ABSTRACT. Ascorbate peroxidase (APX) plays an important role in the metabolism of hydrogen peroxide in higher plants, affording them protection against oxidative stress. We studied the effect of overexpressing a cytosolic ascorbate peroxidase (cAPX) gene—derived from pea (Pisum sativum L.)—in transgenic tomato plants (Lycopersicon esculentum L.). Transformants were selected in vitro using kanamycin resistance and confirmed by polymerase chain reaction (PCR) and northern analyses. An APX native-gel assay indicated that, in the absence of stress, APX activity in transgenic plants was several times greater than that measured in wild-type (WT) plants. Several independently transformed lines were propagated and evaluated for resistance to chilling and salt stress. After placing seeds at 9 °C for 5 weeks, percent germination was greater for seeds obtained from transgenic lines (26% to 37%) compared to the WT (3%). Plants from transgenic lines also had lower electrolyte leakage (20% to 23%) than WT (44%) after exposure to 4 °C. Visual assessment of transgenic and WT lines exposed to salinity stress (200 or 250 mM) confirmed that overexpression of APX minimized leaf damage. Moreover, APX activity was nearly 25- and 10-fold higher in the leaves of transgenic plants in response to chilling and salt stresses, respectively. Our results substantiate that increased levels of APX activity brought about by overexpression of a cytosolic APX gene may play an important role in ameliorating oxidative injury induced by chilling and salt stress.

As with many other environmental stresses, exposing plants to high salt levels or chilling results in oxidative damage from reactive oxygen species (ROS), such as superoxide (O2–), hydrogen peroxide (H2O2), and hydroxyl radicals (OH–) (Bruggemann et al., 1999; Prasad et al., 1994a, 1994b). ROS also may be generated in living cells during normal metabolism (Allen, 1995). ROS can damage plant membranes as well as DNA (Becana et al., 1998; Posmyk et al., 2001). Plants have developed both enzymatic, [e.g., superoxide dismutase (SOD, EC 1.15.1.1) and ascorbate peroxidase (APX) (EC 1.11.1.11)] and nonenzymatic (ascorbate or glutathione) systems to counter the effects of oxidative stress. SOD scavenges O2– radicals and converts them to H2O2. APX catalyses the conversion of H2O2 to water, with ascorbate serving as the electron donor (Asada, 1992). In general, APX activities increase in plants exposed to various environmental stresses. This elevated activity is correlated with a rise in the levels of other antioxidant enzymes, such as catalase (CAT), SOD, and glutathione reductase (GR), which suggests that the components of ROS-scavenging systems are co-regulated (Allen, 1995; Pastori and Trippi, 1992; Sen Gupta et al., 1993; Shigeoka et al., 2002).

The injury manifested by low-temperature and salt stresses is believed to be lipid peroxidation caused by an increase in oxygen radical generation (Prasad et al., 1994a, 1994b; Shalata et al., 2001). After exposure to low temperatures, chilling-tolerant maize (Zea mays L.) exhibited higher SOD and APX activities compared with chilling-sensitive maize (Pinheiro et al., 1997). In tomato, higher chilling tolerance prevents ROS formation and allows for better conversion of light to photochemical energy at suboptimal temperatures (Bruggemann et al., 1999).

The relationship between salt stress and antioxidant enzyme activity has been investigated in various plants (Dionisio-Sese and Tobita, 1998; Hernández et al., 1995, 1999, 2001; Shalata et al., 2001). Gueta-Dahan et al. (1997) have found that cAPX and Cu/Zn-SOD in sweet orange (Citrus sinensis Osbeck) cells were similarly induced by salt and oxidative stresses. APX has been...
proposed as a key enzyme for imparting salt tolerance in citrus because its steady-state activity in salt-sensitive citrus callus is far below that observed in salt-tolerant citrus callus. Mittova et al. (2003) reported that the salt-stress-induced increase in cytosolic antioxidant enzyme activity in salt-tolerant tomato species also conferred cross-tolerance toward enhanced mitochondrial and peroxisomal ROS production. Shalata et al. (2001) found that, under salt stress, membrane lipid peroxidation gradually increased in salt-sensitive tomato roots. This response was accompanied by decreased activities of SOD, APX, and CAT. In contrast, the activity of these enzymes increased in salt-tolerant tomato roots, where the membrane lipid peroxidation levels remain unchanged.

