were derived from the DMO images by dividing the local light intensity by the intensity of some region far from the sample, where it was assumed that $dB/dH = 1$ G/Oe. For quantitative data analysis, intensities were spatially averaged over typical area of $\sim 50 \times 50$ µm$^2$. As described previously, the DMO measurement with field modulation is essentially equivalent to the measurement of the real component of the low-frequency local dc susceptibility as obtained e.g. by Hall sensors. Figure 2(c) shows a DMO image part of the sample, taken at $T = 80$ K and $H = 21$ Oe. The average brightness of the patterned areas M1 and M2 is lower than that of the neighboring pristine sample. This is due to an elevated irreversibility line (IL) in the patterned areas as described below.

III. RESULTS

We first inspect the IL of the patterned regions. The IL is important in the context of possible Bose glass phases because it is thought to be the dynamic manifestation of the thermodynamic Bose glass transition. In DMO measurements, reversibility of the vortex matter is quantified by modulating the applied field by $\Delta H$, and measuring $dB/dH$, the change in the local magnetic induction due to the modulation. Strong pinning results in $dB/dH = 0$, whereas full reversibility corresponds to $dB/dH = 1$ G/Oe. The irreversibility threshold in the following was chosen arbitrarily at $dB/dH = 0.8$ G/Oe, with $T_{IL}$ ($H_{IL}$) denoting the temperature (external field) at which this threshold is reached. We emphasize that the resulting IL reflects the response of the vortex system at low frequencies. Transport measurements or DMO with current modulation could possibly map out additional boundary lines similar to the delocalization line of vortices from columnar defects, however, such measurements are beyond the scope of the present study. Figure 2 shows $dB/dH$ for the pristine region (Fig. 2(a)) and patterned region M1 (Figs. 2(b) and 2(c)), measured by T scans at constant $H$.

Focusing on the pristine region (Fig. 2(a)), we see a series of sharp peaks in $dB/dH$ with paramagnetic $dB/dH > 1$ (light gray, light pink online), corresponding to the first-order melting transition $T_m$ from a low-temperature vortex solid to a high-temperature vortex liquid. The black dots in Fig. 2(b) show the pristine melting line $T_m$, extracted from Fig. 2(a). The patterned region M1 (Fig. 2(b)), in comparison, shows no FOT. It does, however, exhibit two notable features. First, the IL of region M1 is shifted to higher temperature. This is due to an elevated irreversibility line of region M1 in the patterned region. $T_m$ is denoted by black points. (c) $dB/dH$ in the patterned region M1 over a wide range of $T$ and $H$. Matching effects (denoted by arrows) are visible at $H = 33$, $64$, $95$, $126$, and 157 Oe, consistent with integer multiples of the predicted $B_\phi = 29.5$ G. The pristine melting line $T_m$ is denoted by black points. The patches in the data are a result of slightly differing setup parameters for the different experimental runs.

FIG. 2: (Color online) $dB/dH$, the change in magnetic induction due to field modulation of $\Delta H = 1$ Oe, for different sample regions, taken during T-scans. (a) A pristine region. The pristine melting line $T_m$ appears as a series of light gray (light pink) paramagnetic peaks in $dB/dH$ with values above 1 G/Oe. This particular run was carried out on a sparse grid in $T$ and $H$ of 0.4 K and 0.5 Oe (denoted by the lines in the lower left corner). The apparent discontinuity in $T_m$ is an artifact resulting from grid spacing being larger than the width of the melting peak. (b) $dB/dH$ of region M1 in the vicinity of the first matching field, $B_\phi = 29.5$ G. $dB/dH$ values are reduced compared to (a) and a narrow dip appears at $H = 33$ Oe. The location of the pristine melting line $T_m$ is denoted by black points. (c) $dB/dH$ in the patterned region M1 over a wide range of $T$ and $H$. Matching effects (denoted by arrows) are visible at $H = 33$, $64$, $95$, $126$, and 157 Oe, consistent with integer multiples of the predicted $B_\phi = 29.5$ G. The pristine melting line $T_m$ is denoted by black points. The patches in the data are a result of slightly differing setup parameters for the different experimental runs.
ggers, or narrow regions of $H$ in which $dB/dH$ of M1 is highly suppressed, occur at $H = 33, 64, 95, 126,$ and \( 157 \) Oe (denoted by arrows), consistent with integer multiples $B/B_\phi = 1, 2, 3, 4,$ and 5 of the predicted matching field \( B_\phi = 29.5 \) G. The minima in $dB/dH$ as a function of $H$ at matching fields are of both dynamic and thermodynamic origin. Enhanced pinning at matching fields suppresses vortex motion, and hence also $dB/dH$. As discussed below, these minima also indicate narrow ranges of $H$ with reduced equilibrium compressibility, since the compressional modulus $c_{11}$ is proportional to $dH/dB$\(^{15}\).

