Abstract

BACKGROUND

To investigate the prognostic effects and risk factors of the omission and delay of postoperative chemotherapy of stage II/III gastric cancer (GC).

METHODS

The clinicopathological data of 1520 patients undergoing radical gastrectomy for stage II/III GC were collected and retrospectively analyzed. We defined the chemotherapy delayed until more than 60 days after radical gastrectomy and the complete omission of chemotherapy as unacceptable chemotherapy initiation (UAC group), while the chemotherapy conducted within 60 days of radical gastrectomy was defined as acceptable chemotherapy initiation (AC group). The survival between the two groups was compared, and the trends and risk factors of UAC were analyzed.

RESULTS

There were 539 (35.5%) patients with UAC. The OS and DFS of the UAC group patients were significantly inferior to those in the AC group (p<0.001). Cox multivariate analysis demonstrated that UAC is an independent predictor of OS (p<0.05). The OS and DFS of the patients in UAC group were close to those of the patients without chemotherapy (p>0.05). Logistic analysis showed female, old age, a self-paid status, a very low social status, high ASA scores, intra-abdominal surgery history, and serious postoperative complications were independent risk factors of UAC (p<0.05). The radar chart shows the risk factors of UAC changed with time.

CONCLUSIONS

UAC after radical gastrectomy is an independent risk factor for the prognosis of stage II/III GC patients. However, no significant decline of UAC has been achieved recently and should call for the attention of both government and clinicians.
Introduction

Although the incidence of gastric cancer (GC) has declined in recent years, its mortality rate remains at the forefront of cancer-related deaths (1-3). Scholars have spent great effort to explore how to improve the survival rate of GC, particularly in advanced stage patients, including the constant perfection of surgical methods and the continuous improvement of chemotherapy regimens (4-10); however, the effect is still not ideal. Therefore, it may not be enough to rely solely on clinicians to improve the overall survival rate of GC. The concerted efforts of the government, the family and the patients should be employed. In particular, for the majority of Chinese patients with locally advanced GC (Stage II/III) (11), the regulation of D2 radical surgery may only be the beginning of treatment. Whether adjuvant chemotherapy can be performed in time may also determine the overall effect of treatment. We observed in clinical practice that some patients with delayed chemotherapy had a significantly poorer prognosis compared with those with timely chemotherapy. The delay or omission of chemotherapy may occur for various reasons in patients with GC, particularly in developing countries, such as China. It is critical for clinical workers and health departments to determine its precise effect on prognosis and how to detect high-risk patients as early as possible. However, to our knowledge, there are no accurate data for the omission and delay of chemotherapy in GC, and there is a lack of relevant research on its effect on the prognosis of GC patients. Closure of this knowledge gap is critical for researchers, surgeons, and administrators.

Clearly, it is unfeasible and unethical to explore this issue through prospective trials. Therefore, this paper aims to investigate the effects of the omission and delay of chemotherapy in stage II/III GC and its risk factors in recent years from a large tertiary referral center in southern China; moreover, the goals are to assess the effect on prognosis and identify the high-risk factors of delayed chemotherapy and the trends in
recent years to provide a reference for the intervention of relevant departments, including the government and clinicians.

Methods And Materials

Study design and patients

In this study, the clinical and pathological data of 2604 patients with gastric cancer at the Fujian Medical University Union Hospital (FMUUH) from January 2011 to April 2015 were retrospectively analyzed, and the case exclusion criteria were as follows: (1) The postoperative pathology was confirmed as stage I or IV gastric cancer (n = 1025 cases); (2) Histological identification of a tumor type other than adenocarcinoma (n = 13 cases); (3) Remnant gastric cancer (n = 23 cases); and (4) Survival time is less than 3 months (n = 23 cases). Finally, 1520 patients with stage II/III gastric adenocarcinoma treated with D2 radical resection were included. Supplementary Fig. 1 shows the screening process. This study was conducted with the approval of the institutional review boards at FMUUH. The time of chemotherapy was defined as the interval between the radical gastrectomy and the first initiation time of chemotherapy. According to the correlation between the overall survival (OS) rate and the chemotherapy time, the cutoff value of the chemotherapy time was selected (supplementary Fig. 2). The results showed that the OS of the patients treated with chemotherapy within less than 4 weeks, 4–6 weeks and 6–8 weeks were significantly better than those who had no chemotherapy (p<0.05), while the OS of the patients treated with chemotherapy after 8–10 weeks, 10–12 weeks and more than 12 weeks were similar to those without chemotherapy (p>0.05). To facilitate the analysis, we selected the cutoff point with the duration of chemotherapy over 60 days as the delay of chemotherapy. Accordingly, we defined chemotherapy that was delayed until more than 60 days after radical gastrectomy and the complete omission of chemotherapy as unacceptable.
chemotherapy initiation (UAC group), while chemotherapy conducted within 60 days of radical gastrectomy was defined as acceptable chemotherapy initiation (the AC group). The chemotherapy regimen does not change for each patient unless there is a severe chemotherapy reaction. This retrospective study was approved and implemented by the Ethics committee of Fujian Medical University Union hospital.

