Abstract. In this paper we study the ground state phase diagram of a one-dimensional \( t-U-J \) model, at half-filling. In the large-bandwidth limit and for ferromagnetic exchange with easy-plane anisotropy, a phase with gapless charge and massive spin excitations, characterized by the coexistence of triplet superconducting and spin density wave instabilities is realized in the ground state. With reduction of the bandwidth, a transition into an insulating phase showing properties of the spin-\( \frac{1}{2} \) \( XY \) model takes place.

1 Introduction

Superconductivity near a magnetic instability is a topic of increased current interest in condensed matter physics. Magnetically mediated Cooper pairing near the antiferromagnetic instability is widely discussed in the context of superconductivity in copper-oxide systems. Moreover, the discovery of Triplet Superconductivity (TS) in \( Sr_2RuO_4 \) and the recent discovery of coexistence of the TS phase with ferromagnetism in \( UGe_2 \), \( URhGe \) and \( ZrZn_2 \) has triggered an increased activity in studies of correlated electron models showing close proximity of triplet superconducting and ferromagnetically ordered phases.

Another group of unconventional superconductors with close proximity of magnetic and superconducting ordering belongs to the \( (TMTSF)_2X \) family of quasi-one-dimensional conductors (Bechgaard salts). Growing experimental evidence has been collected in the last few years, indicating that \( (TMTSF)_2ClO_4 \) and \( (TMTSF)_2PF_6 \) under pressure are triplet superconductors. Most interesting is the phase diagram of \( (TMTSF)_2PF_6 \) which shows a spin-Peierls (SP) phase in the ground state at atmospheric pressure. Increasing pressure leads first to a transition from the SP phase into a spin density wave (SDW) phase, and finally to the suppression of the SDW ground state in favor of superconductivity. Recent detailed experimental studies of the phase diagram of the \( (TMTSF)_2PF_6 \) compound indicate the possibility of a coexistence regime between SDW and superconductivity . Although the very presence of a homogeneous coexistence phase in the phase diagram was questioned in the more recent publication , the SDW-SC competition is common in organic materials and therefore models of correlated electrons exhibiting such phases are of great interest.

Various models of strongly correlated electrons showing close proximity of magnetic (ferromagnetic) and superconducting (triplet superconducting) phases have been subject of intensive research in attempt to construct a theoretical model for new superconducting materials. Usually these models are based on some extensions of the Hubbard model. In particular, several extended versions of the repulsive Hubbard model have been employed for a long time as standard models for metal-insulator transitions, antiferromagnetism and high-\( T_c \) superconductivity . At the same time, the Hubbard model in the case of sufficiently narrow band and/or low doping is a standard model for metallic ferromagnetism of itinerant electrons.

Taking into account the experimentally observed easy-plane anisotropy of the spin exchange in some of these materials, Japaridze and Müller-Hartmann proposed a rather simple extension of the Hubbard model with transverse \( (XY-) \) anisotropy as a suitable approach to such systems with coexisting orders. Indeed, this model was shown to exhibit an extremely rich weak-coupling phase diagram. In particular in the case of a half-filled band the weak-coupling ground state phase diagram consists of two insulating antiferromagnetic phases with easy-plane anisotropy and a spin gapful metallic phase with an identical decay of the \( triplet \) superconducting and spin density wave \( (SDW^{(2)}) \) instabilities. Strong evidence for the presence of an additional transition into a ferromagnetic \( XY \) phase has also been given.
The model describes a system of itinerant electrons with transverse spin-exchange interaction between electrons on nearest-neighbor sites. The one-dimensional version of the Hamiltonian reads:

\[
\mathcal{H} = -t \sum_{n,\sigma} \left( c_{n,\sigma}^\dagger c_{n+1,\sigma} + c_{n+1,\sigma}^\dagger c_{n,\sigma} \right) + U \sum_n n \rho_\uparrow(n) \rho_\downarrow(n) + \frac{J_{xy}}{2} \sum_n \left( S_{n}^{+} S_{n+1}^{-} + h.c. \right). (1)
\]

Here \( c_{n,\alpha} \) (\( c_{n,\alpha} \)) is the creation (annihilation) operator for an electron at site \( n \) with spin \( \alpha \), \( \rho_\alpha(n) = c_{n,\alpha}^\dagger c_{n,\alpha} \), \( S(n) = \frac{1}{2} \sigma_\alpha \sigma_\beta c_{n,\alpha}^\dagger c_{n,\beta} \) where \( \sigma^i \) (\( i = x, y, z \)) are the Pauli matrices. Below we restrict our consideration to the case of repulsive on-site interaction \( U \geq 0 \) while the sign of the exchange interaction is arbitrary.

One can easily verify that besides the obvious \( U(1) \) spin symmetry in the half-filled case the model is characterized by a \( SU(2) \) charge symmetry. An electron-hole transformation for one spin component interchanges the charges and spin degrees of freedom, and maps \ref{eq:hamiltonian} to the attractive Hubbard model with pair-hopping interaction \ref{eq:pair-hopping}.