In addition to the fingers observed at integer $B/B_\phi$, we see that $T_{IL}$ between matching fields is step-like, with $T_{IL}(H)$ weakly dependent on $H$ between matching fields, and shifts in $T_{IL}(H)$ occurring at matching fields. For example, $T_{IL} \approx 76.5$ K for $3 < H/B_\phi < 4$, and $T_{IL} \approx 74$ K for $4 < H/B_\phi < 5$ (white contour).

We now focus on the IL of the patterned regions below and in the vicinity of the first matching field. Figure 3 shows $dB/dH$ measured simultaneously in the pristine region and in the patterned regions M1 and M2, for $B \lesssim B_\phi$. $T_{IL} (dB/dH = 0.8 \text{ G/Oe, white contour})$ of the pristine region is located below the pristine melting line $T_m$. In region M1 (Fig. 3(b)), $T_{IL}$ is shifted to higher temperatures at all fields when compared to the $T_{IL}$ of the pristine region (Fig. 3(a)). An additional sharp finger in the IL, extending to $T_{IL} \approx 87$ K, occurs near $H = 33$ Oe, or $B = B_\phi$. The IL of patterned region M2 (Fig. 3(c)) is shifted somewhat less, yet it too displays a sharp shift to higher $T$ at the matching field $B_\phi$. The reason for the difference in the shift of the IL of the two arrays may be a result of the difference in the arrays’ locations (M2 is closer to the sample’s edge) or due to some difference in the holes of the two arrays, which are not identical and may have different pinning properties. Still, for both arrays the IL is shifted upward, with an additional sharp finger at $B_\phi$. In BSCCO crystals irradiated with low concentration of CDs the sharp finger is absent. Instead, a kink is observed in the vicinity of $B_\phi$ which is believed to be the result of depinning of two different vortex populations. Below $B_\phi$, $T_{IL}$ is the temperature at which vortices located at CDs depin. Above $B_\phi$, $T_{IL}$ is the depinning temperature of interstitial vortices\(^{14}\). Also, fractional matching features have been observed\(^{27}\) in BSCCO samples with periodic surface defects. We do not detect any fractional matching features in the IL of the patterned regions; the reason for this is not clear, but is consistent with results shown elsewhere\(^{27}\).

The IL in BSCCO is known to be a dynamic feature of the phase diagram\(^{14,45-47}\). However, since it indicates a region of the phase diagram in which there is a change in the system’s dynamic response, it may indicate an underlying thermodynamic transition that occurs at similar values of field and temperature. In order to detect a possible underlying FOT, and to determine whether the reduced $dB/dH$ regions are truly a thermodynamic feature of the phase diagram, we studied the behavior of the first matching field in the presence of shaking. The shaking technique\(^{48}\) utilizes an in-plane, ac magnetic field. It is known to suppress hysteretic behavior in BSCCO, enabling the observation of thermodynamic properties\(^{49,50}\).