Methods
Preoperative imaging studies were routinely performed following endoscopic and upper gastrointestinal examinations with contrast to confirm the tumor location and included chest radiography, computed tomography (CT) scanning, ultrasonography (US) of the abdomen and bone scanning and positron emission tomography-computed tomography (PET-CT) as required to evaluate the clinical stage. We used CT scans and the 7th edition of the International Union Against Cancer (UICC) classification system to assess the clinical and pathologic stage(12). According to the 2014 version of the Japanese Gastric Cancer treatment guidelines(13), our center recommended 5-fu-based chemotherapy for patients with postoperative pathological stage II/III. The patient’s residential address, marital status, procreation status, type of medical insurance, occupation, smoking history, alcohol consumption and other information were routinely recorded in the electronic database of the Fujian Medical University union Hospital medical records. The financial condition of the patient was recorded by the health care system. We conducted a comprehensive assessment of the patient’s social status based on the patient’s occupation, residential address, education, and economic conditions according to literature(14).

Follow up
The last follow-up time was April 2018. The follow-up rate of the 1520 patients was 95.9%. Postoperative follow-up using outpatient, hospitalization, etc., every 3 months for the first
2 years, every 6 months for 3–5 years and every year for after 5 years. The overwhelming majority of the patients routinely received physical examinations, laboratory tests (including CA19-9, ca72-4, and CEA levels), chest films, full belly color Doppler ultrasound or abdominal CT, and an annual gastroscopy. The OS time represents the time from the operation to the last follow-up or death. Disease-free survival (DFS) was defined as the time from the surgery to the time of recurrence or death from any other cause.

Statistical analysis

All data were processed using SPSS 20.0 (SPSS Inc., Chicago, IL). Continuous variables were analyzed with Student’s t tests, and categorical variables were analyzed with χ² or Fisher’s tests. The survival rate was calculated using the Kaplan-Meier method, and the survival rates were compared with the Log-rank test. The risk factors related to UAC were analyzed using a logistic model, with a Cox proportional risk model for multivariate prognostic analysis. Stepwise backward variable removal was applied to the multivariate model to identify the most accurate and parsimonious set of predictors. A p-value less than 0.05 was considered statistically significant.

Results

Patient characteristics between UAC and AC groups

Of all patients, there were 539 patients with UAC, with an incidence of 35.5%. Table 1 shows the clinicopathologic data of the patients in the AC and UAC groups. There were significant differences in terms of age, gender, medical insurance type, income, social status, residential address, ASA score, intra-abdominal surgery history, comorbidities, Charlson score, surgery period, and postoperative complications between the two groups (p<0.05); however, the BMI, occupation, marital status, procreation status, smoking and drinking consumption, abdominal surgery history, tumor site, pT stage, pN stage, pTNM staging, tumor size, number of harvested lymph nodes, lymphatic vessel infiltration and
pathological differentiation degree were not significantly different between the groups (p>0.05). The median follow-up times for the AC and UAC groups were 43 (3–86) months and 37 (3–91) months, respectively. The analysis of the UAC status from 2011 to April 2015 showed that the rates in 2011, 2012, 2013, 2014 and 2015 were 53.2%, 31.7%, 29.7%, 29.1% and 30.7%, respectively (Fig. 1). The difference reached statistical significance (P<0.001). A further stratified analysis showed a significant improvement in UAC in 2012 compared to that in 2011 (p<0.001), while there was no significant improvement during 2012–2015 April (p = 0.880); moreover, it increased from 29.1 percent in 2014 to 30.7 percent in 2015.

