Within the AMPT Monte Carlo model, fluctuations in the initial transverse parton density are shown to lead to harmonic flows. The net back-to-back dihadron azimuthal correlation after subtraction of contributions from harmonic flows still has a double-peak that is independent of the initial geometric triangularity and unique to the jet-induced Mach cone and expanding hot spots distorted by radial flow. The longitudinal structure of hot spots also leads to a near-side ridge in dihadron correlation with a large rapidity gap. By successively randomizing the azimuthal angle of the transverse momenta and positions of initial partons, one can isolate the effects of jet-induced medium excitation and expanding hot spots on the dihadron azimuthal correlation. The double-peaks in the net dihadron and $\gamma$-hadron correlation are quantitatively different since the later is caused only by jet-induced Mach cone.

Dihadron correlation in high-energy heavy-ion experiments provides a useful tool to study jet quenching $^1$ that suppresses not only single inclusive large $p_T$ hadrons $^2$ but also large $p_T$ back-to-back correlation $^3$. By decreasing $p_T$ of the away-side hadrons associated with a high $p_T$ triggered hadron, one can further study the medium modification of hadron distribution from an energetic jet as well as jet-induced medium excitations. Experimental data in $Au + Au$ collisions at the Relativistic Heavy-Ion Collider (RHIC) $^4$-$^6$ show a double-peaked back-to-back azimuthal dihadron correlation with a maximum opening angle of $\Delta\phi \approx 1$ (rad) relative to the back-side of a high $p_T$ trigger. Such a feature in dihadron correlation was suspected to be caused by Mach-cone excitation induced by jet-medium interaction $^7$-$^8$. However, hydrodynamic study of jet-induced medium excitation with a realistic source term for energy-momentum deposition $^9$ and parton transport study of jet propagation $^{10}$ both show that it is the deflection of jet showers and medium excitation by radial flow that produces double-peaked back-to-back dihadron correlation. Moreover, recent studies also found that expanding hot spots in the initial parton transverse density distorted by radial flow $^{11,12}$ and the triangular flow $^{13,14}$ all contribute to a double-peaked back-to-back dihadron correlation. If these local fluctuations are extended in the longitudinal direction like a string model $^{15}$ or plasma $^{16,17}$, they would also lead to a ridge structure in the near-side dihadron correlation with large rapidity gap $^{18,19}$. With these different mechanisms contributing to the dihadron correlation, it is important to explore ways to separate different contributions and study the characteristics of the dihadron correlation from each of them.

In this Letter, we will use a multiphase transport (AMPT) model $^{20}$ to study dihadron correlation as a result of harmonic flows, expanding hot spots, jets and jet-induced medium excitation. We first study harmonic flows of hadron spectra due to fluctuations in initial parton density, which all contribute to dihadron azimuthal correlation. The dihadron correlation after subtraction of contributions from harmonic flows should provide information on the unique structures of hadron correlation from medium modified jets, jet-induced medium excitation and expanding hot spots distorted by radial flow in high-energy heavy-ion collisions. We will also investigate the longitudinal structures of hot spots and the resulting dihadron azimuthal correlation with large rapidity gap. By successively randomizing the azimuthal angles of transverse momenta and coordinates of initial jet shower partons, we can isolate the effect of medium modified dijets, jet-induced medium excitation and expanding hot spots. We will also compare dihadron correlation after subtraction of the contributions from harmonic flow with $\gamma$-hadron correlation which is only affected by jet-induced medium excitation. The AMPT results shown in this paper are central $Au + Au$ collisions with fixed impact-parameter $b = 0$ at the RHIC energy $\sqrt{s} = 200$ GeV.

AMPT $^{20}$ model combines initial conditions from HIJING model $^{22}$ with parton and hadron cascade for final state interaction. We will use a version of AMPT with string melting and parton recombination for hadronization which was shown to better describe the collective phenomenon in heavy-ion collisions at RHIC $^{21}$. The parton cascade employed in AMPT includes only elastic parton collisions whose cross sections are controlled by the values of strong coupling constant and the Debye screening mass. Within HIJING, Glauber model for multiple nucleon scattering is used to describe the initial parton production in heavy-ion collisions. Nucleon-nucleon scatterings contain both independent hard parton scattering and coherent soft interaction that is modeled by string formation for each participant nucleon. Strings are then converted into soft partons via string melting scheme in AMPT. Such multiple scatterings lead to fluctuation in local parton number density or hot spots from both soft and hard interactions which are proportional.
to local transverse density of participant nucleons and binary collisions, respectively.

Shown in Fig. 1 are contour plots of initial parton density in the transverse plane $dN/dxdy$ (left panel) and $dN/dxdη$ (right panel) in $x−η$ (pseudorapidity) plane in a typical AMPT central $Au+Au$ event ($b = 0$) at $\sqrt{s} = 200$ GeV, with ellipticity $c_2 = 0.02$ and triangularity $c_3 = 0.02$ of the transverse parton distribution.