The effect of shaking is shown in Fig. 4 for the pristine and patterned regions M1 and M2 at 77 K. Increasing shaking amplitude $H_{ac}^\bot$ leads to a systematic increase in $dB/dH$, which saturates near 1 G/Oe, as expected for a fully penetrable sample. A feature common to all three plots in Fig. 4 and thus unrelated to the surface holes, is an abrupt change from zero to negative $dB/dH$ at $\approx 8$ Oe. Below $\approx 8$ Oe, the sample is in the Meissner phase, with $B = 0$. $dB/dH < 0$ immediately above the Meissner phase corresponds to negative local permeability\(^{51}\). This effect, which occurs in BSCCO samples with platelet geometry, is a result of the geometrical barrier\(^{52-54}\) and the modulation of the vortex dome during the modulation cycle of the applied field $H \pm \Delta H/2$. This negative permeability is also visible as a black strip at low fields in Fig. 3(a). It is interesting to note that the negative $dB/dH$ values are not visible at the highest shaking amplitude, $H_{ac}^\bot = 121.8$ Oe. This indicates that the shaking field enables the vortices to overcome the geometrical barrier. Consequently, the local negative permeability changes to high positive local permeability, as seen in Figs. 3(a) and 3(c). This is the expected behavior in the absence of geometrical barriers, as demonstrated for prism-shaped samples\(^{54}\).

There are two notable differences between the pristine (Fig. 3(a)) and patterned (Figs. 3(b) and 3(c)) regions. The first difference is the appearance of the matching feature in the form of a dip in $dB/dH$ near 32 Oe, denoted by arrows in Fig. 4. Shaking extends the range of temperatures for which this dip is visible well into the vortex solid region below $T_m$. Without shaking, the first match-
Fig. 2), due to the enhanced pinning in the vortex solid. The plateaus in $dB/dH$ vs. applied field $H$ for low $H_{ac}^\perp$ that develops into a dip for higher $H_{ac}^\perp$ are visible also for higher matching fields. Interestingly, increasing $T$ and increasing shaking amplitude $H_{ac}^\perp$ have similar effects on $dB/dH$ immediately below the IL. This can be seen by comparing Figs. 5(a) and 5(c), in which $dB/dH$ of region M2 in the vicinity of $B/B_\phi = 2.3$ is plotted for different values of $H_{ac}^\perp$ and $T$, respectively. Increasing $H_{ac}^\perp$ and increasing $T$ (bottom to top curves) both tend to increase $dB/dH$, and both have the effect of transforming the matching feature from a step to a dip. However, the overshoot in $dB/dH$ immediately below the matching feature appears only at nonzero $H_{ac}^\perp$. Similar behavior is observed for $B/B_\phi = 3.4$ in Figs. 5(b) and 5(d).

We now address the question of first-order melting within the patterned regions in the presence of shaking. For the results shown below, we applied a 15 Hz, $H_{ac}^\perp = 81.2$ Oe shaking field. We find that shaking shifts the IL to lower fields and temperatures and thus enables the observation of a FOT in the patterned regions of the sample. Figure 6 shows detailed scans of the $H$–$T$ region in which the pristine $T_m$ line intersects the $B/B_\phi = 1$
matching line. \(dT/dH\) is shown for both patterned regions and for the pristine region, without and with shaking (top and bottom panels, respectively). For the pristine region (Figs. 6(a) and 6(b)), \(dB/dH\) at lower \(T\) and \(H\) is raised slightly by shaking, and the pristine melting line \(T_m\), which appears as a line with paramagnetic \(dB/dH > 0.1\) G/Oe (light gray, light pink online), remains essentially unchanged. For the patterned region M1, no FOT was visible without shaking (Fig. 6(c)). With shaking (Fig. 6(d)), a FOT became visible. It appears to be located at the same temperatures and fields as the pristine melting line \(T_m\). Remarkably, the \(T_m\) line is clearly visible even at the bottom of the \(B_\phi\) matching dip. For the patterned region M2, shaking was not needed to uncover the FOT (Fig. 6(e)). While shaking raised \(dB/dH\) values overall, it did not change the location or the nature of the FOT (Fig. 6(f)). Similar results are shown for \(B/B_\phi = 2\) in Fig. 6. In this case, shaking was necessary to view the FOT in both patterned regions M1 (Fig. 7(c) and 7(d)) and M2 (Fig. 7(e) and 7(f)). Note that the location of the FOT of the patterned regions in the phase diagram is indistinguishable from the location of the pristine melting line, \(T_m\). Moreover, \(T_m\) and the \(nB_\phi\) lines seem to intersect with no apparent interaction, as if the periodic pinning potential of the holes has no effect on melting. No additional FOT was detected for either of the patterned regions. We emphasize that at the points in the phase diagram where the FOT meets the matching fields, a contradictory behavior of the vortex lattice occurs. On one hand, at the FOT there is a jump in vortex density. On the other hand, at matching fields the vortex matter exhibits a strongly enhanced compressibility modulus \(c_{11} \sim (dB/dH)^{-1}\) that exists both below and above \(T_m\). This apparent contradiction is discussed below.