That the TS phase can be realized in 1D correlated electron systems is well known from standard “qology” studies \ref{eq:qology}. The extended \((U-V)\) Hubbard model with nearest-neighbor attraction \((V < 0)\) has been intensively studied to explain the competition between SDW and superconducting instabilities in \( TMTSF \) compounds \ref{eq:tmtsf}. However, due to spin rotational invariance, in the extended Hubbard model the TS phase is realized only in the Luttinger liquid phase for \(|U| < 2V \) \ref{eq:luttinger}, where both charge and spin excitations are gapless. Singlet superconducting (SS) and TS correlations show identical power-law decay at large distances and the TS instability dominates only due to weak logarithmic corrections \ref{eq:logarithmic}. On the other hand, in the spin gapped phase \( U < 2V \), the dynamical generation of a spin gap leads to the complete suppression of the TS and SDW instabilities. In marked contrast, the ferromagnetic transverse exchange between electrons on neighboring sites provides the possibility for realization of the SDW-TS phase in the case of gapped spin excitation spectrum \ref{eq:gap}.

In this paper we study the model \ref{eq:hamiltonian} in the case of a half-filled band using the DMRG techniques. We investigate the excitations spectrum of the system as well as the behavior of various correlation functions. Our numerical results confirm the predictions of a weak-coupling analysis. In addition, we study in detail the strong-coupling sector of the phase diagram, focusing our attention on the ferromagnetic transition. With increasing transverse ferromagnetic exchange this will reveal the possibility for two different scenarios of transition into the easy-plane XY ferromagnetic phase: in the case of weak on-site repulsion \((U < U_c \approx 2t)\) the first transition at \( J_{xy} = J_{xy}^{(1)} \) takes place from a spin gapped metallic phase into the insulating SDW phase with long-range order (LRO) and the latter becomes unstable towards the spin-flip transition into the ferromagnetic XY phase at \( J_{xy}^{(2)} \). On the other hand, in the case of strong on-site repulsion, the metallic phase is absent and only the spin-flip transition from the SDW phase into the ferromagnetic XY phase takes place at \( J_{xy}^{(2)} \). The critical value of the exchange strongly depends on the on-site repulsion. At \( U = 0 \), \( J_{xy}^{(1)} = -3t \) and \( J_{xy}^{(2)} = -4t \). In the case of weak \( U \ll t \) these parameters are renormalized linearly in \( U \), \( J_{xy}^{(1)} = 0 \) at \( U \approx 2t \), while for \( U \gg t \) we have \( J_{xy}^{(2)} \sim 1/\sqrt{U} \).

The paper is organized as follows: in the next section the weak-coupling continuum-limit version of the model is investigated. In Sect. 3 results of DMRG studies for chains up to \( L = 120 \) sites are presented. Finally, Sect. 4 is devoted to a discussion and concluding remarks.

### 2 The continuum-limit theory

In this section we consider the low-energy effective field theory of the initial lattice model. Although this procedure has a long history and is reviewed in many places \ref{eq:procedure}, for clarity we briefly sketch the most important points and fix our notation and conventions. Considering the weak-coupling limit, \(|U|, |J_{xy}| \ll t \) we linearize the spectrum and pass to the continuum limit by substituting

\[
c_{n,\alpha} \rightarrow \sqrt{n} R_\alpha(x) + (-i)^n L_\alpha(x) \tag{2}
\]

\[
x = n a_0, \text{ where } a_0 \text{ is the lattice spacing, and } R_\alpha(x) \text{ and } L_\alpha(x) \text{ describe the R(right) and L(left) excitations with dispersion relations } E = \pm \sqrt{v_F p} \text{. These fields are assumed to be smooth on the scale of the lattice spacing and can be bosonized in a standard way} \ref{eq:bosonization}.
\]

\[
R_\alpha(x) = \frac{1}{\sqrt{2\pi a_0}} e^{\sqrt{4\pi} \varphi_{R,\alpha}}(x), \tag{3}
\]

\[
L_\alpha(x) = \frac{1}{\sqrt{2\pi a_0}} e^{-\sqrt{4\pi} \varphi_{L,\alpha}}(x) \tag{4}
\]

where \( \Phi_{R(L),\alpha}(x) \) are the Right (Left) moving Bose fields, carrying spin \( \alpha \). Next we define

\[
\phi_\alpha = \phi_{L,\alpha} + \phi_{R,\alpha}, \quad \theta_\alpha = \phi_{L,\alpha} - \phi_{R,\alpha}. \tag{5}
\]

and introduce linear combination

\[
\varphi_c = (\phi_\uparrow + \phi_\downarrow)/\sqrt{2}, \quad \vartheta_c = (\theta_\uparrow + \theta_\downarrow)/\sqrt{2}, \tag{6}
\]