Increased expression of antioxidant enzyme activity appears to be very effective in overcoming chilling and/or salt stresses in several crop species (Payton et al., 2001; Roxas et al., 2000; Tanaka et al., 1999; Van Breusegem et al., 1999) but has not been explored in horticultural plants. The objective of the present research was to evaluate changes in tolerance to chilling and salt stresses resulting from the overexpression of a pea cytosolic APX gene in tomato.

Materials and Methods

Production and Propagation of Transgenic Plants. Tomato plants (cv. Zhongshu No. 5) were transformed with a binary vector containing pea cAPX cDNA (Mittler and Zilinskas, 1992) under the control of a dual cauliflower mosaic virus 35S promoter and 35S terminator (Payton et al., 2001). The T-DNA contained the nopaline synthase (NOS) promoter fused to a neomycin phosphotransferase II gene (NPT II). This construct, pCGN1578, was transferred to the tomato cells via Agrobacterium tumefaciens [A. tumefaciens (Smith & Towns.) Conn.] strain EHA105. Kanamycin-resistant plants were then regenerated using a technique described by Frary and Earle (1996), with modifications (Wang, 2003). Cotyledonary and hypocotyl explants were excised from 8- to 10-d-old seedlings. These were incubated for 10 to 15 min in an Agrobacterium suspension diluted to an OD600 of 0.2 in a liquid Murashige-Skoog (MS) medium (Murashige and Skoog, 1962) that had been supplemented with 30 g L−1 sucrose (MSO; pH 5.8). Afterward, they were blotted on sterile paper towels, plated on a co-cultivation medium (MS + 40 mg L−1 acetylsyringone + 1 mg L−1 zeatin + 7 g L−1 agar), and placed in the dark for 2 to 4 d. The explants were then transferred to a selection medium (MS + 1 mg L−1 zeatin + 50 mg L−1 kanamycin + 400 mg L−1 cefotaxime + 7 g L−1 agar), and the resultant shoots were placed on a rooting medium (MS + 50 mg L−1 kanamycin + 0.2 mg L−1 NAA + 400 mg L−1 cefotaxime + 7 g L−1 agar). Culture was at 23 °C /21 °C (± 2 °C, day/night temperature) under cool white vapor lights (1000 W; Philips, Eindhoven, The Netherlands) from 0600 to 1000 hr. These original transgenic lines (T0 generation) were self-pollinated to produce T1 progeny. The T1 plants were then self-pollinated to yield the T2 generation. All the transgenic plants were resistant to kanamycin.

Analysis of Transgenic Plants. Putative transformants were screened for T-DNA insertion using PCR primers to amplify the 35S::APX fusions. Genomic DNA was isolated from wild-type (WT) and APX-overexpressing plants (T1), according to procedures described by Doyle and Doyle (1987). The sequences for the forward and reverse primers for 35S::APX included 5′-CAC-GTCTTCAAAGCAAGTGG-3′ and 5′-GACTGCAGCTTCAGCAAATCC-3′, respectively. About 20 ng DNA was used for PCR reaction, under the following conditions: 1 min at 94 °C, 1 min at 60 °C, and 2 min at 72 °C for 30 cycles. The amplified products were then separated electrophoretically on a 0.8% agarose gel, stained with ethidium bromide, and visualized and photographed under ultraviolet light. For the segregation analysis, ±50 seeds from WT and each independent line (T0) were germinated on a solid MS medium containing kanamycin. After 7 to 10 d, the cutting shoots were transferred to a selective rooting medium. Seedlings were scored for kanamycin resistance, and the ratio of resistant to sensitive plants was used to estimate the number of independent T-DNA insertions. All transformants were grown in potting mix to maturity in the greenhouse. These plants were then self-fertilized, and the resulting seed was collected from individual lines.

Northern Blots. Total RNA was prepared from the leaves of the WT and transgenic plants, using Tri-reagent as specified by the manufacturer (Molecular Research, Cincinnati). In order to ensure even loading, quantification of total RNA in all samples was determined with a spectrophotometer and by ethidium bromide staining of agarose gels. Briefly, 30-µg aliquots of total RNA were separated on a 1% (w/v) denatured agarose gel and transferred to a nylon membrane. This procedure was followed by a Super Hyb Kit northern blot system procedure (Molecular Research). The membrane was probed with a 32P-labeled APX-PCR fragment, and hybridizations were detected by a Phosphor-Imager SI (Molecular Dynamics, Sunnyvale, Calif.). The predicted size of the transcript is 0.75 kilobases (kb).

