Abstract

Motivation: Identification of system-wide causal relationships can contribute to our understanding of long-distance, intercellular signalling in biological organisms. Dynamic transcriptome analysis holds great potential to uncover coordinated biological processes between organs. However, many existing dynamic transcriptome studies are characterized by sparse and often unevenly spaced time points that make the identification of causal relationships across organs analytically challenging. Application of existing statistical models, designed for regular time series with abundant time points, to sparse data may fail to reveal biologically significant, causal relationships. With increasing research interest in biological time series data, there is a need for new statistical methods that are able to determine causality within and between time series data sets. Here, a statistical framework was developed to identify (Granger) causal gene-gene relationships of unevenly spaced, multivariate time series data from two different tissues of Arabidopsis thaliana in response to a nitrogen signal.

Results: This work delivers a statistical approach for modelling irregularly sampled bivariate signals which embeds functions from the domain of engineering that allow to adapt the model’s dependence structure to the specific sampling time. Using maximum-likelihood to estimate the parameters of this model for each bivariate time series, it is then possible to use bootstrap procedures for small samples (or asymptotics for large samples) in order to test for Granger-Causality. When applied to the A.thaliana data, the proposed approach produced 3078 significant interactions, in which 2012 interactions have root causal genes and 1066 interactions have shoot causal genes. Many of the predicted causal and target genes are known players in local and long-distance nitrogen signalling, including genes encoding transcription factors, hormones and signalling peptides. Of the 1007 total causal genes (either organ), 384 are either known or predicted mobile transcripts, suggesting that the identified causal genes may be directly involved in long-distance nitrogen signalling through intercellular interactions. The model predictions and subsequent network analysis identified nitrogen-responsive genes that can be further tested for their specific roles in long-distance nitrogen signalling.

Availability and implementation: The method was developed with the R statistical software and is made available through the R package ‘irg’ hosted on the GitHub repository https://github.com/SMAC-Group/irg where also a running example vignette can be found (https://smac-group.github.io/irg/articles/vignette.html). A few signals from the original data set are made available in the package as an example to apply the method and the complete A.thaliana data can be found at: https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE97500.

Supplementary information: Supplementary data are available at Bioinformatics online.
1 Introduction

Time series data are important for understanding the biological processes that are activated at different times and for inferring causality (Bar-Joseph et al., 2012). Many time series studies are designed to analyze dynamic and stationary processes in response to changes in the environment, which result in unevenly spaced time points, with dense sampling early and sparse sampling at later time points (Colon et al., 2010; Gargouri et al., 2015; Krouk et al., 2010; Spellman et al., 1998; Zha et al., 2000). In biology, this is a commonly used sampling scheme to efficiently capture transient transcriptional and metabolic responses for example. However, the analysis of this irregular data is challenging, among others, since traditional time-lagged or cross-correlation analyses, designed for regularly spaced intervals, cannot be used. To date, it can be argued that no statistical approach has been able to comprehensively account for these unique features common to many biological time series (see e.g. Rehfeld et al., 2011).

Among the current approaches, methods designed for time-independent or regularly-spaced processes have been used to analyze unevenly-spaced time series data. For example, ‘static-based’ clustering methods like hierarchical clustering and K-means have been used to organize and identify genes differentially expressed over development time in *Zea mays* (Chen et al., 2014), or in response to drought stress in *Arabidopsis thaliana* (Bechtold et al., 2016). However, clustering methods are not suitable to predict causal relationships between genes. Hence, other employed approaches include, among others, the transformation of irregularly sampled data into evenly spaced time series (Hamilton, 1994), in which the irregularity of the time interval can be approximated by forced regular intervals (Maller et al., 2008), or (resampling) strategies that estimate missing data points to fill in gaps between observations (Broersen and Bos, 2006; Remondini et al., 2005; Thiebaut and Roques, 2005). Other methods directly address the irregular nature of the processes but do not consider the multivariate dependence and, consequently, the causal relation between signals (see e.g. Erdogan et al., 2005; Eyheramendy et al., 2018). These approaches have different drawbacks (Eckner, 2014) including: (i) an inability to capture the variable nature of multivariate dynamic transcriptome experiments; and (ii) resampling strategies often change the Granger-causal relationship of the multivariate time series (Bahadori and Liu, 2012). All of these approximations can lead to incorrect correlations and predictions, and are unable to determine causal relationships within or between time series. Another commonly used approach in the analysis of (biological) time series is to perform a correlation analysis which however often does not account for non-stationary features of the data (Gargouri et al., 2015; Zhao et al., 2006). Indeed, the latter form of analysis can be highly misleading, for example, the mean and/or variance of the series change over time which can often be the case for many experimental settings.

In response to the above limitations, this work puts forward a statistical approach that provides a general framework to determine Granger-causality (Granger, 1969) for (short) irregularly sampled bivariate signals. Broadly speaking, a time series (say x) ‘Granger-causes’ the other (say y) if the prediction of future values of y, based only on its past values, is significantly improved when also using passed values of x. Considering this intuitive definition, existing approaches have been proposed to perform Granger-causal analysis in (unevenly sampled) biological (and other) signals for stationary networks (Shojaie and Michailidis, 2010; Zhang et al., 2010) or for dynamic models (Carlin et al., 2017; Fujita et al., 2010; Zhang et al., 2010). However, for the specific purposes of this work, these existing methods either (i) lack the dynamic component (e.g. the dependence structure changes based on the distance between observations), or (ii) do not include statistical inference tools to ascertain significant relationships or (iii) do not include information on the sign, delay and intensity of the detected causal relationship (or do not capture a dynamic change of these properties). As a result, the proposed approach tackles the problem of detecting Granger-causal relationships in dynamic transcriptome studies for plants by addressing all of the above points. While in this work it is employed for dynamic transcriptome studies, this approach could be applied broadly to different problems dealing with causal relationships such as ‘omics’ data sampled irregularly over time, allowing researchers to uncover and explore causal relationships between same signals (e.g. gene-gene, metabolite-metabolite) separated in space (e.g. roots and shoots of the same plant), but also between different signals in the same or different spaces (e.g. gene-protein, gene-metabolite, protein-metabolite). This can be relevant for the increasing prevalence of scRNA-sequencing or, more specifically, for the multiplexed fluorescence in situ hybridizations.