Collective expansion due to parton rescattering will translate the initial geometric irregularities into harmonic flows in momentum space [23]. Shown in Fig. 2 are dihadron correlations before (dot-dashed) and after (solid) the removal of contributions from harmonic flows, where $B$ is a normalization factor determined by the ZYAM scheme, $v_n^{\text{trig}}$ and $v_n^{\text{asso}}$ are harmonic flow coefficients for trigger and associated hadrons. Shown in Fig. 3 are dihadron correlations for trigger and associated hadrons. Shown in Fig. 3 are dihadron correlations before (dot-dashed) and after (solid) the removal of contributions from harmonic flows, where $B$ is a normalization factor determined by the ZYAM scheme, $v_n^{\text{trig}}$ and $v_n^{\text{asso}}$ are harmonic flow coefficients for trigger and associated hadrons. Shown in Fig. 3 are dihadron correlations before (dot-dashed) and after (solid) the removal of contributions from harmonic flows, where $B$ is a normalization factor determined by the ZYAM scheme, $v_n^{\text{trig}}$ and $v_n^{\text{asso}}$ are harmonic flow coefficients for trigger and associated hadrons. Shown in Fig. 3 are dihadron correlations before (dot-dashed) and after (solid) the removal of contributions from harmonic flows, where $B$ is a normalization factor determined by the ZYAM scheme, $v_n^{\text{trig}}$ and $v_n^{\text{asso}}$ are harmonic flow coefficients for trigger and associated hadrons.
modified dijets and jet-induced medium excitations and hadrons from expanding hot spots under strong radial flow. The structure therefore should be unique and insensitive to the fluctuation of the initial geometry of dense matter at a fixed impact-parameter. As shown in Fig. 3 the dihadron correlations after subtraction of contributions from harmonic flows become independent on the initial geometric triangularity $\epsilon_3$.

In order to study the structure of dihadron azimuthal correlation from jets (including jet-induced medium excitation) and hot spots separately, we successively switch off each mechanism and calculate the dihadron correlation within AMPT model. We first randomize the azimuthal angle of each jet shower parton in the initial condition from HIJING simulations. This effectively switches off the initial back-to-back correlation of dijets. The dihadron correlation (dashed) denoted as “hot spots” in Fig. 4 still exhibits a double-peak on the away-side that comes only from hot spots. It has roughly the same opening angle $\Delta \phi \sim 1$ (rad) as in the “full” simulation (solid). However, the magnitude of the double-peak in the away-side correlation is reduced by about 40%, which can be attributed to dihadrons from medium modified dijets and jet-induced medium excitation. Without knowing the relative yields of hadrons from jets and hot spots, it is difficult to extract dihadron correlation from dijets (and jet-induced medium excitation) alone. When
jet production is turned off in the HIJING initial condition, fluctuation in soft partons from strings can still form what we denote as “soft hot spots” that lead to a back-to-back dihadron correlation (dot-dashed) with a weak double-peak. It is clear that jet shower partons increase the local parton density in “hot spots” and lead to a stronger double-peaked dihadron correlation than that of “soft hot spots”. Such “soft hot spots” are the likely candidate mechanism for the observed back-to-back dihadron correlation in heavy-ion collisions at the SPS energy [24] where jet production is insignificant. Without jets in AMPT, one can further randomize the polar angle of transverse coordinates of soft partons and therefore eliminate the “soft hot spots”. The dihadron correlation from such “smoothed” initial condition becomes almost flat (dotted).

Because of the elongated shape of hot spots in the longitudinal direction as shown in Fig. 1 (left panel), the structure of dihadron azimuthal correlation should resemble similar with a large range of rapidity gaps as shown in Fig. 5. Since dihadron correlation from a single jet is only restricted to small rapidity gap $\delta y \sim 1$, the near-side azimuthal correlation with a large rapidity gap, referred to as ridge, can only come from a hot spot. This is confirmed by our observation that dihadron correlation in AMPT with the “smoothed” initial conditions does not have any ridge structure. In addition, jet production is approximately proportional to binary nucleon-nucleon collisions and should also be correlated with hot spots. Therefore, the ridge in dihadron correlation can occur for both hard and soft trigger hadrons. In non-central collisions, the effects of jet-medium interaction and hot spots are shown to give only a broad single peak in dihadron correlation on the away-side [25]. With a large rapidity gap, it amounts to a dihadron correlation due to momentum conservation [26].

Since hard direct photons are produced uniformly in azimuthal angle, any structure in $\gamma$-hadrorn azimuthal correlation with large $p_T^{\gamma}$ can only come from $\gamma$-triggered jets and jet-induced medium excitation [10]. Shown in Fig. 7 are dihadron correlations (solid) after subtraction of harmonic flows as compared with $\gamma$-hadrorn correlation (dashed). The two correlations are comparable in magnitude but dihadron has a more pronounced double-peak which can be attributed to additional di-hadrons from hot spots and the geometric bias toward surface and tangential emission that enhances deflection of jet showers and jet-induced medium excitation [10] by radial flow. Such difference is important to measure in experiments that will provide critical information on jet-induced medium excitation and hydrodynamic evolution of hot spots in high-energy heavy-ion collisions.
