Abstract
In nature, the zinc metalloenzyme carbonic anhydrase II (CAII) efficiently catalyzes the conversion of carbon dioxide (CO2) to bicarbonate under physiological conditions. Many research efforts have been directed towards the development of small molecule mimetics that can facilitate this process and thus have a beneficial environmental impact, but these efforts have met very limited success. Herein, we undertook quantum mechanical calculations of four mimetics, 1,5,9-triazacyclododecane, 1,4,7,10-tetraazacyclododecane, tris(4,5-dimethyl-2-imidazolyl)phosphine, and tris(2-benzimidazolylmethyl)amine, in their complexed form either with the Zn2+ or the Co2+ ion and studied their reaction coordinate for CO2 hydration. These calculations demonstrated that the ability of the complex to maintain a tetrahedral geometry and bind bicarbonate in a unidentate manner were vital for the hydration reaction to proceed favorably. Furthermore, these calculations show that the catalytic activity of the examined zinc complexes was insensitive to coordination states for zinc, while coordination states above four were found to have an unfavorable effect on product release for the cobalt counterparts.

Introduction
In recent years a growing awareness of carbon dioxide atmospheric levels sparked interest in developing rapid methods for the capture and sequestration of the gas from industrial gas streams [1]. Most industrial separation processes for CO2 involve a liquid in which the dissolved gas ionizes under highly basic conditions, leading to its full dissolution and concomitant adsorption into the medium [2]. The rate-limiting step in such processes is well known to be the formation of carbonic acid. The slow kinetics nature of this reaction also hinders the uptake of CO2 near the sea’s surface [3]. This mass transfer limitation also applies to industrial gas separations [4], [5], [6] and results in overall decreases by a factor of 1000-fold over that which could be obtained, if the hydration of the CO2 was not the rate-limiting step. Accelerating such processes through the use of catalysts or enzymes would permit smaller and less expensive separation processes to remove CO2 from industrial gas emissions [7] and could conceivably be fast enough to permit removal of CO2 from the atmosphere in processes of the type envisioned by Elliot et al [8] and Keith et al [9].

In biological systems the reversible hydration of CO2 to bicarbonate is carried out with formidable efficiency by the zinc metalloenzyme, carbonic anhydrase (CA) [10]. In humans, carbonic anhydrase II (CAII, EC 4.2.1.1) is the most efficient isoform exhibiting activity that approaches diffusion limited kinetics. The reaction is catalyzed by a zinc-hydroxide containing center that is formed upon deprotonation of a water molecule coordinated to the active site’s zinc (Zn-OH2, pKa ~7) [11]. The reaction mechanism, which follows ping-pong kinetics, occurs via two independent steps [10], [12]. In step one, the zinc-hydroxide in the active site of CA nucleophilically attacks CO2 to form a Zn3+ bound bicarbonate intermediate whose reaction with water results in the expulsion of bicarbonate.

\[
\begin{align*}
E-\text{OH}^- + \text{CO}_2 & \rightleftharpoons E-\text{HCO}_3^- \\
& \rightleftharpoons E-\text{H}_{2}\text{O} + \text{HCO}_3^- 
\end{align*}
\] (1)

In the second step, the zinc bound water is deprotonated by a nearby histidine (His64 in human CAII) regenerating the catalytic species while the proton is shuttled into the bulk solvent.

\[
E-\text{H}_2\text{O} + \text{B} \rightleftharpoons E-\text{OH}^- + \text{BH}^+ 
\] (2)

Deprotonation of the water is the rate-limiting step in carbonic anhydrase [12]. The extremely high hydration turnover of CO2 by human CAII is \(\sim 10^6\) sec\(^{-1}\) at pH 9 and 25°C [11], [13]. The reverse reaction, dehydration of bicarbonate occurs when the solution pH is below 7.

The X-ray crystal structures of different CAs have been solved and studied in great detail [10]. Crystallographic studies of human
Comparison of Zinc and Cobalt CO₂ Catalyst

Quantum Mechanical Calculations

The hydration reaction of CO₂ catalyzed by N₃, N₄, Ph, and Ben, chelating Zn²⁺ and Co²⁺, was investigated using quantum mechanical calculations. All calculations were carried out using the programs Gaussian03 [27] and Gaussian 09 [28]. Geometry optimizations were performed at the B3LYP/6-311+G(d) level of theory [29], [30]. The catalytically active form of cobalt in carbonic anhydrase is experimentally known to be a high-spin quartet (S = 3/2) [31]. Ground state calculations of these mimetics containing low-spin (S = 1/2) Co²⁺ were consistently higher in energy than the high-spin system. Thus, calculations on the cobalt-containing mimetics were carried out with a fixed quartet multiplicity. The stability of the wavefunction was determined by using the STABLE option within Gaussian. The counterpoise method of Boys and Bernardi was used to account for basis set superposition error (BSSE) [32]. To test the suitability of the B3LYP functional for these calculations, full optimizations of N₄-metal reaction were performed, using a recent functional (MPWLYP1M/6-311+G(d)) that has been successfully used for several organometallics (Figure S1) [33]. Harmonic frequency calculations were performed on all the structures to characterize the stationary points. Transition states were characterized by a single imaginary frequency, and their values are provided in Table S1. The calculated zero-point energies (ZPE) were not scaled. To investigate the effects of solvation on the hydration reaction, single point calculations using the gas-phase geometries were carried out, using a conductor-like polarizable continuum model (CPCM) [34] to approximate solvent effects (water, ε = 78.4). It has been previously shown that the solvation free energies from single point PCM calculations, using gas-phase geometries from density functional calculations, are in reasonable agreement with values obtained from full optimizations [35], [36]. All solvation calculations used the simple united atom topological model (UA0) [37], using UFF radii [38]. The gas phase zero point energies were included in the solvation calculations. Natural population analysis was performed on the optimized structures to assess the charge distributions on these complexes [39].