IV. DISCUSSION

In order to understand the observed behavior of the IL, we consider two possible physical scenarios\(^{23}\). In the first scenario, shown schematically in Fig. 5(a), we assume that each hole can pin only a single vortex. As a result, two vortex populations are present for \(B > B_\phi\): vortices located at holes, and interstitial vortices located between holes. The interstitial vortices are subject to a caging potential caused by the vortices located at holes\(^{23}\) that is assumed to be weaker than the pinning potential at holes, but stronger than the pristine pinning. This gives rise to a depinning transition of the interstitials, which we identify with \(T_{IL}\), at a temperature above the pristine melting temperature \(T_m\). Alternatively, we consider a scenario in which there is multi-quanta pinning by holes. We assume that below the IL, all vortices are located at holes, while above the IL, some vortices are depinned from holes, and thus mobile, as shown schematically in Fig. 5(b). Due to repulsion between pinned vortices, the pinning force per vortex is expected to decrease as a function of the number of vortices pinned to the hole\(^{23}\). We therefore assume that the pinned vortices residing at holes depin one at a time, as \(T\) is increased. Within this multi-quanta scenario, \(T_{IL}\) corresponds to the temperature at which the first vortices depin from holes. Either of the two scenarios must provide an explanation for the observed behavior of the IL: the plateaus in the IL away from matching, the shift in the IL to lower \(T\) and \(H\) in the presence of shaking, and the sharp dips at the matching fields.

We begin with the plateaus and steps in the IL. In the multi-quanta scenario, the maximum number of vortices per hole \(n_{max}(T)\) is determined by temperature-dependent hole pinning strength and repulsive interactions between vortices located at the hole, and decreases with increasing temperature\(^{23}\). We denote the tempera-
Finite temperature and slight hole variability are likely to cause some variation in $n_{\text{max}}(T)$ at different holes. This would lead to some smearing of the irreversibility transition and to a weak dependence of $T_{1L}$ on $B$ between matching fields due to different mixing of the $T_n$ as field is varied. This schematic description neglects the effects of thermal fluctuations, which will be discussed later on.

The IL shown in Fig. 8(c) (white contour) indicates that $T_{1L}$ displays three discrete steps in the temperature range $T = 72 - 77$ K. The weak temperature dependence of the IL between matching fields, as well as the plateaus in $dB/dH$ in Figs. 4 and 5 seem to indicate that the IL is not strongly affected by interactions between vortices at neighboring holes. Rather, it is governed by the hole pinning energy and the repulsion between vortices within a single hole, leading to the step-like $T_{1L}$. Within the single-vortex pinning scenario, in contrast, $T_{1L}(H)$ is the depinning temperature of interstitial vortices, that is expected to decrease rather smoothly with field as the density of interstitials increases.

We now address the the shift of the IL to lower temperatures in the presence of shaking. Shaking and increased thermal fluctuations seem to have a similar effect on the IL (see Fig. 5). Within the multi-quantum scenario both provide a mechanism for hopping of vortices between vacancies at holes, thus increasing the dynamic $dB/dH$ and decreasing $T_{1L}$. Between matching fields and slightly below $T_{1L}$, the holes are below their full pinning capacity, so shaking may provide a way for vortices to hop between holes more easily, or to depin from holes and move to interstitial positions. The plateau-like behavior indicates that this shaking-induced hopping is roughly independent of the number of vacancies that exists. Instead, the degree of hopping or depinning is dependent on the balance between the roughly field-independent pinning energy of the $n_{\text{max}}$th vortex and the activation energy of the applied shaking. Within the single-vortex pinning scenario, above the IL the interstitials are mobile, therefore immediately below the IL they are weakly pinned. Shaking will thus assist in overcoming the weak pinning potential, decreasing $T_{1L}$. The existence of the plateaus, however, cannot be easily explained in this case.