\[
\varphi_s = (\phi_\uparrow - \phi_\downarrow)/\sqrt{2}, \quad \vartheta_s = (\theta_\uparrow - \theta_\downarrow)/\sqrt{2} \tag{7}
\]

to describe the charge \((c)\) and spin \((s)\) degrees of freedom, respectively. Then the Hamiltonian density of the bosonized model is given by

\[
\mathcal{H} = \mathcal{H}_c + \mathcal{H}_s,
\]

\[
\mathcal{H}_c = v_c \int dx \left\{ \frac{1}{2} (\partial_x \varphi_c)^2 + (\partial_x \vartheta_c)^2 \right\} + \frac{M_0^2}{\alpha_0^2} \cos(\sqrt{8\pi R_0^c} \varphi_c), \tag{8}
\]

\[
\mathcal{H}_s = v_s \int dx \left\{ \frac{1}{2} (\partial_x \varphi_s)^2 + (\partial_x \vartheta_s)^2 \right\} + \frac{M_0^2}{\alpha_0^2} \cos(\sqrt{8\pi R_0^s} \varphi_s), \tag{9}
\]
Here we have defined
\[ 2(K_{c(s)}^0 - 1) = g_c = -\frac{1}{\pi\nu_F}(U + J_{\perp}), \] (10)
\[ 2\pi M_0^c = g_u = -\frac{1}{\pi\nu_F}(U + J_{\perp}), \] (11)
\[ 2(K_{s(s)}^0 - 1) = g_s = \frac{1}{\pi\nu_F}(U + J_{\perp}), \] (12)
\[ 2\pi M_0^s = g_\perp = \frac{1}{\pi\nu_F}(U - J_{\perp}), \] (13)
\[ v_{c(s)} = \frac{\tilde{v}_F}{K_{c(s)}^0}, \quad \tilde{v}_F = 2t \left(1 + \frac{J_{\perp}}{2\pi\nu_F}\right). \] (14)

This mapping of the lattice electron system model onto the quantum theory of two independent quantum Bose fields described in terms of an "effective" sine-Gordon (SG) Hamiltonians will allow to extract the ground state properties of the initial model using the far-infrared properties of the quantum SG theory.

The infrared behavior of the SG Hamiltonian is described by the corresponding pair of renormalization group (RG) equations for the effective coupling constants \(K_{c(s)}(l)\) and \(M_{c(s)}(l)\)
\[ \frac{dM_{c(s)}(l)}{dl} = -2(K_{c(s)}(l) - 1) M_{c(s)}(l), \] (15)
\[ \frac{dK_{c(s)}(l)}{dl} = -\frac{1}{2} M_{c(s)}^2(l) \]
where \(l = \ln(a_0)\) and the bare values of the coupling constants are \(K_{c(s)}(l = 0) \equiv K_{c(s)}^0\) and \(M_{c(s)}(l = 0) \equiv M_{c(s)}^0\). The pair of RG equations [K9] describes the Kosterlitz-Thouless transition [K9].

The flow lines lie on the hyperbola
\[ 4(K_{c(s)} - 1)^2 - M_{c(s)}^2 = \mu^2 = 4(K_{c(s)}^0 - 1)^2 - (M_{c(s)}^0)^2 \] (16)
and exhibit two different regimes depending on the relation between the bare coupling constants [K9].

**Weak-coupling regime.** For \(2(K_{c(s)}^0 - 1) \geq \left| M_{c(s)}^0 \right|\) we are in the weak-coupling regime: the effective mass \(M_{c(s)} \to 0\). The low energy (large distance) behavior of the corresponding gapless mode is described by a free scalar field.

The vacuum averages of exponentials of the corresponding fields show a power-law decay at large distances (\(\eta \equiv c, s\))
\[ \langle e^{i\sqrt{2\pi\theta_F}e^{-i\sqrt{2\pi\theta_F}}} \rangle \sim |x - x'|^{-K_{\eta}}, \] (17)
\[ \langle e^{-i\sqrt{2\pi\theta_F}e^{-i\sqrt{2\pi\theta_F}}} \rangle \sim |x - x'|^{-1/K_{\eta}}, \] (18)
and the only parameter controlling the infrared behavior in the gapless regime is the fixed-point value of the effective coupling constants \(K_{c(s)}^* = K_{c(s)}(l = \infty)\) determined from the Eq. [K9]. Note that in the \(SU(2)\) symmetric case \(\mu = 0\) and \(K_{c(s)}^* = 1\).