Synthesis

Tris(6-sulfobenzimidazolylmethyl)amine (sulfonated-Ben). The ligand was synthesized following a previously published protocol for the synthesis of tris-benzimidazole-based compounds [40]. Thus, 4-sulfo-1,2-diaminobenzene [41] (4.0 g, 21.2 mmol) was transferred into a 250 mL round bottom flask equipped with a large stir bar. The solid was made into a suspension with the addition of ethylene glycol (120 mL). To the suspension, nitritolriacetic acid (1.13 g, 5.89 mmol) was added in one portion, the flask equipped with a condenser (set with water at 10°C) and the resulting mixture was heated to 210°C, using a sand bath overnight. After 18 hours of heating, the flask was removed from the sand bath, and the black-colored reaction mixture was allowed to cool down to ambient temperature. The mixture was subsequently poured into a 1000 mL Erlenmeyer flask containing ice water (300 mL) in small portions with constant swirling. The grey precipitate was collected using vacuum filtration and washed copiously with cold, deionized water (5 × 50 mL) and dried under vacuum to afford the title compound (2.90 g, 74%).

Methods
Comparison of Zinc and Cobalt CO2 Catalyst

Results and Discussion

Our ab initio calculations investigated the hydration of CO2 catalyzed by the Zn2+ containing catalysts (Figure 1). The hydration of CO2 by carbonic anhydrase and mimetics is believed to follow the same reaction pathway. Thus, the catalytic cycle begins with nucleophilic attack on the CO2 by the zinc-hydroxide species to form Zn2+-bicarbonate intermediate followed by displacement of the bicarbonate from Zn2+ by water; the water then loses a proton to regenerate the catalysis. Cobalt substituted carbonic anhydrase also utilizes the above metal-hydroxide reaction mechanism for CO2 hydration, but it has ~50% of the catalytic activity exhibited by the wild-type enzyme [17]. To gain insight in the possible fine differences between the two metals, chelators containing Co2+ were also studied. The cobalt complexes are assumed to be in alkaline conditions which favor tetrahedral geometries and share similar characteristics to the zinc complexes [42], [43]. There have been several ab initio studies on the hydration of CO2 by CAII [44], [45], [46], [47], [48], [49] but a thorough comparative study between Zn2+ and other metals ions within CA have not been as widely studied [50], [51], [52]. Additionally, tris(4,5-dimethyl-2-imidazolyl)phosphine (Ph) was chosen for computational tractability and can provide insights into the reaction mechanism.

Panel (C) shows how the atoms are denoted in the text. The structures of tris(4,5-dimethyl-2-imidazolyl)phosphine (D) and tris(2-benzimidazlylmethyl)amine (E) are denoted Ph and Ben in the text, respectively. doi:10.1371/journal.pone.0066187.g001

Nucleophilic Attack of CO2

The first step of the catalyzed hydrolysis of CO2 in the gas-phase is formation of an encounter complex (EC) between the separated reactants (Figure 2). The EC is formed when CO2 interacts weakly with one of the amine hydrogens in the ring structure of the macrocycles N3 and N4 (Figure 3). Due to the lack of N-H moieties around the catalytic OH- group in the Ph and Ben ligands, only van der Waals complexes were formed with CO2. The stabilization energy is approximately ~1 to ~4 kcal/mol for each of the Zn2+ and Co2+ encounter complexes relative to the separated reactants (Figures 4). The N3 and N4 ECs were found to have greater stabilization energies than the Ph and Ben ECs. The amine hydrogen to CO2 oxygen distances were measured to be 2.071 and 2.124 Å for N3-Zn and N4-Zn, respectively, while the Co2+ complexes had similar distances of 2.090 Å (N3-Co) and 2.322 Å (N4-Co). Additionally, the angle formed by the CO2 oxygen with the hydrogen and nitrogen of the amine (O···H-N) of N3 and N4 shows that the CO2 is likely not forming a strong hydrogen bond. Both N3 and N4- complexes have angles close to 180°, whereas the N4 complexes possess angles of 137° for Co2+ and 158° for Zn2+. The distances between the CO2 carbon and the M2+-hydroxide oxygen were 2.674 Å (N3) and 2.640 Å (N4) for the Zn2+ EC structures, while the Co2+ complexes had slightly longer distances. The value obtained for N3-Zn is similar to that obtained by Brauer et al. at the HF/6-311+G(d) level of theory, while our N4-Zn value is almost 0.1 Å shorter than Brauer’s value [53]. Calculations using the B3LYP or MPWLYP1M functional provide similar results for both M2+-complexes. Only minor differences in the energies and geometries were found for the N4 reaction with either Zn2+ or Co2+ between these fully optimized calculations (Figure S1).