We now address the third experimental finding, namely the finger-like dips in $dB/dH$ at matching fields. Focusing on Figs. 6 and 7 we see that unlike the rest of the IL, the temperatures at which the fingers terminate are not affected by in-plane shaking. This strongly suggests that unlike the IL, which is a dynamic feature of the phase diagram, the fingers at matching fields are a thermodynamic feature. A thermodynamic minimum with $dB/dH = 0$ would indicate a plateau in the equilibrium $B(H)$ and a diverging bulk modulus $c_{11} \sim \partial H/\partial B$ clear signatures of the incompressible MI phase. The finite, positive minima observed in $dB/dH$ (see Figs. 4(b), 4(c), and 5) correspond to a reduction in the positive slope of $B(H)$ at $nB_\phi$. These finite values at $nB_\phi$ may be a consequence of the finite size of the patterned region, which prevents infinite divergence of $c_{11}$, or of the broadening of $dB/dH$.
due to the modulation of $\Delta H = 1$ Oe, which is at least as wide as the width of the dip. For samples with random defects, it has been argued that the MI phase is destroyed by repulsive vortex interactions, possibly retaining “lock-in” effects such as a finite peak in the bulk modulus $c_{11}$. In our measurements, however, the pinning is ordered. At matching fields, pinning energy and vortex-vortex interactions both stabilize the vortex lattice. In this case, observation of a MI phase is possible. We believe that the sharp matching features we observed in $dB/dH$ at $nB_\phi$, that are not affected by shaking, are a strong indication of thermodynamic MI phases.

The fingers of reduced $dB/dH$, or MI phases, may be understood in the context of the multi-quantum scenario. For $(n-1) < B/B_\phi < n$ and $T < T_n$, in the absence of thermal fluctuations, all vortices are pinned to holes (see Fig. 8(c)). The maximum number of vortices that can be pinned $nB_\phi/\phi_0$ is greater than the actual number of vortices $B/\phi_0$, resulting in below-full occupancy, or “vacancies”, at some of the multi-quantum holes. Thermal fluctuations (which were neglected in the schematic description in Fig. 8(c)) are expected to lead to vortex hopping between the vacancies, resulting in enhanced vortex mobility. Thus, for $(n-1) < B/B_\phi < n$, vortex dynamics lead to a reduction in $T_{IL}$ from $T_n$ (Fig. 8(c), dashed lines) to some lower temperature $\tilde{T}_n$. Exactly at matching, an additional thermodynamic consideration enters. The total hole capacity equals the number of vortices, and therefore there is a finite energy cost for adding an extra interstitial vortex. As a result, the equilibrium $B(H)$ will exhibit a plateau over a finite range of $H$, that is not affected by shaking. The corresponding minima in $dB/dH$, or equilibrium MI phases, may thus be observed up to $T_n$ (black fingers in Fig. 8(d)).

The fingers of reduced $dB/dH$ may also be partially understood within the single-vortex pinning scenario. At matching fields, we expect both the vortices at holes and the interstitials to be ordered in a configuration commensurate with the hole array, that enhances the pinning potential and may result in a thermodynamic MI phase. Although this picture is correct for commensurate matching fields ($B/B_\phi = 1, 3, 4, 7$, etc. for a triangular array of holes), it is not strictly correct for incommensurate matching fields. At $B/B_\phi = 2$, for example, there are two interstitial positions with equal energy per unit cell. This would imply that hopping of interstitials is possible also at incommensurate matching fields, resulting in greater interstitial mobility, and hence a weaker matching effect. This is not what we observe in Fig. 8(c), where the fingers appear similar at the first and second matching fields.

We now consider the theoretical plausibility of the multi-quantum scenario. The condition given for multi-quantum pinning in holes in $r^3 > \xi\lambda^2$ for $\lambda \ll d$, where $r$ is the hole radius, $d$ is the inter-hole distance, and $\lambda = \lambda_0/\sqrt{T-T_c}$ is the London penetration depth. For $r = 0.2$ $\mu$m, and $\lambda_0 = 0.15$ $\mu$m, we may expect multiple-quantum vortices for $T \leq 88$ K for our sample.