**Strong coupling regime.** For \(2(K_{c(s)}^0 - 1) < \left| M_{c(s)}^0 \right|\) the system scales to strong coupling: depending on the sign of the bare mass \(M_{c(s)}^0\), the renormalized mass \(M_{c(s)}\) is driven to \(\pm \infty\), signaling a crossover to one of two strong coupling regimes with a dynamical generation of a commensurability gap in the excitation spectrum. The flow of \(\left| M_{c(s)} \right|\) to large values indicates that the \(M_{c(s)}\cos/8\pi K\phi\) term in the sine-Gordon model dominates the long-distance properties of the system. Depending on the sign of the mass term, the field \(\varphi\) gets ordered with the expectation values [K9]
\[ \langle \varphi_{c(s)} \rangle = \begin{cases} \sqrt{\pi/8K_{c(s)}} & (M_{c(s)}^0 > 0) \\ 0 & (M_{c(s)}^0 < 0) \end{cases}. \] (19)

Using the initial values of the coupling constants, given in [K16], we obtain that flow trajectories in the charge sector (due to the \(SU(2)\)-charge symmetry) are along the separatrix \(g_c = g_u\). Therefore, at
\[ U + J_{xy} > 0. \] (20)
there is a gap in the charge excitation spectrum (\(\Delta_c \neq 0\)) and the charge field \(\varphi_c\) is ordered with the vacuum expectation value
\[ \langle \varphi_c \rangle = 0, \] (21)
while at \(U + J_{xy} < 0\) the charge sector is gapless and the fixed-point value of the parameter \(K_s^*\) is one.

The \(U(1)\) symmetry of the spin channel ensures more alternatives. Depending on the relation between the bare coupling constants there are two different strong-coupling sectors in the spin channel. For
\[ U \leq \min\{0, J_{xy}\} \] (22)
the spin channel is massive (\(\Delta_s \neq 0\)) and the field \(\varphi_s\) gets ordered with the vacuum expectation value
\[ \langle \varphi_s \rangle = 0, \] (23)
while for
\[ J_{xy} > \min\{0, U\} \] (24)
the spin channel is massive (\(\Delta_s \neq 0\)), with vacuum expectation value
\[ \langle \varphi_s \rangle = \sqrt{\pi/8K_{s}^*}. \] (25)

In all other cases the excitation spectrum in the corresponding channel is gapless. The low-energy behavior of the system is controlled by the fixed-point value of the Luttinger-liquid parameter \(K_s^* = 1 + \frac{1}{2} g_c^*\). In the particular case of vanishing on-site interaction \((U = 0)\) and antiferromagnetic exchange \((J_{xy} > 0)\) one has to use a second order RG analysis to define accurately the fixed point value of the parameter \(K_s^*\) (for details, see Ref. [K9]).
2.1 Order parameters

To clarify the symmetry properties of the ground states of the system in different sectors we consider the following set of order parameters:

1) the on-site density operator $\rho(n) = \rho_\uparrow(n) + \rho_\downarrow(n)$

\[ \hat{\rho}(n) = \sum_\alpha \left( c_{n,\alpha}^{\dagger} c_{n,\alpha} - 1 \right) \simeq \sqrt{\frac{2K_c}{\pi}} \partial_x \varphi_c 
+ (-1)^n \sin(\sqrt{2\pi K_c} \varphi_c) \cos(\sqrt{2\pi K_s} \varphi_s), \] (26)

2) the on-site spin-density

\[ S_z(n) \simeq \sqrt{\frac{K_s}{2\pi}} \partial_x \varphi_s 
+ (-1)^n \cos(\sqrt{2\pi K_c} \varphi_c) \sin(\sqrt{2\pi K_s} \varphi_s), \] (27)

\[ S_x(n) \simeq \frac{i}{\pi a_0} \cos(\sqrt{2\pi K_c} \varphi_c) \sin\left(\frac{2\pi}{K_s} \varphi_s\right) 
+ (-1)^n \cos(\sqrt{2\pi K_c} \varphi_c) \sin\left(\frac{2\pi}{K_s} \varphi_s\right), \] (28)

\[ S_y(n) \simeq \frac{-i}{\pi a_0} \cos(\sqrt{2\pi K_c} \varphi_c) \cos\left(\frac{2\pi}{K_s} \varphi_s\right) 
+ (-1)^n \cos(\sqrt{2\pi K_c} \varphi_c) \cos\left(\frac{2\pi}{K_s} \varphi_s\right), \] (29)

and in addition we use superconducting order parameters corresponding to

3a) the on-site singlet

\[ \mathcal{O}_S^{\dagger}(n) = c_{n,\uparrow}^{\dagger} c_{n,\downarrow}^{\dagger} 
\sim \cos(\sqrt{2\pi K_c} \varphi_c) \exp\left(i \frac{2\pi}{K_c} \varphi_c\right) 
- (-1)^n \sin(\sqrt{2\pi K_c} \varphi_c) \exp\left(i \frac{2\pi}{K_c} \varphi_c\right), \] (30)

3b) the extended singlet

\[ \mathcal{O}_{ES}^{\dagger}(n) = \frac{1}{\sqrt{2}} \left( c_{n,\uparrow}^{\dagger} c_{n+1,\downarrow}^{\dagger} - c_{n,\downarrow}^{\dagger} c_{n+1,\uparrow}^{\dagger} \right) 
\sim (-1)^n \cos(\sqrt{2\pi K_c} \varphi_c) \exp\left(i \frac{2\pi}{K_c} \varphi_c\right), \] (31)