The calculated distances for the EC structures are in reasonable agreement with a recently solved crystal structure of human carbonic anhydrase (HCAII) with CO2 [54]. In this crystal structure (PDB ID 3D92), the CO2 carbon to Zn2+-hydroxide

Comparison of Zinc and Cobalt CO2 Catalyst

Results and Discussion

Our ab initio calculations investigated the hydration of CO2 catalyzed by the Zn2+ containing catalysts (Figure 1). The hydration of CO2 by carbonic anhydrase and mimetics is believed to follow the same reaction pathway. Thus, the catalytic cycle begins with nucleophilic attack on the CO2 by the zinc-hydroxide species to form Zn2+-bicarbonate intermediate followed by displacement of the bicarbonate from Zn2+ by water; the water then loses a proton to regenerate the catalysis. Cobalt substituted carbonic anhydrase also utilizes the above metal-hydroxide reaction mechanism for CO2 hydration, but it has ~50% of the catalytic activity exhibited by the wild-type enzyme [17]. To gain insight in the possible fine differences between the two metals, chelators containing Co2+ were also studied. The cobalt complexes are assumed to be in alkaline conditions which favor tetrahedral geometries and share similar characteristics to the zinc complexes [42], [43]. There have been several ab initio studies on the hydration of CO2 by CAII [44], [45], [46], [47], [48], [49] but a thorough comparative study between Zn2+ and other metals ions within CA have not been as widely studied [50], [51], [52]. Additionally, tris(4,5-dimethyl-2-imidazolyl)phosphine (Ph) was chosen for computational tractability and can provide insights into the reaction mechanism.

Nucleophilic Attack of CO2

The first step of the catalyzed hydrolysis of CO2 in the gas-phase is formation of an encounter complex (EC) between the separated reactants (Figure 2). The EC is formed when CO2 interacts weakly with one of the amine hydrogens in the ring structure of the macrocycles N3 and N4 (Figure 3). Due to the lack of N-H moieties around the catalytic OH- group in the Ph and Ben ligands, only van der Waals complexes were formed with CO2. The stabilization energy is approximately ~1 to ~4 kcal/mol for each of the Zn2+ and Co2+ encounter complexes relative to the separated reactants (Figures 4). The N3 and N4 ECs were found to have greater stabilization energies than the Ph and Ben ECs. The amine hydrogen to CO2 oxygen distances were measured to be 2.071 and 2.124 Å for N3-Zn and N4-Zn, respectively, while the Co2+ complexes had similar distances of 2.090 Å (N3-Co) and 2.322 Å (N4-Co). Additionally, the angle formed by the CO2 oxygen with the hydrogen and nitrogen of the amine (O···H-N) of N3 and N4 shows that the CO2 is likely not forming a strong hydrogen bond. Both N3 and N4- complexes have angles close to 180°, whereas the N4 complexes possess angles of 137° for Co2+ and 158° for Zn2+. The distances between the CO2 carbon and the M2+-hydroxide oxygen were 2.674 Å (N3) and 2.640 Å (N4) for the Zn2+ EC structures, while the Co2+ complexes had slightly longer distances. The value obtained for N3-Zn is similar to that obtained by Brauer et al. at the HF/6-311+G(d) level of theory, while our N4-Zn value is almost 0.1 Å shorter than Brauer’s value [53]. Calculations using the B3LYP or MPWLYP1M functional provide similar results for both M2+-complexes. Only minor differences in the energies and geometries were found for the N4 reaction with either Zn2+ or Co2+ between these fully optimized calculations (Figure S1).

The calculated distances for the EC structures are in reasonable agreement with a recently solved crystal structure of human carbonic anhydrase (HCAII) with CO2 [54]. In this crystal structure (PDB ID 3D92), the CO2 carbon to Zn2+-hydroxide
The CO$_2$ is bound in a hydrophobic pocket within HCAII, and one of its oxygens interacts with the amide backbone nitrogen of Thr199 (3.493 Å). Interestingly, the same study also showed that a metal ion is not even necessary for CO$_2$ to bind in the correct location in the HCAII active site. Although Ph-metal and Ben-metal complexes lack an N-H group to stabilize the CO$_2$ around the ligands, the distance from the M$^{2+}$-hydroxide oxygen to the CO$_2$ carbon was comparable to the N$_3$ and N$_4$ ligands, even though their stabilization energy is smaller (Figure 3). Natural population analysis (NPA) of the complexes show that there is little charge difference between Zn$^{2+}$ in N$_3$ or N$_4$ (Table S2), a finding that is consistent with the work of Brauer et al [53]. Two additional pieces of information obtained from NPA are: (1) there exists some charge polarization occurring in the CO$_2$ molecule from its interaction with the amine and (2) the Zn$^{2+}$-hydroxide is more nucleophilic in nature than its Co$^{2+}$ counterpart.