As stated earlier, in this work we specifically use this approach to describe causal gene-gene relationships from above- (shoot) and below- (root) ground organs of *A. thaliana* in response to a nitrogen signal. Through identification and bioinformatic exploration of the detected causal relationships, we achieve a greater understanding of the underlying molecular and biochemical pathways involved in the nitrogen-signal response. This increase in understanding of nitrogen-responsive biochemical pathways in different plant tissues may help to predict emergent plant properties under nitrogen sufficiency and deficiency. Further testing of model-predicted causal relationships may uncover new molecules, pathways, and processes involved in the root-to-shoot-to-root nitrogen-signal relay, providing biological insight into complex, whole-plant nitrogen response.

2 Granger-causal analysis for irregular data

An irregularly spaced time series is a sequence of observations that are observed in time in a strictly increasing manner but where the spacing of observation times is not necessarily constant. More formally, let $(t_i; i = 1, \ldots, n) \in \mathbb{T}_n$ denote a strictly increasing time sequence of length $n$ where:

$$\mathbb{T}_n = \{(t_1 < \cdots < t_n) : t_i \in \mathbb{R}, 1 \leq i \leq n\}$$

In addition, let $(X_i; i = 1, \ldots, n) \in \mathbb{R}^n$ and $(Y_i; i = 1, \ldots, n) \in \mathbb{R}^n$ denote two sequences of real-valued random variables such that we can denote a bivariate irregularly spaced time series with $n$ time points, as $(t_i, X_i, Y_i; i = 1, \ldots, n)$, where $t_i$ denotes the time at which $X_i$ and $Y_i$ are to be observed. In the context of this paper, we focus on those random sequences that are observed at the same points in time (i.e. the sequences $(t_i; i = 1, \ldots, n)$ correspond for both series). However, as discussed further on, this condition can also be relaxed as a result of the research developed in this work.

As highlighted previously, the literature on irregularly spaced time series is not abundant and methods available to practitioners for estimation and inference in these cases are lacking as well. In this section we therefore put forward a pertinent statistical model that we will denote as $F = \{F_\theta : \theta \in \Theta \subset \mathbb{R}^p\}$, with $\Theta$ being the vector containing the parameters of this model. The latter model needs to deal with irregularly spaced bivariate time series and should allow to test for Granger causal links between the series themselves. In order to achieve this goal, we firstly define $\mu(x)$ and $\mu(y)$ as the expected values of $X_i$ and $Y_i$, respectively. These quantities represent, in the case of dynamic transcriptome data, the natural (deterministic) variation in gene expressions due, for example, to changes in environmental conditions or natural cycles and would remove all external effects that would generate correlation between the signals (as opposed to correlation induced by the idiosyncratic signal behaviours which is the aim of a Granger-causal analysis). In addition, removing the mean allows to make the signals (mean) stationary and to employ models and reliable inference frameworks for such settings. In the latter sense, if we were considering evenly spaced observations, it would appear reasonable to consider the class of AutoRegressive Moving Average (ARMA) models to describe the variations of $(X_i)$ around its mean (see e.g. Box et al., 2015, for details). A commonly used model within this class, especially when dealing with small sample sizes, is the first-order autoregressive model, i.e. an AR(1), which is defined as
where $\rho$ represents the parameter which explains the dependence between consecutive observations and $W_t$ is an independent sequence of random variables with a certain (finite) variance $\sigma^2$. This model allows to approximate many covariance structures delivering a behaviour that is often reasonable for many biological and natural phenomena. In order to determine whether another time series (signal) has an impact on the time series under consideration, the above model can be extended to the following:

$$X_t - \mu_{t|s} = \rho(X_{t-1} - \mu_{t-1}) + \varepsilon_t,$$

where $\varepsilon_t$ therefore represents the impact that the time series $(X_s)$ has on the time series $(X_t)$. In general terms, we can say that $(Y_t)$ Granger-causes $(X_t)$ if the latter model explains the behaviour of $(X_t)$ better than the previously defined AR(1) model that only depends on the sequence $(X_s)$. The concept of Granger-causality was introduced in Granger (1969) and the goal of the biological study considered in this work would therefore be to perform a statistical test to confirm the stronger explanatory power of the second model over the first.

However, these models are not well-adapted to irregularly spaced time series that are the focus of this work. For example the parameter $\rho$, that measures the relation between consecutive observations, remains constant regardless of the distance in time between $X_t$ and $X_{t-1}$ (as well as the parameters $\lambda$ and $\sigma^2$). For this reason, the next sections put forward a new framework for these settings.

### 2.1 The Proposed model

The first step required to address the problem of modelling irregularly spaced time series consists in integrating the distance in time between observations within the model specification. Firstly, one needs to assume that an appropriate technique is used to estimate $\mu_{t|s}$, such as parametric approaches (e.g. linear regression) or other semi- or non-parametric approaches such as splines or techniques such as functional data analysis. (The use of functional data analysis would appear particularly pertinent for the considered setting since it could also provide information on strength and sign of association through the required shift and alignment needed to register the irregularly-sampled patterns. This avenue of investigation is left for future research and the authors thank one of the reviewers who put forward this idea.) Given this, we denote the centred observations as $\tilde{X}_t := X_t - \mu_{t|s}$ and the distance in time as $d_t := t - t_{i-1}$, with $d_t \in \mathbb{R}^+$ by definition. Based on this, the AR(1) model for irregularly spaced data can be represented as follows:

$$\tilde{X}_t = f(d_t) \tilde{X}_{t-1} + W_t,$$

where $f(\cdot)$ is a deterministic function, possibly known up to some parameter values, that plays the same role as the constant $\rho$ but takes into account the distance between observations. For different reasons, among which estimation feasibility, the independent sequence $(W_t)$ is usually considered as being Gaussian (although other distributions can be considered). Without loss of generality, we will make this assumption and therefore state that $W_t \sim \mathcal{N}(0, \sigma^2)$ with $g(\cdot)$ being another deterministic function. Both the functions $f(\cdot)$ and $g(\cdot)$ need to respect certain properties which will be discussed further on. The above model could be extended in several ways, for example, by considering a dependence between $\tilde{X}_t$ and $\tilde{X}_{t-1}$ with $j > 1$ or between $\tilde{X}_t$ and $W_t$ as in general ARMA models (as well as considering non-Gaussian distributions for $W_t$ as mentioned earlier). However, given the small sample sizes usually encountered in dynamic transcriptome and metabolome studies, it is rather unlikely that more complex models can be appropriately estimated and the above model is a very reasonable approximation for more general dependence structures.