3c) and the triplet pairing

\[ \mathcal{O}_{TS}^{\dagger}(n) = \frac{1}{\sqrt{2}} \left( c_{n,\uparrow}^{\dagger} c_{n+1,\downarrow}^{\dagger} + c_{n,\downarrow}^{\dagger} c_{n+1,\uparrow}^{\dagger} \right) 
\sim \sin(\sqrt{2\pi K_c} \varphi_c) \exp\left(i \frac{2\pi}{K_c} \varphi_c\right), \] (32)

Note that the smooth part in Eq. (30) corresponds to the usual BCS-type pairing while the oscillating terms in (30) and (31) describe the eta-pairing superconductivity.

2.2 Phases

With the results of the previous section for the excitation spectrum and the behavior of the corresponding fields Eqs. (17–19) we now analyze the weak-coupling ground state phase diagram of the model (11) (see Fig. 1).

Let us first consider the case $U = 0$, where the weak-coupling analysis shows existence of two different phases: in the case of antiferromagnetic exchange, at $J_{xy} > 0$, there is a gap in the charge excitation spectrum while the spin sector is gapless. Ordering of the field $\varphi_c$ with vacuum expectation value $\langle \varphi_c \rangle = 0$ leads to a suppression of the CDW and superconducting correlations. The SDW and Peierls correlations show a power-law decay at large distances $\sim 25$. Due to the $U(1)$-spin symmetry, $K^*_s > 1$ and the “in-plane” correlations dominate in the ground state,

\[ \langle S^+ \rangle \sim r^{-K^*_s - 1/2}, \] (34)

while the longitudinal spin correlations

\[ \langle S^z \rangle \sim r^{-2} + (-1)^r r^{-K^*_s} \] (35)

and Peierls correlations decay faster.

We now focus on the case of ferromagnetic exchange between spins. At $U = 0$ and $J_{xy} < 0$ there is a gap in the spin excitation spectrum while the charge excitation spectrum is gapless. As common in the half-filled band case, the gapless charge excitation spectrum opens a possibility for the realization of a superconducting instability in the system. Moreover, due to the $U(1)$-symmetry of the system, ordering of $\varphi_s$ with vacuum expectation value $\langle \varphi_s \rangle = \sqrt{\pi/8K^*_s}$ leads to a suppression of the CDW and singlet correlations as well as $S^z = \pm 1$ channels of the triplet pairing. However, the $S^x$ and triplet correlations in the $S^z = 0$ channel show an identical power-law decay

\[ \langle S^x \rangle \sim \langle \mathcal{O}_{TS}^{\dagger}(n) \rangle \mathcal{O}_{TS}(0) \sim (-1)^{r^{-1}} \] (36)

at large distances and are the dominating instabilities in the system.

Let us now consider the effect of the on-site Coulomb repulsion. At $J_{xy} > 0$ the easy-plane antiferromagnetic phase remains unchanged at $U > 0$. However, at $J_{xy} < 0$ the TS+SDW(c) phase is stable only towards influence of a weak $U < -J_{xy}$ on-site coupling. In the case of repulsive Hubbard interaction, at $U > -J_{xy}$ a charge gap opens.
This regime corresponds to the appearance of a long-range ordered antiferromagnetic (Néel) phase

$$\langle S^z(r)S^z(0) \rangle \sim \text{constant}$$

in the ground state.

![Diagram](image)

**Fig. 1.** The weak-coupling phase diagram of the itinerant XY-model at half-filling. Solid lines indicate borders between phases. The shaded region qualitatively marks the transition into the XY magnetic phase ($J_{xy}^c \approx -4t$).

### 2.3 The ferromagnetic transition

Let us now discuss the ferromagnetic transition in the itinerant XY model ($U = 0$). The very presence of this transition can already been seen within the weak-coupling studies, however detailed analysis of the phase diagram close to transition is out of scope of the continuum-limit approach. As we obtained, at $J_{xy} < 0$, $|J_{xy}| \ll t$, the charge excitation spectrum is gapless and the spin excitation spectrum is massive. However, in the limit of strong ferromagnetic exchange $|J_{xy}| \gg t$, the model is equivalent to the XY spin chain. Therefore, with increasing coupling one has to expect a transition from the regime with massive spin and massless charge excitation spectrum into a insulating magnetic phase with gapless spin excitations. On the other hand, in the case of antiferromagnetic exchange $J_{xy} > 0$ the weak-coupling study shows a phase with gapless spin, gapped charge and dominating easy-plane spin correlations. One expects that this phase evolves smoothly to the strong coupling limit.