The first transition state (TS1) in the hydration reaction is formed when the distance between the M$^{2+}$-hydroxide oxygen to the carbon of CO$_2$ falls below 2 Å. In the Co$^{2+}$ complexes, the distances for the N$_3$-Co, N$_4$-Co, Ph-Co, and Ben-Co transition states were 1.767, 1.870, 1.777, and 1.720 Å, respectively (Figure 3). The N$_3$-Zn complex has a similar transition state distance to N$_3$-Co of 1.732 Å, but the N$_4$-Zn structure has a much shorter distance of 1.660 Å relative to N$_4$-Co. The reaction barriers are similar for N$_3$-Zn, N$_4$-Zn, and N$_3$-Co (~12 kcal/mole), while the reaction barrier for N$_4$-Co is significantly lower at 7.2 kcal/mole (Figure 4B). The difference in energy is due to an earlier transition state for N$_4$-Co than found in the other complexes. Although the CO$_2$ to M$^{2+}$-hydroxide distance in N$_4$-Co is longer than in N$_4$-Zn, the oxygen in CO$_2$ shows greater

Figure 2. Schematic of the nucleophilic attack of CO$_2$ by the mimetics and the resulting geometries of the Lindskog and Lipscomb intermediates.
doi:10.1371/journal.pone.0066187.g002
coordination to Co\(^{2+}\) (2.353 Å) relative to Zn\(^{2+}\) (2.428 Å). The TS1 geometries for both Ph-metal structures are similar. The distance between the hydroxyl oxygen and carbon of CO\(_2\) is 1.747 for Ph-Zn. Both Ben-metal structures had late transition states that lead to high activation barriers for the final formation of bicarbonate (\(\approx 13\) kcal/mole). There is minimal change in the charge on either metal in going from EC to TS1 except for Ph-Co. When TS1 is formed, the charge on the hydroxyl oxygen drops to almost the same values (ranging from \(-1.02\) to \(-1.09\) |eu|) for all eight complexes even though the Zn\(^{2+}\) complexes were found to possess higher charges in the EC structures (Table S2).

After passing the first transition state, a bicarbonate complex directly chelated to the metal is formed. There has been great deal of debate about the actual conformation of the bicarbonate around the metal center in carbonic anhydrase. From these calculations and others, a Lindskog intermediate (OH of bicarbonate is oriented towards the metal, Figure 2) will clearly be formed first in this reaction (denoted I1) [51], [53], [55]. The geometry of both N3 complexes is very similar with one oxygen directly coordinated to the metal center (1.886 Å and 1.900 Å for Co\(^{2+}\) and Zn\(^{2+}\), respectively), and the bicarbonate hydroxyl group weakly interacting with the metal ion (2.972 Å and 2.949 Å for Co\(^{2+}\) and Zn\(^{2+}\), respectively). The geometry around the metal is tetrahedral. Similar asymmetrical bicarbonate coordination geometries for I1 were obtained for the Ph and Ben complexes for both metal ions (Figure 3). The N4-Zn structure resembles the N3-metal structures with a single oxygen coordinated to Zn\(^{2+}\), and the hydroxyl group asymmetrically interacting with the zinc ion (1.909 Å and 2.933 Å). The I1 N4-Co geometry differs from the other complexes. The oxygens coordinating Co\(^{2+}\) are much more symmetrical. The metal to coordinating oxygen distance is 1.976 Å, and the hydroxyl oxygen is 2.398 Å away. Although not perfectly octahedral, this structure shows cobalt’s ability/preference to coordinate six ligands.

Figure 3. Calculated structures for the zinc complexes of N3, N4, Ph, and Ben complexes during the nucleophilic attack portion of the hydration reaction of CO\(_2\) when forming the encounter complex (EC), first transition state (TS1), Lindskog intermediate (I1), and Lipscomb intermediate (I2). Distances are listed in angstroms and values in the parenthesis are the corresponding distances for the cobalt complexes.

doi:10.1371/journal.pone.0066187.g003
Rotation about the oxygen bond coordinated to the metal center in the Lindskog intermediate (I1) leads through a shallow transition state (TS2) to the lower energy Lipscomb intermediate (I2), which has both carboxylate oxygens of bicarbonate directed towards the metal [56]. This second transition state occurs when the dihedral angle (OC – C, see Figure 1C) has rotated approximately 90°. For both metal ion complexes of N3, Ph, and Ben structures, TS2 has almost identical geometries. Interestingly, the TS2 structures for N4 differ significantly (Figure S2). N4-Zn has a transition state that resembles the N3 structures, but the N4-Co TS2 structure still shows a preference for octahedral binding even though one site is unoccupied. It should be pointed out that proton transfer from the hydroxyl oxygen (OH) of bicarbonate to the non-coordinated oxygen (O) is also a viable mechanism for conversion of I1 to I2 but requires additional water molecules for this to have an activation barrier as low as bond rotation [57]. In either case, this portion of the reaction is not expected to be rate-limiting.