Considering the extension of AR(1) processes to irregularly spaced settings, we can consider the same extension when modelling the joint behaviour of two time series. For this purpose we define the following bivariate model, which is a natural extension of a vector AR(1) model for irregularly spaced data:

$$Z_t = A(d_t) Z_{t-1} + V_t,$$

where

$$Z_t := \begin{bmatrix} X_t - \mu_{t|s} \\ Y_t - \mu_{t|s} \end{bmatrix}, \quad A(d_t) := \begin{bmatrix} f_1(d_t) & b_1(d_t) \\ b_2(d_t) & f_2(d_t) \end{bmatrix},$$

and where $b(\cdot)$ is another deterministic function (which may depend on unknown parameters). In addition, we have $V_t := [W_t, Y_t]$, with $(V_t, i = 1, \ldots, n) \in \mathbb{R}^{2\times n}$ denoting a bivariate independent sequence with distribution $V_t \sim \mathcal{N}(0, \Sigma)$, with $0$ being a two-dimensional zero vector and

$$\Sigma = \begin{bmatrix} g_1(d_t) & 0 \\ 0 & g_2(d_t) \end{bmatrix}.$$ (2)

It can be observed how the matrix $A(d_t)$ plays the main role in describing the dependence ‘within’ and ‘between’ the two time series. Indeed, on one hand the functions $f_1(d_t)$ and $f_2(d_t)$ determine to what extent the time series depend on themselves to describe the behaviour of their future observations while the functions $b_1(d_t)$ and $b_2(d_t)$, on the other hand, determine the degree of dependence between the two time series. Also within this setting it is possible to recognize the idea of Granger-causality where one is interested in assessing whether past values of a certain time series can significantly increase the explanation of the behaviour of another time series. In general, this assessment is based on statistical tests which are typically related to characteristics of the matrix $A(d_t)$. In fact, if this matrix is diagonal, this implies that the two time series are independent from each other (under the Gaussian assumption) while if it is full this entails that the two time series are also inter-dependent. Moreover, if the matrix is upper or lower triangular, this would imply that only one of the series depends on itself and on the other series (the latter therefore only depending on itself).

**Remark:** The above-defined modelling framework can be applied also to settings with a different number of observations as well as different measurement times between pairs, requiring an ‘adaptive’ definition of the matrix $A$ (i.e. a different structure of $A$ at each time point of either signal), while the currently considered setting allows to explicitly define and write out the model for all pairs. More complex models and the inclusion of more signals (e.g. triplets of signals or more) can also be considered but this would require a much larger number of observations per signal and increased computational resources since the number of model parameters would increase exponentially.

Considering the above modelling framework, there is a need to estimate the unknown parameters in the model and test whether the estimated parameters appear to explain the data sufficiently well to draw reliable conclusions. Firstly, to estimate these kind of models we propose a likelihood approach based on the assumption of a jointly normal distribution of the observations which, for the bivariate series, gives the following conditional distribution:

$$Z_t | Z_{t-1} \sim \mathcal{N}(\bar{\mu}_t, \Sigma),$$ (3)

where $\Sigma$ is defined in (2), and

$$\bar{\mu}_t := \begin{bmatrix} f_1(d_t) \tilde{X}_{t-1} + b_1(d_t) Y_{t-1} \\ b_2(d_t) \tilde{X}_{t-1} + f_2(d_t) Y_{t-1} \end{bmatrix}.$$
\[ L(\theta) = l(Z_1) \prod_{i=2}^{n} l(Z_i|Z_{i-1}), \tag{4} \]

where, using (3), we have

\[ l(Z_i|Z_{i-1}) = \frac{1}{2\pi|\Sigma_i|^{1/2}} \exp \left( -\frac{1}{2} (Z_i - \mu_i)^T \Sigma_i^{-1} (Z_i - \mu_i) \right). \]

Applying the log(\cdot) function to \( L(\theta) \) and fixing \( l(Z_1) \) as constant (neglecting constant terms) we obtain the following estimating equation which defines the maximum likelihood estimator (MLE):

\[ \hat{\theta} = \arg \min_{\theta \in \Theta} Q_n(\theta), \tag{5} \]

where

\[ Q_n(\theta) = \frac{1}{n} \sum_{i=2}^{n} \log(\Sigma_i) + (Z_i - \mu_i)^T \Sigma_i^{-1} (Z_i - \mu_i). \]

Under a set of conditions (see Section S1 in the Supplementary Material), the estimator defined in (5) has appropriate statistical properties. Among these conditions there are constraints on the deterministic functions that characterize the dependence structure of the model defined in (1). For this reason, we define these functions accordingly taking from the domain of (navigation) engineering (see e.g. Titterton et al., 2004). In the latter field, a model that is often used is the discrete-time first-order Gauss-Markov model that can be defined as:

\[ \hat{X}_i = \exp \left( -\frac{\delta_i}{\phi} \right) \hat{X}_{i-1} + W_i, \tag{6} \]

where \( \phi \in \mathbb{R}^+ \) is a parameter that determines the ‘range’ of dependence in the data and

\[ W_i \sim \mathcal{N}(0, \sigma^2 \left[ 1 - \exp \left( -\frac{2\delta_i}{\phi} \right) \right]). \]

Having been mainly proposed to deal with time series measured at different frequencies, the idea behind this model is very close to the structure of an exponential model for spatial data (see e.g. Ripley, 2003). Indeed, the latter explains the dependence in space through an exponential structure and roughly corresponds to the above-mentioned Gauss-Markov process when considering \( \delta_i \) as a measure of Euclidean distance. The above model therefore gives an explicit form to the functions \( f(\cdot) \) and \( g(\cdot) \) mentioned earlier but of course other explicit forms can be envisaged.

While the above defined functions characterize the dependence of a time series on itself, it is still necessary to give an adequate form to the function \( h(\cdot) \) that describes the behaviour of a signal based on another. Given the short time series available, we decide to impose a reasonable structure to this behaviour which allows the dependence of a signal on the other signal to grow exponentially over time (reaching its maximum) and then decay exponentially. Indeed, while we consider the impact of past values of a time series on its future values as a function only of their distance in time, we postulate that the impact of another time series is not constant but increases and then decreases as a function of the distance in time over the chosen experimental time-frame. This behaviour can be justified from a biological point of view since genes have been shown to influence the expression of other genes in a ‘hit and run’ manner (Doudy et al., 2016). The causal gene physically interacts with the target gene then dissociates, but the transient target gene’s expression continues to be affected after the dissociation. For this reason, we propose to use the following function:

\[ b(\delta_i) := \psi \exp \left( -\frac{(\delta_i - \gamma)^2}{\eta} \right), \]

where \( \psi \in (-1, 1) \) is a parameter that describes the ‘intensity’ and ‘direction’ of the dependence of a time series on the other while \( \gamma \in \mathbb{R}^+ \) denotes the distance in time at which the dependence of a time series on another is maximal. Finally, \( \eta \in \mathbb{R}^+ \) plays a similar role to \( \phi \) in the previously defined function \( h(\cdot) \).