The $J_{xy} \leftrightarrow -J_{xy}$ asymmetry is already seen on the level of the Hartree regularization of the band-width cut-off parameter $W = 2\pi t$ as given by the Eqs. 141

$$W_{\text{eff}} = 2\pi \left(1 + \frac{J_{xy}}{2\pi t}\right).$$

The weak-coupling approaches fail when the effective dimensionless coupling constant $|g_i| = \frac{J_{xy}}{2\pi t} = |g_i^c| \simeq 1$. This condition immediately gives $J_{xy}^c = -\pi t$. As we show below, using the DMRG studies of chains up to $L = 120$ sites, indeed the transition into the ferromagnetic easy-plane ordering discussed above takes place at $J_{xy}^c \approx -4t$.

### 3 Numerical results

We use the density-matrix renormalization-group (DMRG) method to study the ground-state properties of this model. Our calculations have been performed for open chains up to 120 sites using the infinite-size version of the DMRG routine. A comparison with the finite-size algorithm, which requires more CPU time and memory, does not give a substantial improvement of the results. For most of the numerical results reported here we have kept 400 states in each block, which produces truncation errors smaller than $10^{-7}$.

In order to reduce edge effects we average correlation functions $C(|i - j|)$ over a number of pairs ($i, j$) of lattice sites separated by the same displacement $r := |i - j| \geq 39$. Typically we take nine pairs and for each value $r$ we place the pairs as close to the center of the chain as possible.

The asymptotic behavior of correlations (e.g. exponents) has been determined by an appropriate fitting of the data [40].

#### 3.1 Excitation spectrum at $U = 0$

Let us start from the limiting case of the itinerant XY model ($U = 0$) and analyze its excitation spectrum. The charge and spin gap for a half-filled $L$-site system are evaluated by

$$\Delta_C(L) = \frac{1}{2} \left[ E_0 \left( \frac{L}{2} + 1, \frac{L}{2} + 1 \right) + E_0 \left( \frac{L}{2} - 1, \frac{L}{2} - 1 \right) \right. 
\left. - 2E_0 \left( \frac{L}{2}, \frac{L}{2} \right) \right],$$

$$\Delta_S(L) = E_0 \left( \frac{L}{2} + 1, \frac{L}{2} - 1 \right) - E_0 \left( \frac{L}{2}, \frac{L}{2} \right),$$

respectively, where $E_0(N_\uparrow, N_\downarrow)$ is the ground-state energy for $N_\uparrow$ up-spin and $N_\downarrow$ down-spin electrons. The extrapolation for $L \rightarrow \infty$ is then performed by fitting a polynomial in $1/L$ to the calculated finite-chain results. Figure 2 displays the extrapolated values as a function of $J_{xy}$.

We observe the following four sectors: at $J_{xy} > 0$ the system is characterized by gapless spin and gapped charge excitation spectrum, while the weak-coupling ferromagnetic sector exhibits gapless charge and gapful spin degrees of freedom.

Moreover, our numerical results show the presence of two new regions. At $J_{xy}^{(c)} \approx -3t$ a charge gap opens, while the spin gap starts to decrease and finally closes at $J_{xy}^{(c)} \approx -4t$. This defines two new sectors: for $J_{xy}^{(c)} < J_{xy} < J_{xy}^{(c)}$ both the spin and charge sectors are gapped, while at $J_{xy} < J_{xy}^{(c)}$ the spin sectors become gapless. There are no indications for further transitions in the system. Note that similar behavior of the gaps, with interchange of spin and charge degrees of freedom, was first observed by Sikkema and Affleck in the Penson-Kolb model [41].
3.2 Correlation functions at \( U = 0 \)

To investigate the nature of ordering in the different phases we study the behavior of the correlation functions. In the sectors with gapless excitation spectrum and at half-filling we expect the usual expression for correlation functions

\[
C(r) \equiv \langle \mathcal{O}(r)\mathcal{O}(0) \rangle \approx A_1 r^{-\theta_1} + (-1)^r A_2 r^{-\theta_2}
\]

consisting of a smooth part decaying with exponent \( \theta_1 \) and an oscillating part decaying with \( \theta_2 \). In determining the asymptotics of correlation functions we focus on the dominating part given by \( \theta = \min\{\theta_1, \theta_2\} \).

In the following we will present results for correlation functions in different sectors of the phase diagram.

3.2.1 Sectors I and I' (\( \Delta_C \neq 0, \Delta_S = 0 \)): The XY-phases

In Fig. 2 we have plotted the longitudinal and transverse spin-spin correlations in the case of strong easy-plane exchange. Although the amplitudes of the transverse correlation functions are different, the estimated exponents are similar. In the case of ferromagnetic exchange we obtained \( \theta \approx 0.57 \), whereas for the antiferromagnetic exchange we have \( \theta \approx 0.61 \). The results are in a good agreement with the exact value \( \theta = 0.5 \) obtained for the XY-model [12]. The longitudinal correlation functions decay faster. The calculated exponents \( \theta \approx 1.79 \) (for \( J_{xy} = -8t \)) and \( \theta \approx 1.66 \) (for \( J_{xy} = 8t \)) are close to the exact XY-value \( \theta = 2 \).