We now estimate the number of vortices pinned at a hole as a function of temperature. We consider two physical possibilities, following Ref. 50. The first is that the $n$th vortex is pinned as long as there is some force near the edge of the hole that pushes it inwards. This corresponds to a pinned state that may be metastable, depending on its free energy. The saturation number

$$n_s \approx r/(2\xi)$$

is the maximum $n$ for which this occurs. The second possibility for multiple-quantum pinning is to require an equilibrium pinned state, namely, the free energy of the $n$th vortex located in the hole must be lower than its free energy far from the hole. In this case, the number of pinned vortices is given by

$$n_0 \approx \frac{1}{2} \ln \frac{r}{2\xi} \frac{2\lambda T}{1.78\sqrt{\mu_n}}.$$  

Both $n_s$ and $n_0$ decrease with $T$, which is consistent with the observed downward steps in $H_{IL}(T)$. Substituting $r = 0.2$ $\mu$m, $\xi = 2$ nm, $\lambda_0 = 0.15$ $\mu$m, and $T_c = 90.5$ K, we obtain $n_s = 1 - 21$ for $T = 90.46$ K down to $T = 74.5$ K and $n_0 = 1 - 2$ for $T = 85.2$ K down to $T = 76.1$ K. Note that Eq. 2 was derived from the pinning energy of a single hole. In the case of an array of holes, one should compare the free energy of a pinned nth vortex to its free energy at the midpoint between two neighboring holes. At this midpoint, there are positive contributions to the free energy from the neighboring occupied holes. Thus a higher free energy of the pinned vortex, or $n > n_0$, would still be an equilibrium state of the system. Eq. 2 should therefore be considered a lower limit on the equilibrium number of vortices pinned to a hole. The fact that interactions should raise estimated occupation numbers was also noted by 51.

We now compare these theoretical estimates to the experimental values of $n_{\text{max}}$. We observed three decreasing steps in $T_{IL}$ (see Fig. 3(c)), with $T_1 \approx 72$ K, $T_2 \approx 75$ K, and $T_3 \approx 77$ K. According to the schematic phase diagram plotted in Fig. 8(d), the values of $\tilde{T}_n$ are lower than the temperatures $T_n$ at which the $n$-th multi-quantum vortex depins in the absence of thermal fluctuations. From the schematic description in Fig. 8(c), we see that the difference $T_n - \tilde{T}_n$ may be estimated from the difference in the $T_{IL}$ at, and slightly away from, $B/B_\phi = n$. From Figs. 4(c) and 7(c), we estimate this difference to be $T_n - \tilde{T}_n \approx 2$ K. $T_3$, $T_5$, and $T_4$ are thus 74, 77 and 79 K, respectively, or equivalently, $n_{\text{max}}(T < 74) = 6$, $n_{\text{max}}(74 < T < 77) = 5$, $n_{\text{max}}(77 < T < 79) = 4$, and $n_{\text{max}}(T > 79) = 3$. We find that the extracted $n_{\text{max}}$ values are much lower than the estimated $n_s$ and, slightly higher than the estimated $n_0$. Thus the equilibrium multi-quantum pinning scenario described by Eq. 2 is more plausible. Note, however, that Eqs. 1 and 2 are based on the assumption of fully penetrating holes;
the number of vortices trapped by surface holes may be lower.

Summarizing our discussion of the IL, the multi-quantum scenario provides a more consistent explanation as compared to single-vortex pinning, both for the steps in the IL and for the similar MI fingers at both commensurate and incommensurate matching fields. Indeed, recent simulations of BSCCO with surface holes similar to those in the experiments indicate that multiple-quantum occupation of surface holes does occur, and that depinning may occur directly from holes.

Finally, we address the apparent contradiction of observing a FOT within the patterned regions at matching fields $B/B_\phi = 1, 2$, as shown in Figs. 6 and 7. The observed FOT occurs at the same field and temperature values as the pristine solid-liquid transition $T_m$, and we therefore assume that both transitions are of similar nature. This, however, seems to contradict the existence of MI phases at matching fields, since in the MI phase the vortex lattice is ordered, pinned, and incompressible, up to temperatures well above the pristine $T_m$.