As stated earlier, other explicit (more complex) forms can be defined for these functions. However, other forms would probably require more parameters to characterize them and would be complicated (if not impossible) to estimate in practice given the small sample sizes collected in many experimental settings such as the one considered in this work. Hence, in order to respond to the need to balance model complexity with practical feasibility, we will consider the above functions to understand the relationship between different root and shoot signals since they can be considered as appropriate approximations to the underlying dependence structure.

### 2.2 Testing procedure

Once the model is defined, the goal of this work is therefore to understand which structure of the matrix \( A(\delta_i) \) in (1) best describes the observed data (e.g. diagonal, lower/upper triangular). In this perspective, we are interested in making a decision on the following set of hypotheses:

\[ H_0 : A(\delta_i) \text{ is diagonal.} \]
\[ H_A : A(\delta_i) \text{ is lower triangular.} \]

Hence, the null hypothesis \( H_0 \) states that neither signal has an impact on the other (i.e. no Granger-causality in the bivariate time series) while the alternative \( H_A \) states that the first signal Granger-causes the second. This alternative can of course be changed to ‘\( A(\delta_i) \) is upper triangular’ therefore reversing the direction of dependence. In the setting of this work, one could also consider the alternative hypothesis stating that ‘\( A(\delta_i) \) is a full matrix’, implying that both signals Granger-cause each other. However, rejecting the null \( H_0 \) in favour of the latter alternative would not be able to conclude on whether only one signal Granger-causes the other, therefore requiring more computational time (as described further on) to also test the two ‘triangular’ alternatives. On the other hand, if the null hypothesis under a ‘triangular’ alternative were rejected, this would suggest that the null would be rejected also with the ‘full’ alternative (with high probability) thereby supporting the use of two ‘triangular’ tests for each bivariate time series.

The MLE defined in (5) allows to estimate the parameters of the proposed model using the likelihood function in (4). Based on the latter, a commonly used test to determine the performance of a more ‘simple’ model (such as the one considered in the null hypothesis stated above) with respect to a more ‘complex’ model (such as the one in the alternative hypothesis) is the likelihood-ratio test whose statistic is given by

\[ LRT := -2 \log \left( \frac{L(\hat{\theta}_0)}{L(\hat{\theta}_1)} \right) = 2 \left( Q_n(\hat{\theta}_0) - Q_n(\hat{\theta}_1) \right), \]

where \( \hat{\theta}_0 \) and \( \hat{\theta}_1 \) represent the estimated parameters of the models under the null and alternative hypothesis respectively. In order to perform this test one needs to derive the distribution of the \( LRT \) statistic under the null hypothesis which is asymptotically chi-squared with \( p^r \) degrees of freedom, where \( p^r \) represents the number of extra parameters contained in \( \theta_1 \in \mathbb{R}^{p_1} \) with respect to \( \theta_0 \in \mathbb{R}^{p_0} \) (i.e. \( p^r := p_1 - p_0 \)). Using this distribution and the observed \( LRT \) statistic one can then reject or not the null hypothesis thereby concluding whether or not a signal Granger-causes the other.
2.3 Implementation

As highlighted before, the sample sizes coming from target biologic
al applications are typically small (i.e. 5 < n < 20 time points) and it
therefore seems unreasonable to make use of asymptotic proper-
ties in these cases. For this reason, Monte-Carlo-based techniques
appear to be a natural alternative that are able to consider the small
sample distribution of the test statistics of interest. More specifically,
we propose to use parametric bootstrap to derive the small sample
distribution of the LRT statistic under the null hypothesis as described
in Algorithm 1.

Algorithm 1: Parametric Bootstrap for LRT Statistic

Result: Estimated LRT distribution under H0.
initialize b = 0, H ≥ 100 and a zero vector LRTboot of dimension H;
while b ≤ H do
  1. b = b + 1;
  2. Simulate a bivariate time series (Zi(b)) of the same sam-
     ple size as the original signals from the model Fθ0; 
  3. Estimate θ0 and θ1 from the simulated sample (Zi(b))
     to obtain θ(b)
     0 and θ(b)
     1 respectively;
  4. Compute LRTboot = 2(Q(θ(b)
     0) − Q(θ(b)
     1))

Step 2 of Algorithm 1 requires the simulation of a bivariate time
series under a Gaussian assumption. To do so, using the estimated
parameters under the null hypothesis θ0, one first simulates the inde-
pendent bivariate Gaussian variables (V -m,...,V0, V1,..., Vn)
where m ∈ N+ represents the number of observations to use for the
‘burn-in’ phase (usually m ≫ n). Then one replaces Z -1 and V1 in
(1) with V -m and V -1 respectively in order to obtain Z -m. In
the next step one then again replaces Z -1 and V1 in (1), but this
time with Z -1 and V -2 respectively, to obtain Z -2 and
continuing in this manner until one obtains Zn. In the end, one only
keeps the bivariate time series (Z1,..., Zn) as the simulated series
for step 2 of the algorithm. Instead of simulating from a parametric
model (as defined in (1)), one could also envisage non-parametric
sampling techniques such as the block-bootstrap (see e.g. Kunsch,
1989) but, aside from not being well suited for irregularly sampled
observations, these are only usable and/or reliable on longer signals
than those considered for this work where a parametric approach
would indeed be more reliable if the signals are actually generated
from a model with a similar dependence structure.

Among the advantages of using the parametric bootstrap ap-
proach in this setting, there is also the good approximation (for large
H) that it delivers for the LRT statistic distribution under the null
hypothesis. Indeed, by using the empirical distribution of the
LRTboot(b) values, it is possible to obtain an approximate P-value (see
Davison and Hinkley, 1997) as follows

\[ P - value = \frac{1}{H + 1} \sum_{b=1}^{H} 1 \{ LRT_{boot}^{(b)} > LRT \} \]

If this P-value is smaller than a chosen level of significance \( \alpha \), then we
can reject the null hypothesis \( H_0 \) that there is no Granger-causality
in favour of the specific alternative hypothesis \( H_1 \) being tested.