The effect of UAC on prognosis

Supplementary Fig. 3 shows the OS of the 1520 patients, with a median survival time of 41 months (range 3–91 months). Fig. 2 indicates that the OS and DFS of the UAC group patients are significantly inferior to those in the AC group (p<0.001). In the UAC group, the OS and DFS of the patients with chemotherapy delayed until more than 60 days were close to those without chemotherapy (p>0.05). Further analysis shows that the AC group had significantly better OS than the UAC group (p<0.05) in both men/women, with or without complications, or stage II/III (supplementary Fig. 4).

The stratified analysis by stage II/III shows that the OS in the AC Group in the IIA-IIIC patients was significantly better than in the UAC group (P<0.05). When the DFS was compared, the AC group was significantly superior to the UAC group in both males and females, with or without complications, or stage II/III patients (P<0.05) (Supplementary Fig. 5). A further stratified analysis by stage II/III demonstrates that the DFS in the AC Group exhibited a greater trend than that in the UAC group in the IIb, IIIA and IIIC patients; however, the differences were not significant (p>0.05). In contrast, in the AC group in the IIA
and IIIB patients, the DFS was significantly better than that in the UAC group (p<0.05).

Analysis of risk factors for patient survival

Table 2 shows the results of the Cox univariate and multivariate analyses for OS. The univariate analysis indicates that age, BMI, medical insurance type, ASA score, comorbidities, tumor site, pTNM staging, tumor size, lymphatic vessel infiltration, pathological differentiation degree, number of examined lymph nodes, Clavien-Dindo grade, and UAC were associated with OS (all p<0.05). The multivariate analysis indicates that age, BMI, ASA Score, comorbidities, pTNM staging, number of examined lymph nodes, Clavien-Dindo grade, and UAC were independent predictors of OS (P<0.05).

Supplementary Table 1 demonstrates that age, pTNM staging, tumor size and number of harvested lymph nodes were independent predictors of DFS; however, UAC was not an independent risk factor (p<0.05).

Analysis of risk factors of UAC

Table 3 presents the results of the logistic univariate and multivariate analyses of risk factors associated with UAC. The univariate analysis shows that gender, age, type of medical insurance, income, social status, residential address, ASA score, history of intra-abdominal surgery, Charlson score and Clavien-Dindo grade were related to UAC (all p <0.05). The reduced multivariate model analysis shows that female sex, old age, self-paid status, very low social status, high ASA score, intra-abdominal surgery history, and postoperative serious complications (Clavien-Dindo III-IV) were independent risk factors for UAC (p<0.05).

The change of risk factors for UAC over time

The radar chart shows that the risk factors of UAC changed with time (Fig. 3). In general, the number of patients with self-funded and an extremely low social status significantly decreased from 2011 to April 2015 (all p <0.05). The proportion of self-funded patients
showed a downward trend year by year from 2011 to April 2015, while the proportion of extremely low social status patients gradually decreased (0~3.2%) from 2011 to 2014 and then increased again (4.5%) in 2015 (Supplement Table 2). Between 2011 and April 2015, there was no significant change in the proportion of female patients, aged patients, patients undergoing intra-abdominal surgery, and high ASA patients (all p>0.05). At the same time, the proportion of patients with severe postoperative complications was not significantly improved (p = 0.549).