The Lipscomb intermediates for both N3 complexes are similar; a single oxygen is coordinated to the metal, and the other carboxylate oxygen is weakly coordinated to the metal (1.920 and 2.964 Å for Zn2+ and 1.905 and 3.027 Å for Co2+). For the N4 complexes, the carboxylates of bicarbonate are also bound differently in the Lipscomb intermediate depending on the metal. For N4-Zn, the oxygen to zinc distances are 1.930 and 2.909 Å which is similar to the values for the unidentate N3-Zn complex. For N4-Co, the oxygen cobalt distances are almost identical at 2.113 and 2.158 Å, again reflecting cobalt’s preference for an octahedral geometry in this macrocycle. The bicarbonate geometries for the Ph compounds were unidentate for Zn2+ but bidentate for Co2+. These calculated results are in good agreement with crystal structure data of Zn2+ and Co2+ bound by a tris(pyrazolyl)hydroborato ligand and coordinating nitrate or carbonate [58], [59]. In the Zn2+ compounds, only one nitrate or carbonate oxygen binds to the metal at a distance of 1.98 Å, and the second oxygen is greater than 2.6 Å from the metal. For the Co2+ compounds, the two oxygens bind more symmetrically around the metal at 2.001 and 2.339 Å for nitrate and 2.053 and 2.271 Å for carbonate in the crystal structures. The bicarbonate I2 geometries for the Ben compounds were almost identical. Both metals bind the bicarbonate in a unidentate geometry with oxygen distances of 1.936 and 3.187 Å for Zn2+ and 1.934 and 3.198 Å for Co2+.

The calculated results for nucleophilic attack of CO2 are in qualitative agreement with model studies. The x-ray crystal geometries of tris(pyrazolyl)hydroborato zinc hydroxide and cobalt hydroxide complexes are similar to those obtained for the N3 complexes [60]. These structures all have tetrahedral geometries around the metal center and readily react with CO2 to form bicarbonate. Unfortunately, the tris(pyrazolyl)hydroborato com-
plexes are not soluble in water therefore release of the metal bound bicarbonate is not possible with these catalysts.

Product Release

To study the release of bicarbonate from the metal center, a single water molecule was added to the I1 (Lindskog) and I2 (Lipscomb) structures since it was not obvious which geometry would have the lower activation barrier for product release. Once a water molecule was added to each intermediate, the structures were reoptimized. In all cases, the I2 structure with water was the lower energy structure. The water molecule was stabilized by formation of a hydrogen bond between the oxygen of water (OW) and the hydrogen from the amine group in the ring structure of both N3 and N4 and interaction of a hydrogen from water (H1) with the oxygen of bicarbonate (OC) coordinating the metal (Figure S3). For the Ph and Ben structures, the water hydrogen bonds with the bicarbonate but likely does not interact strongly with the rest of the complex since there are no other polar groups in the vicinity. Interestingly, the structure obtained for the Ph-Zn is very similar to the x-ray structures of 2VVB [61] and 1XEG [62], where a unidentate bicarbonate or acetate is interacting with one water molecule. The original intermediate structures were not significantly affected by the inclusion of the water molecule. The energy difference of I1 relative to I2 did not change significantly by adding the water molecule. Unlike the macrocycles, lower energy structures than the encounter complex were found when the water molecule directly coordinates to the metal ion for both Ph and Ben complexes. When the water coordinates to the metal ion in the Ph complex, a trigonal bipyramidal metal center is formed. Two conformers are possible in the case of zinc, the lowest energy structure has the water in the axial position and the bicarbonate (in the equatorial position) hydrogen bonds to the coordinated water (Figure 5A). Although it is possible to obtain a minimum energy structure with bicarbonate in the axial position and water equatorial (Figure 5B), the energy barrier (TS_{eq}) separating these two structures disappears when the ZPE correction is included. A tunstil pseudorotation occurs to transform one structure to the other, but the amount of rearrangement to have the bicarbonate go from axial to equatorial is small because of the three-fold symmetry of the phosphine complex (Figure S4). Both ligands only need to rotate by ~60° to interconvert between conformations. Similar coordination of water and bicarbonate around the zinc has also been observed in carbonic anhydrase II binding acetate (Figure S5).

In the wild-type (WT) protein (PDB, 1CAY), the coordination around the zinc was a distorted trigonal bipyramid with a water as an equatorial ligand and the acetate as an axial ligand [63]. Comparison of the WT enzyme with the T199A mutant (PDB, 1CAM) shows that the hydroxyl group of T199 is important in the positioning of the water molecule coordinated to the zinc (Figure S6) [64]. The positioning of the water and the bicarbonate around the zinc by Thr199 likely creates a situation in which the geometry is not optimal and makes release of bicarbonate more favorable. The Zn-carboxylate oxygen distances for the WT and T199A proteins are 2.42 and 2.27 Å, respectively. In the 1CAM crystal structure, the angle formed by the His94 NE2– Zn – O of water is 136.6°. The analogous angle in 1CAY is 110.0°. Experimentally, the T199A mutant is ~100 times slower at turning over CO2 than the WT enzyme, and the binding of inhibitors such as thiocyanate and bicarbonate is enhanced by 20-fold [63]. In the E106Q mutant protein (PDB, 1CAZ) [63], the zinc coordination is trigonal bipyramidal, but the water and acetate coordination is now reversed with water as the axial ligand and acetate as the equatorial ligand (Figure S5). These calculations show bicarbonate is more strongly coordinated to the Zn2+ in the equatorial position (Zn-O bond is 1.953 Å) relative to the axial position (Zn-O bond is 2.050 Å) in Ph-Zn and the lowest energy conformation for the trigonal bipyramidal geometry. The carboxylate sidechain of E106 is important for positioning the water around the zinc to avoid this conformation since the E106D mutant shows little change in activity from the wild-type enzyme. The amide sidechain of E106Q rotates away from T199 and functions as a hydrogen donor with T199 instead of an acceptor. This changes the hydrogen bonding network within the active site, resulting in a 1000-fold decrease in the maximal rate for the E106Q mutant [65].