Given this testing framework, there are a couple of issues that
need to be considered: the first of which is the computational burden
of Algorithm 1. In fact, the above defined P-value needs to be com-
pared for all possible bivariate signal combinations and alternative
hypotheses resulting in \( 2 \times N_x \times N_y \) tests, where \( N_x \) and \( N_y \)
are the number of gene expressions measured in the roots and shoots,
respectively (while \( n \) remains the number of measurements included
in each signal for each expression). Considering that the computa-
tional complexity to obtain the above p-value for each pair, given
our assumptions, is approximately of order \( O(nH) \), the final algo-
rithmic complexity of the entire procedure would be of order
\( O(nHNM) \) with \( M = N_x \times N_y \) and \( N_x, N_y \gg 10^3 \). This implies
that the time required to obtain the results can be considerable (roughly
30 seconds for a test on each pair on a standard laptop computer
when choosing \( H = 100 \)). Another issue consists in the multiple test-
ing framework this procedure entails, which therefore has conse-
tquences in terms of False Discovery Rate (FDR). Indeed, each (Xi) signal
is tested \( 2N_y \) times (and vice-versa for the (Yi) signals) which
would require to compare the p-value to the level \( \tau / (2N_y N_x) \) if
applying, for example, a Bonferroni correction. If the sizes \( N_x \) and
\( N_y \) are considerable, this would require to increase the number of
simulations \( H \) in a proportional manner consequently increasing the
computational burden. Unless one uses the asymptotic approxima-
tion to obtain a P-value (which would be highly unreliable for the
small sample sizes used in these settings), there is currently no way
of avoiding such a computational bottleneck. A screening approach
could be envisaged, for example using the method in Carlin et al.
(2017), but this would nevertheless need to be run on all gene pairs
and would therefore probably require a similar total computational
time considering the following use of the proposed approach after
the screening (however such a two-step screening approach can in-
deed be advantageous and is left for future work). (As an additional
result, although not generally comparable, we have run a simulation
study in Section S2 of the Supplementary Material comparing the
proposed approach with that put forward in Carlin et al. (2017) to
understand how our approach performs in detecting Granger-causal
relationships.)

3 Results and discussion

The described approach was applied to the time-evolved transcript-
ometry of Arabidopsis roots and shoots (the (Xi) and (Yi) signals, re-
spectively) whose measurements were made through an experi-
mental setup described in detail in the Supplemental Material along
with the chosen pre-processing (Section 3); additional
descriptions of the individual nitrogen-responsive root and shoot
time series as well as ‘within’ organ analysis can be found in
Varala et al. (2018). This dataset consisted of 568 differentially
expressed root genes and 2173 differentially expressed shoot genes, and
both gene lists were enriched for nitrogen metabolic processes. These
signals, each of length \( n = 10 \) and collected at higher frequencies in the
initial experimental phase (compare: M = 1, 2, 3, 264 possible gene
pairs from significantly differentially expressed root and shoot
genes. Using \( H = 10^3 \), we apply the procedure described in Section
2 which produces a final list of 3078 gene pair interactions whose
details are listed in Table 1, Section S4 of Supplementary Material.
Given the exploratory nature of this study and the discrete nature
of the bootstrap P-value, we choose not to strictly control for FDR but
to consider small P-values (\( \alpha = 0.05 \)) in order to suggest biologically
justifiable future avenues of research. Nevertheless, in the follow-
ing sections we mainly discuss the detected Granger-causal relations-
hips whose P-value is below 0.2% (meaning that the null is not rejected
at most once among the \( 10^3 \) bootstrap replicates). Out of the total of
interactions tested, 2012 had a predicted root-to-shoot direction of
influence meaning that the root gene was identified as being the
(Granger) causal gene, or the influencer on the expression of the
shoot gene. The remaining 1066 interactions had a predicted shoot-
to-root direction of influence. In addition, using the hat symbol to
denote the MLE estimates, the approach predicted 1616 positive
interactions (i.e. \( \hat{\psi} > 0 \)) and 1462 negative interactions (i.e. \( \hat{\psi} < 0 \)).
Due to the limited and irregular number of samples across time, we
choose to classify the time of influence at which the maximum influ-
ence between two genes occurred (measured by the \( \hat{\psi} \) parameter)
to into three general groups: Early (0–15 min), Middle (20–45 min)
and Late (60–120 min). Based on this, among the 3078 interactions,
2,502 occur Early, 548 occur during the Middle time frame, and 28
occur Late. In the following paragraphs we analyse only some of the
model-predicted interactions in terms of their known properties
and/or based on how they have a coherent biological interpretation.
Table 1. TGA1 target genes in root and shoot with which genes have a TGA1 motif occurrence of \( P < 0.0001 \) from the FIMO promoter analysis, and genes with which TGA1 has been shown to physically bind to based on DAP-Seq and TARGET experiments

| Gene ID          | Gene description                                | Influence | FIMO | DAP-seq | TARGET |
|------------------|-------------------------------------------------|-----------|------|---------|--------|
| Shoot AT1G5390   | Tetrasplice peptide repeat (TPR)-like superfAMILY | Positive  |      |         |        |
| AT1G71980        | Protease-associated (PA) RING- \( \text{-} \) box | Negative  |      |         |        |
| AT1G73100        | SDG19, SUVH3, SU(VAR)3-9 homolog 3             | Positive  |      |         |        |
| AT2G15230        | ATLP1, LIP1, lipase 1                          | Negative  |      |         |        |
| AT3G06780        | glycine-rich protein                            | Positive  |      |         |        |
| AT3G17510        | CIPK1, SnRK3.16, CBL-interacting protein kinase | Negative  |      |         |        |
| AT4G21215        | unknown protein                                 | Negative  |      |         |        |
| AT5G04840        | bZIP protein                                    | Positive  |      |         |        |
| AT5G18640        | alpha/beta-Hydrolases superfAMILY protein      | Negative  |      |         |        |
| AT5G62020        | AT-HSFbeta2A, HSFbeta2A, heat shock transcription factor B2A | Negative  |      |         |        |
| Root AT3G01310   | Phosphoglycerate mutase-like family protein     | Negative  | Y    |         | Y      |
| AT3G61190        | BAPI1, BON association protein 1                | Negative  |      |         | Y      |
| AT4G12290        | Copper amine oxidase family protein             | Positive  | Y    |         | Y      |
| AT5G28770        | AtbZIP63, BZO2H3, bZIP transcription factor family protein | Negative  |      |         |        |

‘Y’ indicates existing evidence for a predicted interaction from a specific experiment, whereas empty cells indicate possible avenues of future investigation.