Enzyme Activity Assays. For the APX activity-gel assays, about 100 mg of the leaf tissue was ground to a fine powder in liquid nitrogen, and homogenized in 200 µL of grinding buffer [100 mM NaPO4 (pH 7.0), 5 mM ascorbate, 1 mM EDTA (pH 8.0), 10% glycerol, and 0.001% bromophenol blue]. The supernatant was collected and protein concentration was determined using a Protein Assay System (Bio-Rad, Hercules, Calif.). About 70 µg of total protein was loaded on a non-denaturing, 10% polyacrylamide gel. It was then electrophoretically separated (via PAGE) for 5 h at 4 °C in a 1× Tris-glycine buffer (24 mM Tris and 192 mM glycine), followed by staining for APX activity, as described by Mittler and Zilinskas (1993).

For the SOD activity-gel assays, ±100 mg of the leaf tissue was finely ground in liquid nitrogen and homogenized in 200 µL of grinding buffer [50 mM Tris (pH 6.8), 10% glycerol, and 0.001% bromophenol blue]. About 70 µg of soluble protein was then loaded on a non-denaturing, 10% polyacrylamide gel and electrophoretically separated for no more than 6 h at 4 °C, as described by Van Camp et al. (1996). After staining, the gels were scanned with a Densitometer SI (Molecular Dynamics). ImageQuant 5.2 was used for image analysis (Molecular Dynamics).

Evaluation of Tolerance to Chilling Stress. About 50 seeds each from WT and T1 generation were surface-sterilized and germinated at 9 °C in the dark on a solid MS medium. They were considered viable if the radicles were fully extended from the seed coats. After 5 and 8 weeks, percent seed germination was determined. Means ± SE for four replicates were determined. Differences between means were evaluated by Duncan’s multiple range test (NCSS-PASS software; NCSS, Williamsport, Pa.).
Arcsine square root transformation was performed before data analysis.

Four-week-old transgenic T₂ and the WT plants grown in plastic pots (15 cm diameter, 14.5 cm height) in the greenhouse were transferred to 4 °C in the dark for chilling treatment. Two disks (1.02 cm in diameter) from the fourth or fifth leaf from the apex were excised after 2, 6, 8, or 10 d and ion leakage was determined with a conductivity meter (Markson Science, Del Mar, Calif.) according to the method described by Wisniewski et al. (1997). The percentage of electrolyte leakage due to the chilling treatment was calculated from these values. Means ± se for three replicates were determined. Differences between means were evaluated by Duncan’s multiple range test. Arcsine square root transformation was performed before data analysis. For enzyme activity assay, leaf disks (under 4 d of the chilling stress) were taken from the WT and transgenic plants, frozen in liquid nitrogen, and stored at –80 °C.

Evaluation of tolerance to salt stress. Cuttings from WT and transgenic T₂ were grown in rooting medium for two weeks. Transgenic cuttings were screened on media containing 50 mg·L⁻¹ kanamycin. Healthy seedlings were transferred in 5.8 × 5.8 × 8-cm plastic pots filled with peat moss soil and watered with a commercial fertilizer (9N–4.4P–12.5K; Spectrum Brands, St. Louis) designed for tomatoes. Plants were grown under standard greenhouse conditions [≈23 °C/21 °C (±2 °C, day/night temperature)] with natural lighting supplemented with sodium vapor lights (1000W, Philips) from 0600 to 2200 h. After 1 week, plants to be stressed were watered with fertilizer and either 200 or 250 mm NaCl every 3 d, and evaluated after 10, 20, and 30 d. Nonstressed controls were watered only with fertilizer. Growth (from apex to soil) was measured 10 d after applying the salt stress. The extent of injury to leaves and whole seedlings was visually scored, with a scale of 0 to 5 used to estimate damage: 0 = no damage symptoms; 1 = reduced growth and <20% leaf area exhibiting injury; 2 = yellowing leaves, 21% to 40% of the leaf area injured; 3 = plants wilted, 41% to 60% leaf area injured; 4 = seriously damaged, the plant becoming flaccid and not remaining upright, 61% to 80% leaf area injured; 5 = 81% to 100% of the leaf area injured or else the plant had died. WT and the entire set of individual transgenic lines represented one block in the experimental design. The complete design was arranged as a randomized complete block with five blocks (replicates). Means ± se of five replicates were determined. The nonparametric Kruskal–Wallis test was used for analysis of ranks. The leaf discs from WT and transgenic plants under 10-d NaCl (200 mM) stress were then frozen in liquid nitrogen and stored at –80 °C for further enzyme activity gel analyses.