The asymmetry of this model is clearly seen in Fig. 3, where the ground state energy as a function of \( J_{xy} \) is presented. As we observe from Fig. 3 in the case of ferromagnetic exchange the ground state energy of the itinerant model becomes very close to that of the spin-\( \frac{1}{2} \) XY chain.

3.2.2 Sector II (\( \Delta_C = 0, \Delta_S \neq 0 \)): The TS+SDW\(^{(z)}\) regime

Let us now focus on the case of ferromagnetic exchange \( J_{xy} < 0 \) at \( U = 0 \). The bosonization results predict a suppression of the CDW and singlet correlations, whereas SDW\(^{(z)}\) and triplet correlations show identical power-law decay (cf. with Eq. (44)). Furthermore, they are the dominating instabilities in this phase. Figure 4 displays DMRG results for the singlet- and triplet-pair correlation function. One can clearly observe a strong triplet-pair correlation. Note that the on-site and extended singlet-pair correlations show an almost identical behavior. This is expected from the bosonization results (44) and (45) since the smooth part of the on-site singlet correlations does not contribute due to (46). In the double logarithmic plot (see lower figure) all correlation functions indicate a
Fig. 5. Pair correlation functions in the case of ferromagnetic exchange $J_{xy} = -2t$ and $U = 0$ (sector II). The lower figure shows the algebraic decay of the triplet and singlet correlation, plotted on a double logarithmic scale.

power-law decay with fast decaying singlet-pairing correlators ($\theta \approx 2.18$) and a slowly decaying triplet correlation function ($\theta \approx 1.03$). The results are in a good agreement with those predicted by bosonization.

Fig. 6. DMRG results for the longitudinal and transversal spin correlation function, plotted against the real space distance $|i - j|$ (upper figure) at $J_{xy} = -2t$ (sector II). The exponents (lower figure) were calculated using a suitable subset of the data to reduce finite size effects and numerical inaccuracies at large distances.

In Fig. 6 we show calculations for the longitudinal and transversal spin-spin correlation for ferromagnetic exchange ($J_{xy} = -2t$). We observe that the correlation functions exhibit an algebraic decay in which the transverse spin-spin correlation function decays faster. The calculated exponent of the longitudinal spin correlation function is, in agreement with bosonization results, close to that of the triplet-pairing correlations. Compared to the other results, the scaling behavior of the spin correlations is not very good in this sector. However, we have verified that with increasing system size and number of states kept in the DMRG algorithm the region with algebraic decay increases. Nevertheless, the numerical estimates for the exponents are less reliable than those for other correlation functions.

To complete the weak-coupling picture of sector II, we performed calculations for the density-density correlation. The results are shown in Fig. 7. Since in the double logarithmic plot we observe strong oscillations we additionally calculate the average value

$$\bar{C}(r) = \frac{1}{4} [C(r - 1) + 2C(r) + C(r + 1)]$$

(42)

to smoothen the curve. As its clearly seen from the lower part of Fig. 7 the oscillations are removed, but the estimated exponent remains almost unchanged. Thus the DMRG result indicates a fast decay of density-density correlations, in agreement with the bosonization results.

Therefore, we can conclude that coexisting triplet-pairing and antiferromagnetic SDW\textsuperscript{(z)} ordering are the dominating instabilities in this sector.

3.2.3 Sector III ($\Delta C \neq 0$, $\Delta S \neq 0$): The intermediate phase

In this subsection we analyze the intermediate sector at $-4t \leq J_{xy} \leq -3t$ which is absent in the weak-coupling phase diagram (cf. with Fig. 1).
We start to examine the asymptotic behavior of the superconducting and spin-spin correlations. In Fig. 8 we present DMRG data for the pairing correlation functions. As is clearly seen from the figure, especially from the logarithmic plot, the superconducting correlations decay exponentially in agreement with the presence of a charge gap.

In Fig. 9 we plot the spin-spin correlation functions. The logarithmic plot shows that the transverse spin correlation functions decay exponentially. Contrary, the longitudinal spin correlations show well-established long-range order.

The appearance of LRO is consistent with the $U(1) \otimes Z_2$ spin-symmetry of the present model $\mathbf{I}$. The continuous $U(1)$ symmetry is generated by the operators $S^x$ and $S^y$, while the discrete $Z_2$ symmetry comes from the invariance with respect to the $S^z \to -S^z$ transformation. Since the SDW$^z$ ordering violates the discrete $Z_2$ and translation symmetries, the true LRO state is not forbidden.

3.3 Behavior for nonvanishing on-site interaction

3.3.1 Excitation spectrum at $U \neq 0$

Let us now consider the effects of a repulsive Coulomb interaction on the ground state phase diagram of the model. We start with the excitation spectrum.