3.1 Global analysis of model-predicted interactions reveal links between biological processes and pathways

Gene Ontology (GO) term analysis was performed to understand what pathways and processes are influenced across tissues over time (see Table S3 in Supplementary Material for more details). As highlighted also in Figure 1, at early time points (0–15 min), causal root genes reflect the early response to the nitrogen stimulus, while at later time points there is a shift in metabolism in which causal root genes are involved in hormone response (20–45 min) followed by regulation of mRNA catabolic processes (60–120 min) (GO enrichment \( P \)-value < 0.01). Target shoot genes at early and middle time points are enriched in GO terms for cellular nitrogen compound metabolic process and peptide biosynthesis (see Tables S2 and S11, Section S4 of Supplementary Material). GO analysis of the causal shoot genes reflect the synthesis of shoot-derived signals, such as peptides and hormones, while the identified target root genes are involved in phosphorus metabolic processes (0—15 minutes), lateral root development (15–45 min), and response to cytokinin (45–120 min) (see Tables S5–S10, Section S4 of Supplementary Material). This analysis reflects much of the current knowledge about long distance nitrogen signalling between roots and shoots (Ko and Helaeriuuta, 2017; Poitout et al., 2018; Ruffel et al., 2011).

3.2 Model predictions are supported by in planta observations

A gene network was constructed where nodes (1322 nodes) represent genes and edges (3078 edges) constitute the model-predicted interactions described above (see Section S3 in Supplementary Material). Network analysis revealed that the gene interaction network with model-defined edges closely follows a power law distribution \( (R^2 = 0.92) \), indicative of a scale-free biological network (Albert, 2005; Barabási, 2003). The validity of this finding was supported by a simulation of 10^3 randomly generated networks using the same number of nodes and edges whose \( R^2 \) values for the power law distribution were all between 0 and 0.35 (see Fig. 2). While being scale-free is not a ubiquitous feature of all biological networks (Broido and Clauset, 2019), comparison of the \( R^2 \) values between the 10^3 random networks and the model-predicted network showed that the proposed model appears to detect relationships in a non-random manner. Network analysis for out-degree identified causal hub genes that are predicted to be highly influential in the temporal root-shoot transcriptomes in response to nitrogen treatment. Taking into consideration directionality, the top ten hubbiest genes in the network, based on out-degree, include factors previously implicated in the Arabidopsis nitrogen response: AFB3 (AT1G12820) (Vidal et al., 2013b, 2014; Xu and Cai, 2019), BT1 (AT5G63160) (Araus et al., 2016; Sato et al., 2017; Vidal et al., 2013a), and WRKY38 (AT5G22570) (Gaudinier et al., 2018; Scheible et al., 2004) (see Table S4, Section S4 of Supplementary Material). Other network hubs include the TF RD21A (AT1G47128) that is involved in autophagy and senescence which are key nitrogen turnover processes; and the RNA binding protein C1D10 (AT3G49390), which is a pol(A) binding protein potentially involved in mRNA stability or degradation (see 'Supplemental Network File'). Further investigation of the interaction network revealed a number of previously identified genes and gene–gene relationships involved in local and long-distance nitrogen signalling, namely those involved in transcriptional regulation and in long-distance signalling by hormones and peptides, which are described in detail in the following sections.

3.3 Regulators of nitrogen processes

The transcription factors TGA1 and TGA4 were shown to be involved in mediating the primary nitrate response in roots by regulating the expression of the nitrate transporters NRT1.1 and NRT2.2, and also by coordinating the root developmental response to nitrate (Alvarez et al., 2014). From our analysis, root-expressed TGA1 is predicted to influence the expression of ten shoot genes, while shoot-expressed TGA1 is predicted to influence the expression of four root genes (see Table 1). To further investigate these predicted relationships, promoter analysis using FIMO from MEME Suite (Bailey and Machanick, 2012) was performed (as outlined in
Section S3 of Supplementary Material). At least one TGA1 binding motif had a significant occurrence (FIMO P-value < 0.0001) in the putative promoters of two of the targeted shoot genes: a protease-associated RING/U-Box zinc finger family protein (AT1G71980) and HSFB2A heatshock transcription factor B2A (AT3G62020). The TGA1 motif also had a significant occurrence (FIMO P-value < 0.0001) in the three root target genes: a phosphoglycerate mutase-like family protein (AT3G01310), BAPI BON association protein 1 (AT3G61190) and a copper amine oxidase family protein (AT4G12290). DAP-seq (DNA affinity purification sequencing) is an experimental technique allowing for the discovery of transcription factor binding sites on genomic DNA in vitro. A recent DAP-seq experiment showed that TGA1 actively binds to three shoot genes, AT1G71980, CIPK1 (AT3G71510) and an unknown protein (AT4G21215), as well as the three root target genes from the promoter analysis (O’Malley et al., 2016) (see Table 1). Furthermore, the model-predicted targets of TGA1, Phosphoglycerate mutase-like family protein (AT3G01310), and alpha/beta-Hydrolases superfAMILY protein (AT3G18640) were predicted to be direct targets of TGA1 in a TARGET (Transient Assay Reporting Genome-wide Effects of Transcription factors) assay experiment in root protoplasts by Brooks et al. (2019). A TARGET assay can identify candidate transcription factor targets based on TF-induced changes in gene expression (Brooks et al., 2019). These in-planta results provide support for the predicted interactions between TGA1 and some of its target genes within the same tissue, while unsupported interactions suggest indirect regulation of TGA1 on predicted target genes. Additional studies will be needed to test if these interactions occur directly or indirectly between tissues.