Results

Overexpression of the cAPX gene. No PCR product was obtained from WT plants with 35S promoter- and cAPX-specific primers, whereas an expected 0.9 kb fragment was amplified from DNAs from all transgenic lines (data not shown). As expected and verified using chi square analysis, the majority of lines exhibited a 3:1 segregation for kanamycin resistance (and indirectly cAPX) in T₁ plants (Table 1).

RNA northern blot analyses indicated that when total RNA from the WT and transgenic tomato leaves was hybridized with a full-length cAPX probe, a signal (750 kb) was detected only in the transgenic lines (Fig. 1). Five of 14 lines exhibited relatively high levels of expression. Moreover, APX activity for two se-

### Table 1. Chi square analysis of the expression of kanamycin resistance in seeds of the T₁ generation of transgenic tomato plants. Wild-type = nontransformed plants; ND = not determined. A₁ to A₃₀ are transgenic seeds from independent lines; df = 2. Probability of 1 indicates a perfect fit to the expected segregation ratio whereas P ≤ 0.05 indicates a lack of fit. Kan+/Kan- refers to the number of plants exhibiting kanamycin resistance vs. those that do not exhibit kanamycin resistance.

| Lines tested | Kan+/Kan- Ratio | χ² | P |

plants based on a comparative estimation of the band intensity on the gels (Fig. 2B).

**Effects of Chilling.** Hypocotyls and cotyledons developed normally from the T₁ seeds, obtained from T₀ plants, when they were germinated at 9 °C. However, hypocotyl elongation from the WT seed was inhibited and no cotyledon expansion was apparent even after eight weeks. Germination was significantly greater among T₁ seeds compared to WT seeds (P < 0.05). For example, after 5 weeks, 37% and 26% of the T₁ seeds germinated in lines A9 and A16, respectively, compared to 3% of the WT seeds. After 8 weeks, the percent germination of transgenic seeds was 58% and 35% for lines A9 and A16, respectively, compared to 7% for WT seeds (Fig. 3). At normal growth temperatures (20 °C), no differences in germination were observed between the WT and transformed lines (data not shown).

To study the effect of cAPX expression on chilling tolerance, cellular injury was assessed by measuring solute leakage (Bowler et al., 1991). Significant differences (P < 0.05) were found between WT and cAPX plants after 8 d of the low-temperature (4 °C) treatment, with the transgenics showing lower leakage (23% for A9 and 20% for A16) than from the WT (44%) (Fig. 4). After 10 d, differences in electrolyte leakage persisted and actually increased between WT and transgenic lines, A9 and A16. Electrolyte leakage was ≈60% in the WT and 35% and 29% in transgenic lines A9 and A16, respectively (Fig. 4). APX and SOD enzyme activities were analyzed by gel assays after treatment for 4 d at 4 °C (Fig. 5). APX+ plants exhibited significant levels of activity compared to the WT plants where little to no APX activity could be detected (Fig. 5A). Little difference could be observed in SOD activity between the WT and transgenic lines (Fig. 5B) and SOD activity appeared to be less than the level of activity present in non-stressed controls (Fig. 2B).

**Effects of Salt Stress.** Compared to the control plants, growth (measured as height) of both WT and transgenic plants was severely inhibited by 200 mM NaCl (Fig. 6). However, transgenic plants were visibly less affected in their appearance by the salt solution, especially at 250 mM (Fig. 7). Wilting was obvious in leaves and stems of WT plants after 10 d of salt stress, and leaf injury, leaf and stem chlorosis, and, occasionally, necrosis and stem collapse had occurred. The average injury rating was 2.2 for WT plants receiving 200 mM NaCl (Fig. 8A) and 4 for WT plants receiving 250 mM NaCl (Fig. 8B). Plants from both the A9 and A16 lines (Fig. 8 A and B) began showing symptoms after 10 d of salt treatment but had significantly less injury (P < 0.05) than WT plants. After 10 d, the average injury rating of the transgenic lines was 1 at 200 mM NaCl (Fig. 8A) and 2.2 at 250 mM NaCl (Fig. 8B). After 20 d, WT plants irrigated with 200 mM NaCl had an average injury rating of 3.6 and none of the plants that 250 mM NaCl had survived (Fig. 8A and B). Transgenic lines A9 and A16 were less affected (P < 0.05), with an average injury rating of 2.4 and 1.6, respectively, under the 200 mM treatment. Significant differences were observed in the level of injury of WT and transgenic lines treated with 250 mM NaCl during the first 20 d (Fig. 8B). However, by 30 d both WT and transgenic plants exhibited a severe level of injury.