The Ph-Co encounter complex is a distorted trigonal bipyramidal structure with water in the axial position and bicarbonate in the equatorial position. One oxygen of the bicarbonate is hydrogen bonding with the water molecule. This complex could also be described as having an octahedral geometry but missing the sixth ligand. Interestingly, a formal octahedral complex 3.6 kcal/mole higher in energy relative to the pentacoordinate structure was also obtained. This structure, which has two oxygens of the bicarbonate equatorially coordinated to Co3+ and water at the axial position, is almost identical to the Co3+ bicarbonate binding bicarbonate (PDB 1CAH) [66] (Figure 6) and also the structure of cobalt tris[2-isopropylimidazol-4-(5)-yl]phosphane coordinating to nitrate and water [67]. A similar octahedral structure was also obtained for the Zn2+ complex that was 5.44 kcal/mole higher in energy relative to the I3 structure. The trigonal bipyramidal coordination of the bicarbonate in the enzyme may not be favorable. An overlay of the I3 structure in the active site of 1CAH shows the bicarbonate would be in close contact with the side chain of L198.
Axial and equatorial arrangements for bicarbonate in both Ben-metal complexes were also found, with the equatorial geometry the more stable by 2 kcal/mole, but interconversion between these structures was not possible (Figure 7). When water coordinates to the metal, an octahedral complex forms for both Ben-metal complexes as the bicarbonate shift positions to take up an equatorial arrangement around the metal. The interconversion of conformation by the turnstile pseudorotation in this case would likely have a high barrier since this complex is not symmetric and would require the water molecule and bicarbonate to exchange positions (180° rotation). The octahedral geometry adopted by the Ben-Zn complex is reminiscent of tris(6-amino-2-pyridylmethyl)amine binding Zn²⁺ which catalyzes phosphodiester cleavage [68]. Indeed, complexes of Zn²⁺, Co²⁺, and Cu²⁺ coordinated to tris(2-benimidazylmethyl)amine have been shown to catalyze the hydrolysis of p-nitrophenyl acetate [69].

For product release, an addition-substitution reaction occurs with a water molecule displacing the bicarbonate. At the transition state (TS3), the water molecule coordinates to the metal ion, causing the oxygen of the bicarbonate to weaken (Figure 7 and 8). In the zinc complexes, the oxygen of water is 1.900 Å (N3), 2.024 Å (N4), 1.961 Å (Ph), and 2.049 Å (Ben) from Zn⁷⁺ with the oxygen of the previously coordinated bicarbonate now at 2.938 Å (N3), 2.836 Å (N4), 2.676 Å (Ph), and 2.823 Å (Ben). The displaced oxygen of bicarbonate interacts with one of the hydrogens of the water and ultimately abstracts the proton from the water to form carbonic acid and to reform the metal-hydroxide catalyst. The transition state geometry for N3-Co is almost identical to N3-Zn, with the water bound slightly tighter (1.961 Å) and the bicarbonate more weakly bound to the metal (3.017 Å). The transition state for N4-Co differs from the other three structures. The water is bound tightly to the Co²⁺, and the oxygen of bicarbonate is still coordinated to the metal (2.509 Å). Additionally, the previously mentioned TS3 structures (both N3 and N4-Zn) had the oxygen of bicarbonate interacting with one of the hydrogens on the water molecule. In the TS3 structure of N4-Co, the hydrogen/proton from the water has transferred to the bicarbonate to form carbonic acid. No change in the ring structure occurred for either N4 complex at the transition state.

From these calculations, Ben-Zn should be a poorer catalyst at CO₂ hydration that N3 or N4, although the water soluble sulfonated version of Ben-Zn was reported to be highly active at low temperatures, and its activity was extrapolated to room temperature [70]. Interestingly, no direct kinetic measurements for the sulfonated-Ben-Zn were reported at room temperature. To better understand the catalytic properties of Ben-Zn, the sulfonated benzimidazole compound was synthesized and tested. The sulfonated-Ben-Zn complex did not show any catalytic properties at room temperature and had slight activity at 50°C (Figure S7), which was consistent with the calculated activation barrier for Ben-Zn.