### 3.4 Long-distance signalling by hormones and peptides

**Cytokinin response factors (CRFs):** Transcription factors (TF) with previously described regulatory roles in nitrogen uptake and assimilation include members of the ERF, bZIP, and NLP TF families (Brooks et al., 2019; Konishi and Tanagawa, 2013; Krapp et al., 2014; Varala et al., 2018; Vidal et al., 2015). Of particular interest are the ERF TFs CRF 1-5. These CRFs were previously implicated in nitrogen signalling, targeting genes involved in nitrogen uptake and assimilation (Brooks et al., 2019; Varala et al., 2018). In our analysis, CRF5 expressed in the shoot was predicted to positively influence the expression of a heavy metal transport/detoxification protein (AT3G03380) expressed in the root. Using the wetbool tool ‘Eelfinder’ from the Matt Hudson lab (available at http://stats.crops.niome.uiuc.edu/tools.php), CRF5 has been shown to bind to the GCC-box motif (GGCCGCC) (Fujimoto et al., 2000; Liang et al., 2010; Sakuma et al., 2002) which is over-represented in the 2 kb promoter region of AT5G03380 (E-value = 5.85 · 10^{-4}, see Section S3 of Supplementary Material), indicating potential for a physical protein-DNA binding interaction. Shoot-expressed CRF3 is a predicted target of the causal root-expressed gene AT4G34419 (an unknown protein) in which AT4G34419 positively influences the expression of CRF3. Root-expressed CRF4 is predicted to influence the expression of the shoot genes SAUR-like auxin responsive protein family (AT4G34750), and Late embryogenesis abundant hydroxyproline-rich glycoprotein family (AT3G44380). CRF4 is predicted to positively influence both of these genes during the early time interval. Like CRF5, CRF4 binds to the GCC-box motif, and this motif is over-represented in the 2 kb upstream region of AT4G34750 (E-value = 1.43 · 10^{-5}, see Section S3 of Supplementary Material). Root CRF4 is also predicted to negatively influence the shoot gene Homeobox Protein 6 (HB6, AT2G22430) during the middle time interval. CRF4 was shown to bind to HB6 via DAP-Seq (O’Malley et al., 2016). HB6 is a known negative regulator of the abscisic acid (ABA) signalling pathway (Fujita et al., 2011; Himmelbach et al., 2003). The ABA pathway is a phytohormone signalling pathway that was previously implicated in coordinating the long-distance nitrogen response (Guan, 2017; Kiba et al., 2011). A recent study by Varala et al. (2018) showed that CRF4 targets the TFs SNZ1 and CDF1, which in turn target HB6. The overexpression of CRF4 decreased the rate of nitrate uptake and altered root architecture in response to nitrogen treatment compared to WT plants (Varala et al., 2018). In CRF4 overexpressors, there was a decrease in primary root length and lateral root number under low nitrate conditions. Lateral root development has been shown to be inhibited under low nitrate conditions, which trigger ABA accumulation (Leran et al., 2015; Signora et al., 2001; Sun et al., 2017; Vidal et al., 2010). Thus, the results of our analysis suggest a coherent type 4 feed-forward loop (Mangan and Alon, 2003) in which root CRF4 represses shoot HB6 which represses whole plant ABA signalling (see Fig. 3), and may have physiological consequences for the observed changes in lateral root formation (Varala et al., 2018).

**Arabidopsis response regulators (ARRs):** The cytokinin signalling pathway is triggered by nitrogen and has been shown to be involved in the coordination of both root-to-shoot and shoot-to-root nitrogen-responses. In the shoots, cytokinins stimulate cell division and differentiation, whereas in the roots cytokinins reduce the activity of nitrogen uptake (Sakakibara et al., 2006). Cytokinins have also been shown to induce the expression of ARRs, which then regulate cytokinin signalling through feedback (To et al., 2007, 2004). For example, ARR4 (AT1G0470) is a Type-A response regulator that negatively regulates the cytokinin response (To et al., 2007). In our study, root ARR4 is predicted to influence the expression of three shoot genes (see Table 1, Section S4 of Supplementary Material), including a transmembrane amino acid transporter family protein (ATAVT1B; AT3G34830). During the middle time interval, root-expressed ARR4 is predicted to negatively influence the expression of AVT1 in shoots. Yeast AVT1 homologues have been implicated in the vacuolar uptake of large neutral amino acids including...
glutamine, asparagine, iso-leucine and tyrosine (Russnak et al., 2001; Tone et al., 2015) where they are stored in the vacuole under high nitrogen conditions (Sekito et al., 2008). When nitrogen starvation occurs, several AVT genes are upregulated to facilitate the export of the stored amino acids from the vacuole to the cytoplasm for protein synthesis (Fujiki et al., 2017). The analysis detected a relationship between ARR4 and AVT1B suggesting a potential mechanism by which cytokinin-induced ARR4 in the root may provide a long-distance signal to regulate shoot vacuolar amino acid import under high nitrogen conditions, like those used in this study.

**Peptidases:** Signal peptides have been implicated in the whole plant response to nitrogen (Oh et al., 2018; Ohkubo et al., 2017; Tabata et al., 2014). In the present study, seven peptides were uncovered as causal genes involved in 20 interactions (see Table S16, Section S4 of Supplementary Material). ATPSK4 is a Phytosulfokine 3 precursor and was shown to influence plant growth and cellular longevity, in particular root growth (Matsubayashi et al., 2006). CLE (Clavata/ESR-related) peptides have been long known to be involved in long-distance nitrogen-signalling in legumes and have also been shown to be involved in nitrogen-signalling in Arabidopsis (Bidadi et al., 2014; Okamoto et al., 2016). In the present study, three CLE peptides are present in the predicted long-distance signalling network; CLE3 (AT1G06225), CLE4 (AT2G31081) and CLE27 (AT3G23905). CLE3 is a predicted causal gene expressed in the shoot that influences the root-expressed gene AT3G2530 (dentin sialophosphoprotein-related), while CLE4 is a causal root gene predicted to influence the expression of four shoot-expressed genes other negatively (AT3G67510 translation protein SH3-like family protein; AT1G55890 Tetratricopeptide repeat-like superfamily protein) or positively (AT3G61620 RRP41_3, S-exoribonuclease family protein; AT5G18640 alpha/beta-Hydrolases superfamily protein). Lastly, CLE27 is a Clavata family gene that was previously shown to be repressed by auxin (Wang et al., 2016). In our study, CLE27 is a shoot-expressed causal gene predicted to positively influence the expression of AT3G33380 (Heavy metal transport/ detoxification superfamily protein) in the root. Devil/Rotundifolia Like (DVL) peptides are non-secretory peptides, conserved in plants, that can act as small signalling molecules and influence development in Arabidopsis (Wen et al., 2004). MTDVL1 was previously shown to be involved in symbiosis in Medicago truncatula, in which it has a negative regulatory role in nodulation (Combier et al., 2008). Two Devil peptides were identified in our analysis: DVL4 and DVL11. Of the four interactions involving DVL11, root DVL11 is predicted to be the causal gene influencing three shoot genes. Of these, DVL11 is predicted to positively influence the expression of ICK1, a cyclin-dependent kinase inhibitor family protein (AT2G34340). ICK1 is a known key regulator in development, and can inhibit entry into mitosis (Weinl et al., 2005). Root DVL4 is also predicted by the analysis to influence three shoot genes. Specifically, root DVL4 is predicted to positively influence shoot TCP-1/cpn60 chaperonin family protein (AT3G13470) at a middle time point. A previous study explored the transcriptional landscape of a DVL4 overexpressor line and showed that overexpression of DVL4 resulted in the upregulation of a number of genes encoding transcription factors (Larue et al., 2018). Our re-analysis of the microarray data from this study (see Section S3 of Supplementary Material) revealed that TCP1 was downregulated in DVL4 overexpressor plants compared to wild type Arabidopsis plants, providing support for a gene-gene interaction between DVL4 and TCP1 (see Fig. S2 of Supplementary Material); however, this needs further exploration in the context of a nitrogen-signal.