Discussion

It has been confirmed in animal models that the angiogenesis of the micrometastatic foci will be significantly faster after resection of the primary cancer(15–17); thus, the treatment of advanced cancer cannot rely solely on surgical treatment(18–21). Therefore, although surgery is a key part of the comprehensive treatment for local advanced GC, timely adjuvant chemotherapy plays an important role. Our results show that the patients with a chemotherapy delay (delayed more than 60 days) or without chemotherapy have significantly worse overall and disease-free survival than those with timely chemotherapy. The patients with delayed or omitted chemotherapy did not exhibit significant differences, and the chemotherapy delay patients’ sample size was limited. Thus, we combined them in the subsequent analysis as UAC. Our data show that UAC is a risk factor for OS independent of tumor staging, age and other factors for STAGE II/III stage GC patients. The reason may be that a chemotherapy delay can affect the early inhibition of cytotoxic drugs on angiogenesis in micrometastasis, and it is easy to induce primary drug resistance(17, 22). UAC is not an independent risk factor for the survival of all patients with STAGE II/III GC, and the reasons require further discussion. As an independent risk factor for OS, clinicians should avoid the occurrence of UAC in patients. The rate of UAC in recent years was significantly reduced from 2011 to 2012;
however, the rate did not significantly decrease from 2012 to 2015 and increased from 29.1% in 2014 to 30.7% in 2015. Therefore, it is of importance to identify the high-risk factors of UAC and investigate their changes overtime to facilitate relevant departments to employ appropriate measures to improve this situation. At the same time, we believe that the causes of UAC are not only related to clinical treatment factors, such as surgery, postoperative complications and tumor factors, and individual factors, such as socioeconomic variables, may also play important roles. Therefore, we expanded the included variables, such as the medical insurance type, according to the characteristics of the regional socioeconomic factors and divided the included factors into three categories, including individual, treatment and tumor, for logistic analysis. The results showed that female, elderly, self-paid patients and patients with a low social status, high ASA score, preoperative abdominal operation history and severe postoperative complications exhibited high risk factors of UAC, while tumor factors, such as tumor size and staging, did not affect postoperative chemotherapy time. Further analysis indicated the risk factors change over time in the intervening factors with the increase in time, the surgical experience accumulated, while serious postoperative complications did not significantly improve. Severe postoperative complications often require longer recovery times and may affect patients’ confidence in themselves and their doctors’ treatment(23), thus delaying their first time of receiving chemotherapy. Moreover, low-status groups typically suffer from substantial life pressures; thus, they often delay or give up chemotherapy due to personal or family factors after surgery. Therefore, although through the unremitting efforts of the government, the proportion of self-financed patients decreases year by year (which can improve the patient’s willingness and timeliness of chemotherapy), the rate of UAC has not significantly improved in recent years.

We believe that to improve the OS of gastric cancer, the relevant departments or
personnel should take corresponding measures in response to the various factors that cause UAC. For clinical workers, preoperative evaluation, intraoperative quality control and enhanced postoperative management should be performed to reduce postoperative complications, particularly severe postoperative complications. At the same time, postoperative care and education should receive attention in high-risk groups, such as individuals with a low social status, to inform them of the importance of timely postoperative chemotherapy. The government should continue to improve the medical insurance policy to continue to reduce the proportion of self-funded patients.

This paper is the first study of the effect of postoperative UAC on the prognosis of patients with gastric cancer. It incorporates multiple factors to explore high-risk groups to provide a reference for relevant departments and personnel to employ corresponding measures. However, our research has unavoidable shortcomings: First, as a retrospective study, it is difficult to exclude the effects of confounding factors on the results, i.e., the patient’s personal preferences may have an impact on the UAC; Second, some patients, such as those with a very low social status, are limited in number at the time of stratification, which may affect the results; Third, the risk factors for UAC in different countries may vary due to different national conditions, such as health care policies and income conditions (24, 25). Nevertheless, the results of this retrospective study are important because it is difficult to conduct prospective studies due to ethical concerns. We also look forward to the international, multicenter, retrospective study in the near future to explore the risk factors and their differences in each country, thus providing strategies for improving the overall prognosis of patients with gastric cancer worldwide.

AC: Acceptable chemotherapy, UAC: Unacceptable delay or missing chemotherapy, LN: lymph node

Figures
Fig. 1 The trend of unacceptable chemotherapy in pathological stage II/III stage gastric cancer patients between 2011 and April 2015
Fig. 2 Survival of patients in AC and UAC groups. A: The OS of AC group vs UAC group. B: the OS among AC group, Delay (>60 days) and No chemotherapy. C: the DFS of AC group vs UAC group. D: the DFS among AC group, Delay (>60 days) and No chemotherapy.
Figure 3

Fig. 3 Analysis of the risk factors of unacceptable chemotherapy from 2011 to April 2015, † P value <0.05.