The observed FOT can be understood qualitatively by taking the bulk beneath the surface holes into account. The surface holes are only $\sim 1.4 \mu m$ deep, whereas the sample is $30 \mu m$ thick. Although the depth at which vortices are still sensitive to surface patterning is not known exactly, magnetic decorations of BSCCO crystals with square Fe periodic surface patterns indicate that the hexagonal structure of the lattice is recovered fully just $4.5 \mu m$ beneath the pinning potential at low temperatures. Thus one may expect that sufficiently deep below the upper surface, the vortex “tails” will undergo a first-order melting transition at the pristine $T_m$. At matching fields, however, the “tips” of the vortices at the surface are pinned to the periodic surface holes, and therefore behave as an incompressible solid. The resulting situation immediately above $T_m$ is rather unique: the vortex “tips” are in a solid MI state, while the vortex “tails” are liquid. At the FOT, the vortex density in the bulk increases by $\Delta B/\phi_0$, where $\Delta B$ is the typical step in $B$ at $T_m$. If the “tips” of the vortices were fully incompressible, this $\Delta B$ in the bulk would be completely shielded and unobservable at the top surface. Our data indicate, however, that within our experimental range of parameters the compressibility is high, but finite. Hence the MI top layer is sufficiently transparent to allow observation of the paramagnetic peak at the FOT of the underlying vortex “tails”. We conclude that upon increasing temperature, the FOT observed within the patterned region at matching fields indicates a transition from a solid bulk with an incompressible solid surface to a unique state of an essentially incompressible solid crust of vortex “tips” concealing a vortex liquid in the bulk.

It is interesting to note that this solid crust could be used as a tool to study the interesting possibility of surface melting that was suggested to exist in the vortex lattice, similar to surface wetting in atomic solids. This will require investigating crystals of different thicknesses and samples patterned with holes at both the top and bottom surfaces.

No additional FOTs were observed, even in the presence of shaking. This indicates that the depinning line of the interstitial vortices, and the delocalization line of the vortices pinned to holes, are apparently not FOTs. More accurate magnetization measurements in the presence of shaking are needed to check for the existence of second-order thermodynamic transitions.

V. CONCLUSIONS

BSCCO crystals with arrays of surface holes were measured using differential magneto-optics accompanied by an in-plane shaking field. We observe reduced $dB/dH$ of the patterned regions at integer matching fields $B = nB_\phi$. These features are extremely narrow, with a width in $H$ of less than 1 Oe. The region of reduced $dB/dH$ extends up to 87 K for the first matching field, terminating 3.5 K below $T_c$. Shaking allowed the equilibrium matching feature to be observed both above and below the pristine melting line of the sample. This observation is in contrast to previous dynamic measurements of BSCCO crystals with periodic surface holes, in which matching effects were observed only well above the pristine melting line. Our finding of a sharply suppressed compressibility of an equilibrated vortex lattice at the matching fields is a strong evidence of the existence of Mott insulator phases.

We observe a first-order melting transition within the patterned areas, both away from matching and at the first and second matching fields. Surprisingly, this transition is not shifted with respect to the pristine melting transition. We interpret this transition as first-order melting of the vortices in the pristine bulk beneath the patterned surface, that results in a step in vortex density. The added vortex “tails” beneath the patterned surface force vortex “tips” through the surface, even in regions of reduced compressibility. We emphasize that this is an extremely unusual situation, in which the vortex tails located in the bulk are in a liquid phase, while their tips located near the surface are in a pinned, ordered phase, and therefore solid.

The irreversibility line of the patterned regions is found to be shifted upward in $H$ and $T$ to above the pristine melting line $T_m$, and displays step-like behavior, with almost no temperature dependence between matching fields $B = nB_\phi$. These steps are consistent with a multi-vortex pinning scenario, with an estimated maximum value of $n_{max} = 6$ flux quanta pinned to each surface hole at $H/B_\phi \geq 5$ and $T \leq 72$ K.

Applied shaking shifts the irreversibility line to lower field and temperature, enabling the observation of the first-order transition. However, no first-order transitions related to the surface holes, corresponding to depinning lines of interstitial vortices, or delocalization of vortices pinned to holes, were observed. Further transport mea-
measurements are necessary to determine if an additional de-localization line exists at higher temperatures, in analogy to the delocalization line of the vortices residing on columnar defects, that separates the interstitial liquid from a homogeneous liquid.[12]