For all complexes, the transition state from the I₂ structure was lower in energy than the transition state from the I₁ structure. Interestingly, the activation barrier from I₁ to I₂ to
their respective transition states was almost identical in value. The activation barrier for bicarbonate release ranges from a low value of 14.8 kcal/mole for N4-Zn to a high value of 20.7 kcal/mole for Ben-Co. From these calculations, product release is the rate-limiting step for the hydration of CO2. These values differ from those obtained by Mauksch et al., using the model system [(NH3)3Zn(OH)]+/CO2 [71]. They find that nucleophilic attack is the rate-limiting step for CO2 hydration and only a small barrier for product release. This discrepancy is due to their assumption that one of the protons on the coordinated water molecule transfers to the bicarbonate while both are still coordinated to the zinc. This proton transfer seems unlikely in solution from pKₐ measurement of the macrocycle triamine [2-(2-hydroxyphenyl)-1,5,9-triazacyclododecane coordinated with zinc [72]. This macrocycle is pentacoordinated with a trigonal bipyramidal geometry. The 2-hydroxyphenyl moiety has a pKₐ of 6.8, and the coordinated water has a pKₐ of 10.7. Having a charged oxygen coordinated to the zinc reduces the metal’s ability to acidify the water molecule since the pKₐ of water bound to 1,5,9-triazacyclododecane-zinc is 7.5. The calculated activation barriers for the zinc complexes for N4 (14.8 kcal/mole), N3 (15.7 kcal/mole), Ph (15.6 kcal/mole), and Ben (18.3 kcal/mole) are in reasonable agreement with measured rate constants for CO2 hydration 2494 M⁻¹ S⁻¹ [73], 1083 M⁻¹ S⁻¹ [73], 898 M⁻¹ S⁻¹ [74], and not catalytic, respectively. The correlation between product release and experimental rate constants is consistent with our previous results, showing the bond dissociation energy between bicarbonate and Zn-azamacrocycles corresponds with the experimental results [73].

The calculated hydration reaction catalyzed by the tetrahedral coordinating N3, using either Zn²⁺ or Co²⁺, was very similar in both geometries and energies obtained. This is consistent with experimental results that show almost identical
coordination geometries and wild-type activity for alpha-class carbonic anhydrases that have Zn$^{2+}$ substituted with Co$^{2+}$ [17, 75]. The calculated activation barrier for release of bicarbonate is high in these polyamine complexes yet HCAII experiments have shown this step in the reaction to be rapid and not rate-limiting [76]. In HCAII, both experiment and theory have shown that Thr199 has a destabilizing effect on bicarbonate binding to zinc [65], [77]. Hybrid QM/MM calculations by Merz and Banci show that the active site of HCAII promotes destabilization by pulling one of the carboxylate oxygens of bicarbonate away from the zinc by formation of a hydrogen bond with the hydroxyl group of Thr199 [78]. Using PM3 calculations, they found that having the zinc-bicarbonate active site geometry destabilizes the Lipscomb intermediate by 8.7 kcal/mole relative to the QM optimized structure. These results are also qualitatively in agreement with estimated free energies from kinetics data for carbonic anhydrase that show dissociation of bicarbonate limits the CO$_2$ hydration catalyzed by HCAI and the Thr200His mutant of HCAII [79].

**Solvent Effects on CO$_2$ Hydration**

To estimate the effects of solvent on the CO$_2$ hydration reaction, single-point conductor-like polarization continuum model (CPCM) calculations were performed on the optimized gas-phase geometries. Addition of solvation effects removes the encounter complex as a minimum along the reaction coordinate (Figure 9). The separated reactants go directly to the first transition state, and the activation barrier is significantly lowered. The activation barrier ranged from 0.21 to 3.16 kcal/mole. Once past the transition state, the bicarbonate is formed. When including solvation effects, the energy differences between the Lindskog (I1) and Lipscomb (I2) intermediates are much smaller. In the gas-phase the energy difference was ~5 kcal/mole or greater, but in solution the energy differences are reduced and ranged from 0.18 to 2.31 kcal/mole. Addition of a water molecule to the intermediate structures does not significantly change the energy difference between the two geometries for the CPCM calculations. In some cases, the activation barrier for interconversion of I1 to I2 is the highest barrier.

The activation barrier for bicarbonate release is significantly reduced by solvent effects. In the case of the N3 complexes, the activation barrier is reduced by 12.48 and 11.56 kcal/mole for N3-Zn and N3-Co, respectively. Solvation in the high dielectric medium makes separation of the two charged species more favorable, and the reduction in the barrier is large enough that in the case of N3-metal ion, interconversion of I1 to I2 is rate-limiting. Having the activation barrier for interconversion between the two intermediate structures as the rate-limiting step for this reaction is an unexpected result, and may be an artifact of using the gas-phase geometries. This is the only transition state (TS2) along the reaction coordinate that does not involve either formation or breaking a bond. TS1 and TS3 maybe over stabilized when using the gas-phase geometries. A similar result occurred in a computational study of CO$_2$ being converted to HCO$_3^-$ by a $\zeta$-carbonic anhydrase containing either cadmium or zinc [32]. In the gas-phase, nucleophilic attack of CO$_2$ had the highest activation barrier, but when the dielectric constant was set to 4 (to better simulate the protein environment), the rotation barrier was rate-limiting. Interestingly, when the dielectric constant was set to 80, the rate-limiting step was again the nucleophilic attack. It should also be noted that we chose to model the interconversion of the intermediates by rotation around the bicarbonate for computational ease. Since the bicarbonate is solvent exposed on these mimetics, proton exchange with water might be a lower energy route for interconversion.