From the bosonization results we know the general effect of the Coulomb repulsion on the phase diagram which displays itself in an enlargement of the charge gap sectors at the expense of the spin gap sector. Fig. 10 shows charge and spin gaps for $U = t$ and $U = 2t$. One can clearly see that sectors I and I’, where we have a finite charge gap $\Delta_C > 0$, are enlarged. As a consequence the spin-gapped phase (sector II) becomes smaller with increasing $U$ and finally vanishes completely. Already at $U = 2t$ the charge gap is always finite. Thus the main effect of the presence of Coulomb interactions is the suppression of sector II, i.e. a reduction of the region with dominating superconducting correlations. In analogy with the $U = 0$ case we conclude that the sectors with magnetic correlations become dominating.
3.3.2 Correlation functions at $U \neq 0$

In the following we analyze the effect of the Coulomb interactions on pair and spin correlation functions. We will focus on the behavior in sectors II and III where $\Delta_C = 0$, $\Delta_S \neq 0$ and $\Delta_C \neq 0$, $\Delta_S \neq 0$, respectively.

In the TS + SDW($z$) phase we consider the coupling $J_{xy} = -1.5t$ at $U = t$ as a representative point. The phase is characterized by a spin gap of magnitude $\Delta_S \approx 0.13t$ and massless charge mode. The asymptotic behavior of the pair and spin correlation functions is plotted in Fig. 11 and Fig. 12, respectively. One can clearly see that the triplet-

pairing and longitudinal spin-spin correlations represent the dominating instabilities in the system. Unfortunately the accuracy of the numerics is not sufficient in this case to verify that the exponents are still exactly identical. Instead, we find $\theta \approx 1.2$ (triplet pairing) and $\theta \approx 1.39$ (longitudinal spin).

In the SDW($z$) phase with LRO we compute the correlation functions at $U = 2t$ and $J_{xy} = -2t$. The presence of a charge gap $\Delta_C \approx 0.38t$ leads now to an exponential decay of superconducting correlations.

On the other hand, as is clearly seen from Fig. 13, the longitudinal spin-spin correlations show a true LRO while the transverse spin correlations decay exponentially.

In ferromagnetic phase we use as a representative point $U = 2t$ and $J_{xy} = -4t$. As one can observe from Fig. 14 the longitudinal spin-spin correlations are exponentially suppressed, while the decay of the transverse ferromagnetic spin correlations is almost identical to that of the standard XY-chain.

4 Conclusions

Motivated by recent experimental findings that show evidence for the competition or even coexistence of superconductivity and magnetism we have investigated the ground state properties of an itinerant XY model.

First we considered the case of vanishing on-site Coulomb interactions. The behavior of spin and charge gaps as function of the spin-coupling $J_{xy}$ allows to distinguish four different phases (cf. with Fig. 15). For antiferromagnetic interactions $J_{xy} > 0$ the spin gap vanishes, but the charge gap is always finite. The observed behavior of the correla-
tion functions indicates a smooth evolution to the limiting case of spin-1/2 antiferromagnetic XY chain at \( J_{xy} \to \infty \).

For ferromagnetic couplings \( J_{xy} < 0 \) three different phases appear. Already for weak interactions a spin gap opens, but the charge sector is gapless. Here SDW\(^{(z)}\) and triplet correlations, which decay with similar power-laws, are dominating, i.e. this regime exhibits a coexistence of antiferromagnetic ordering and triplet superconductivity. At \( J_{xy}^{(c1)} \approx -3t \) the spin gap is maximal and a charge gap opens. This intermediate phase, that extends up to \( J_{xy}^{(c2)} \approx -4t \), shows long-range order in the longitudinal spin correlation, whereas superconducting correlations are suppressed and decay exponentially as expected for the case of a finite charge gap. Finally, at \( J_{xy} > -4t \) via a spin-flop transition the system again enters a XY phase characterized by vanishing spin but finite charge gap. Here the behavior is similar to the ferromagnetic XY model.

The presence of a repulsive on-site Coulomb interaction \( U \) has a strong effect on the phase diagram. Generically it leads to an enlargement of the sectors with non-vanishing charge gap at the expense of the sectors with spin gap. Already at \( U = 2t \) the charge gap is finite for all values of the exchange coupling \( J_{xy} \). Therefore the phase where antiferromagnetism and triplet superconductivity coexist is no longer observed and magnetic correlations become dominant everywhere. Only for small values of the Coulomb interaction there is still a finite window of coexistence possible.

Fig. 14 summarizes our findings. The phase diagram shown combines results from bosonization (cf. Fig. 11) and DMRG. However, it is difficult to determine the location of the phase boundaries numerically. E.g. it still has to be clarified whether the coexistence phase extends up to the XY-phase such that two LRO SDW\(^{(z)}\) phases exist (Fig. 15a). Alternatively, only one LRO SDW\(^{(z)}\) phase exists such that it always separates the superconducting from the ferromagnetic XY-phase (Fig. 15b).