### 3.5 Model predictions contain an over-representation of mobile causal gene products

The proposed approach, as stated previously, aims at understanding if the expression of one gene influences the expression of its target gene through the notion of Granger-causality. Biologically, this influence may be direct or indirect. It has previously been shown that in certain mobile mRNAs that originate from one cell-type or organ can translocate to another cell-type or organ and have functional activity there (Banerjee et al., 2009; Lough and Lucas, 2006; Luo et al., 2018). To identify potential direct, long-distance interactions, we took advantage of two recent publications (Guan et al., 2016; Thieme et al., 2015) with extensive lists of experimentally determined mobile mRNAs that travel from root-to-shoot and from shoot-to-root. The lists of directional, causal genes from our model were intersected with the mobile transcripts identified by these studies. This analysis provided support for 204 causal genes involved in 340 predicted root-to-shoot, and 241 predicted shoot-to-root relationships; meaning that the direction of influence of the causal gene was the same in our analysis as that experimentally determined by these studies. An over-representation analysis (see Section S3 in Supplementary Material) was performed with the following hypotheses: ‘H0: the proposed approach (model) is equivalent to detecting known mobile transcripts randomly’ and (alternative) ‘H1: the proposed approach (model) detects more known mobile transcripts than random selection’. In this case, the P-value is 0 allowing us to reject the null hypothesis and hence the model is able to detect mobile transcripts which are potentially able to interact directly with their target genes. At least 36 of the total causal genes are known RNA-binding proteins (Marondedze et al., 2016), and 21 of these are mobile (see Table S17, Section S4 of Supplementary Material). In general, RNA-binding proteins can form ribonucleoprotein complexes (RNPs) that facilitate phloem transport and long distance trafficking of RNA molecules (Ham et al., 2009; Kehr and Kragler, 2018). An additional 79 causal genes involved in 203 relationships (121 root-to-shoot and 82 shoot-to-root) have not been experimentally shown to be mobile, but are predicted to encode a RNA molecule that possesses a tRNA-like motif. Guan et al. (2016) also have hypothesized that some mRNA have a tRNA-like structure in their sequence. This allows the mRNA to fold into a tRNA-like shape that confers some stability to the mRNA strand. This stability allows the mRNA to move long distances in the plant. These results suggest that a large proportion of the model-predicted causal genes have the potential to influence the expression of its target gene (directly or indirectly) via long-distance vascular trafficking. One example of a model-predicted gene interaction that may function through interaction of a mobile causal gene with its target is the relationship between root-derived aconitase 2 (ACO2), predicted to have a negative influence on the expression of malate dehydrogenase (MDH2) in the shoot. ACO2 is the only isoform of aconitase that is specifically induced by nitrogen treatment. Root ACO2 is involved in the TCA cycle, while shoot MDH2 is localized in the mitochondria and involved in gluconeogenesis. One possibility is that a direct or downstream gene product of root ACO2 represses shoot MDH2, resulting in possible down-regulation of shoot gluconeogenesis in response to a large, transient nitrogen signal. Although the specific mechanism of this relationship needs experimental exploration, it is partially supported by existing data describing the tight relationship between carbon and nitrogen metabolism to maintain whole plant C:N balance (Goel et al., 2016; Palenchar et al., 2004; Zheng, 2009). Alternatively, aconitase, an iron-sulphur protein, has been shown to be a bifunctional enzyme/RNA-binding protein that binds to iron-responsive elements in target RNA to stabilize the transcript and function in iron homeostasis (Hentze and Argos, 1991). Our analysis predicted a positive relationship between ACO2 (causal root) and Ironman 1 (target shoot), an Fe-uptake inducing peptide 3 that is involved in the regulation of iron deficiency response genes (Grillet et al., 2018). It was previously shown that nitrogen treatment increases the expression of genes involved in iron uptake, transport, and homeostasis in plants (Wang et al., 2000, 2003) and that the form of nitrogen taken up by roots influences the amount of iron accumulation in leaves (Zou et al., 2001). There is also a well- established relationship between nitrogen and plant growth and there is a component of many enzymes involved in nitrate assimilation (Wang et al., 2003).

### 4 Conclusion

This work puts forward an approach to perform Granger-causal analysis for (small-sample) irregularly-spaced bivariate signals
which overcomes existing limitations in the analysis of biological time series data following this common sampling scheme. Based on this new framework, (Granger) causal relationships were detected and whole-organism molecular response to a nitrogen signal were predicted. The survey of genes with predicted temporal cause-and-effect relationships enabled discovery of coordinated biological processes and chemical pathways that communicate the nitrogen-signal between roots and shoots of plants. These coordinated processes can now be further investigated to identify potential regulatory bottlenecks that influence whole plant nitrogen uptake/utilization efficiency. The abundance of genes involved in the known transcriptional nitrogen-response (nitrogen-transport and assimilation) as both causal and target genes indicate that the proposed approach was able to capture whole-plant response to a transient nitrogen-treatment across tissues. The predicted cross-organ dependencies provide insights and hypotheses about potential signalling cascades that are triggered sequentially as the nitrogen-signal propagates from roots-to-shoots-to-roots. Importantly, regulatory factors that have not previously been implicated in whole plant nitrogen-response were highlighted by the proposed approach. While these possible regulations are assumptions and may even be indirect relationships, these novel factors can be targets for engineering to enhance plant nitrogen uptake/utilization efficiency. The findings from this research will have implications for predicting causal molecular relationships that influence intercellular, long-distance nitrogen-signalling, and the methodological framework proposed in this work is applicable to researchers struggling with meaningful integration of dynamic, system-wide transcriptome data.

Data availability

The data underlying this article are available in the Gene Expression Omnibus of the National Center for Biotechnology Information at https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE97500. The method was developed with the R statistical software and is made available through the R package “irg” hosted on the GitHub repository https://github.com/SMAC-Group/irg. Sample (test) data are made available within the package as an example to apply the method and replicate some results in the paper.

Acknowledgements

We thank James J. Balamuta for his support in the preliminary code which was helpful in directing the following research project presented in this work.

Funding