APX activity was also induced by salt stress, with levels in the transgenic leaves being considerably higher than in WT plants after 10 d of treatment with 200 mM NaCl (Fig. 9A). In contrast,
Salt stress decreased SOD activity in both the transgenic and the WT plants compared to unstressed plants (Fig. 2B and 9B, respectively).

**Discussion**

Overexpression of antioxidant genes in plants has been previously shown to provide enhanced tolerance to oxidative stress in several crop species (Allen, 1995; Gueta-Dahan et al., 1997; Payton et al., 2001; Roxas et al., 2000). Our results support previous reports and demonstrate that ectopic expression of the pea *cAPX* gene in tomato confers increased resistance to oxidative damage caused by exposure to chilling temperatures or high salt levels.

Seed germination is characterized by the rapid generation of superoxide and H$_2$O$_2$ following imbibition (Gidrol et al., 1994; Puntarulo, 1994). Under chilling conditions, the activities of antioxidant enzymes, including SOD, peroxidase, and glutathione reductase, significantly increase to limit the damage caused by such oxidative stress (Posmyk et al., 2001). We demonstrated that, at a low temperature (9 °C), germination rates were higher for seeds from transgenic tomato plants that overexpressed *cAPX* compared with WT seeds (Fig. 3). These results suggest that the enhanced level of APX may detoxify H$_2$O$_2$ to H$_2$O, thereby alleviating oxidative stress and increasing germination. In addition, the leakage of electrolytes was lower in transgenic plants in response to chilling at 4 °C (Fig. 4) suggesting less disruption to the plasma membrane in *cAPX* plants. At 4 °C, APX activity in the transgenic tomatoes was 25-fold higher than in the WT plants (Fig. 5A). Therefore, we suspect that this elevated activity is a requirement for higher rates of H$_2$O$_2$ detoxification at lower temperatures (Pastori et al., 2000), thereby protecting membrane integrity.

Mittova et al. (2002) have demonstrated that salt stress induces up-regulation of an efficient chloroplast antioxidant system in salt-tolerant wild tomatoes but not in the cultivated species. This response by the former is characterized by increased activities of the ROS-scavenging enzymes SOD, APX, and GR. In our study as well, the level of APX was significantly higher in the transgenic *cAPX* tomatoes than in the WT plants watered with 200 mM NaCl (Fig. 9A). This overexpression apparently enabled the transformed plants to better tolerate the salt stress. Since APX is involved in detoxifying ROS, the increased resistance to salt stress was most likely due to an increased ability to recover from injury rather than a direct resistance to the negative effects of exposure to high concentrations of an ionic solution such as sodium chloride. A similar hypothesis regarding the impact of the overexpression of a superoxide dismutase (SOD) gene in alfalfa (*Medicago sativa* L.) was stated by McKersie et al. (1993) and Bridger et al. (1994). In this work, constitutive expression of an SOD gene resulted in increased cold tolerance. Since APX works in conjunction with SOD and other antioxidant enzymes to detoxify ROS, it is possible that the overexpression of the cytosolic APX may have also induced upregulation of native APX, SOD, and antioxidant genes. Increased resistance of tomato to oxidative stress has also been observed when just an SOD gene alone has been overexpressed in transgenic plants (Wang, 2003). Co-regulation of antioxidant enzymes has been previously reported (Allen, 1995; Sen Gupta et al., 1993) and such feed back or cross-talk within a pathway, such as the antioxidant system, is not uncommon.

In both chilling- and salt-stress tests, APX activity was greater in transgenic plants, compared to WT plants, effectively amelio-
rating the effect of chilling and salt stress. This research demonstrates that overexpression of a single gene can lead to enhanced resistance to environmental stress and could be a useful approach to improving stress resistance in existing cultivars of tomato once transgenic technologies are more widely accepted by the general public and the costs associated with regulatory approval once transgenic technologies are more widely accepted by the general public and the costs associated with regulatory approval become less prohibitive. Our data, and the cited literature, also suggest, however, that antioxidant enzymes, such as APX and SOD, may serve as good physiological or molecular markers in marker-assisted breeding programs aimed at increasing resistance to environmental stress.