With the inclusion of solvation, the activation barrier for bicarbonate release is almost identical for either the Lindskog or Lipscomb intermediates for both N3 complexes and N4-Zn. The active site of HCAII has a well ordered solvent network that provides a route for proton release to bulk solvent [80], but this network may also contribute in lowering the barrier for product release. The CPCM activation barriers for product release from Zn$^{2+}$ overestimate the stabilization for the calculated barrier for bicarbonate dissociation in the macrocycles. Loferer et al., using QM/MM methods [81], calculated a barrier of 6.2 kcal/mole for bicarbonate dissociation in CAIL, and from these calculations barriers of 3.19 (N3-Zn) and 4.68 kcal/mole (N4-Zn) were obtained. Interestingly, the activation barriers for product release are much higher for Ph-Zn (9.4 kcal/mole) and Ben-Zn (11.82 kcal/mole). Having a hydrophobic environment around the reacting species (methyl groups in Ph and phenyl groups in Ben) shows that nucleophilic attack is sensitive to solvent exposure, but the product release barrier is less affected by solvent. In fact, other than nucleophilic attack of CO$_2$, the reaction profile for both Ph and Ben are relatively unchanged. In the gas-phase, the overall reaction for all species is endothermic, but with the addition of solvation effects all the reactions become exothermic with the exception of N4-Co.

For N4-Co, solvation effects did not significantly reduce the activation barrier for bicarbonate release and is the only species that is endothermic in solvent. It would appear that N4-Co does not catalyze the hydration of CO$_2$ even though it had the lowest barrier for nucleophilic attack. The preference of an octahedral geometry for N4-Co makes release of bicarbonate improbable. This is consistent with experiments that showed a 5-coordinated Co$^{2+}$ complex (four nitrogens and one oxygen from water) is able to form cobalt-hydroxide but does not catalyze the hydration of CO$_2$ [82], [83]. We should also point out that having an additional water molecule coordinated to the cobalt could contribute to lowering the activation barrier or change the coordination of bicarbonate to unideterminate, but we did not pursue these calculations since it was beyond the scope of the present study. Clearly, solvation has a significant effect on the activation barrier for product release, although the reduction in the barrier could be overestimated because we are not using optimized CPCM structures.

**Conclusions**

Models that mimic the reactivity of carbonic anhydrase are of interest not only academically but to industry, which is trying to lower the amount of CO$_2$ being released into the atmosphere [84]. Two of the most successful mimetics of carbonic anhydrase are the cyclic polyamines, 1,4,7,10-tetraazacyclododecanec [84] and 1,5,9-triazaacyclododecanec [85], and when coordinated to zinc are able to catalyze the reversible hydration of CO$_2$. From our calculations, the Zn$^{2+}$ and Co$^{2+}$ complexes of N3 have very similar coordination geometries to human carbonic anhydrase II and comparable energetics. The N4-Zn complex has slightly higher turnover than the N3-Zn but has been criticized as a mimic for human carbonic anhydrase II because it has pentacoordinate geometry. Although the coordination differs, the calculations show that N4-Zn follows the same reaction as the N3-Zn/Co complexes. The N4-Co complex is able to lower the barrier for nucleophilic attack more than any of the other complexes by having an octahedral
geometry around Co$^{2+}$, but this is at the expense of being able to release bicarbonate later in the reaction.

Interestingly, the gamma-class carbonic anhydrase from *Methanosarcina thermophila* (Cam), which normally uses Fe$^{2+}$ to catalyze the hydration of CO$_2$, may have found a way around this product release problem [85]. This carbonic anhydrase can also utilize pentacoordinated Zn$^{2+}$ or hexacoordinated Co$^{2+}$, and Co-Cam is actually better at catalyzing the hydration reaction than Zn-Cam [86]. The crystal structure of bicarbonate bound in Zn-Cam and Co-Cam show they have different coordination positions around the metal ion (Figure S8) [87]. For Zn-Cam, the geometry of bicarbonate resembles the Lipscomb intermediate for N3 with the carboxylate oxygens 2.48 and 3.11 Å from Zn$^{2+}$. In Co-Cam, only one oxygen in bicarbonate is bound to Co$^{2+}$, and two water molecules take up the other coordination sites. Interestingly, the geometry of bicarbonate around Co$^{2+}$ most resembles the TS2 structure of N4-Co. It would be interesting if a catalyst based on the binding geometry in Cam could be created. If possible, its application to industry could be significant since the susceptibility of Zn-Cam and Co-Cam to anionic inhibitors differs [88]. The difference in the inhibitors is likely due to the coordination preference of the metals.

The activation barriers for N3-Zn and N4-Zn from our calculations are quite low yet these complexes are ~1000 slower at catalyzing the hydration of CO$_2$ relative to HCAII. One aspect of the reaction that could not be readily studied is the importance of reactant positioning. Although the rate-limiting step in HCAII is proton loss from the metal bound water, it would not be expected to be limiting for these mimetics that are solvent exposed and function optimally at alkaline pH. Recent crystal structures show that HCAII contains a hydrophobic pocket that binds CO$_2$ in a conformation that will readily react with the zinc-hydroxide [54]. In fact, the presence of a metal is not even required for CO$_2$ binding in HCAII. Additionally, placement of zinc coordinated by three histidines within the hydrophobic interior of an α-helical triple coiled coil showed CO$_2$ hydration activity within 500-fold of HCAII [89]. Reactant positioning likely is an important aspect of the hydration reaction by HCAII and for these mimetics.
