This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Metal-free Coumarate based ionic liquids and poly(ionic liquid)s as Corrosion Inhibitors

Esther Udabe, Maria Forsyth, Anthony Somers and David Mecerreyes

Mild steel is used extensively in infrastructure and its corrosion susceptibility is a severe issue both economically and with regards to safety. The toxicity of traditional chromate inhibitors requires the discovery of new non-toxic anti-corrosion solutions. Here we show metal-free organic ionic liquids that can be used as direct anodic and cathodic corrosion inhibitors or incorporated into a polymer coating. New p-Coumarate methacrylic UV curable ionic liquids that can be used as direct corrosion inhibitors or incorporated into a polymer coating are reported.

Mild steel, having no more than 2% of carbon and no other appreciable alloying element, makes up the largest part of steel production and is used in a vast range of applications, from concrete reinforcement and small machine parts to containers and construction materials [1][2]. However, despite its relatively low cost and good mechanical properties, mild steel is prone to undergo severe corrosion [1] leading to high economic and safety losses. For this reason, understanding and mitigating corrosion of such alloys is of primary importance. Among the different corrosion protection methods, the use of chemical inhibitors and coatings are the most commonly used [3]. Corrosion inhibitors can be incorporated as an additive into a paint coating to protect external structures or added to water tanks and pipeline streams to protect the mild steel internal surfaces [3]. Generally, most chemical inhibitors reduce the rate of corrosion by forming a passive adsorption layer on the metal surface. [3, 4, 5]. Chromeate based inhibitors loaded into different coatings are known to be the most efficient anticorrosive method for a large range of metals and alloys, reducing both the anodic and cathodic reactions that result in corrosion and metal loss [6]. However, hexavalent chromium was banned due its high toxicity, and thus, alternative and non-toxic chemical inhibitors are needed in order to replace these highly efficient chromate-based compounds [6]. One very promising family of chromium-free chemical inhibitors recently demonstrated has been the rare earth carboxylate compounds. These compounds can suppress both the anodic and cathodic reactions that are involved in corrosion, showing a synergistic effect between the rare earth metal and the carboxylates [6, 7, 8]. Among these, rare earth metal aromatic carboxylates have demonstrated the best anticorrosive performance due to the formation of a passive barrier layer that forms due to adsorption and subsequent reaction with the underlying alloy substrate [7, 9, 10]. From this past work, it is evident that the aromatic carboxylate, p-coumarate, provides very efficient inhibition [2, 13 - 15, 16]. For instance, when comparing lanthanum 3-(4′-hydroxyphenyl) propionate with lanthanum (p-coumarate). Deacon et al demonstrated that the coumarate with the unsaturated double bond in the side group provides better surface passivation than the aliphatic propionate group [14]. In fact, it is reported that the carboxylate group has the ability to create a hydrogen bond with the hydroxide groups of the surface, that contributes to the formation of surface complexes which acts as a barrier against corrosion [11, 12].

Interestingly, metal-free organic inhibitors such as ionic liquids have also shown promising performance in corrosion applications and are of great interest due to their effectiveness at wide range of temperatures, compatibility with protected materials, good solubility in water, low costs and relatively low toxicity [17]. In a pioneering work, Alison L. Chong et al. reported synthesis of salts based on imidazolium cation and carboxylate anions showing an effective corrosion inhibition [18]. More precisely, they found that 2-methylimidazolium p-coumarate was a most effective inhibitor, showing a strong anodic inhibition effect [18]. Aside from the aforementioned salts, inhibitor compounds that can be incorporated into a polymer coating have great potential, since they can add their intrinsic inhibition effect to the protective layer effect of a polymer coating.

In this work, we present a series of easy to make methacrylic monomeric organic salts. First, we investigate their use and properties as corrosion inhibitors and then we show a proof of concept of their easy integration into an anticorrosion polymer coating.

For this purpose three different coumarate based ionic monomers (a, b, c) were synthesized as described in the SI. First, the ionic monomer a [p-OHcoum] MA was easily obtained by instantaneous acid-base proton exchange reaction between commercially available 2-dimethylaminoethyl methacrylate and p-coumaric acid (Scheme S1.B). Moreover, it is known that inhibition efficiency increases with an increase in the anion or cation size or aliphatic chain length [18, 19]. For this reason, two additional monomers were synthesized using as reactants 2-dimethylaminoethyl methacrylate and butoxy p-coumaric acid and hexoxy p-coumaric acid leading to two additional monomers [p-O(C$_6$H$_13$)coum] MA and [p-O(C$_6$H$_13$)coum] MA, b and c respectively.

First, the corrosion inhibition properties of the monomers were evaluated by immersing mild steel AS1020 foils into an aqueous solution, [p-OHcoum] MA, [p-O(C$_6$H$_5$)coum] MA and [p-O(C$_6$H$_5$)coum] MA monomers suppressed the anodic activity as compared to the control without ionic liquid monomer. The corrosion potential (E$_{corr}$) of [p-OHcoum] MA shifted towards a more positive potential from -0.523 V to -0.012 V, showing a corrosion current density (i$_{corr}$) of 0.009 µA and an inhibitor efficiency of 99.1%. Moreover, the compound with the hexyl substituent on the coumarate, [p-O(C$_6$H$_5$)coum] MA, shifted the E$_{corr}$ towards a positive potentials, from -0.523 V to -0.140 V, representing a corrosion current density (i$_{corr}$) of 0.026 µA and an inhibitor efficiency of 97.2%. Finally, the compound with the hexyl substituent on the coumarate, [p-O(C$_6$H$_5$)coum] MA, shifted the E$_{corr}$ towards a positive potentials, from -0.523 V to -0.140 V, representing a corrosion current density (i$_{corr}$) of 0.009 µA and an inhibitor efficiency of 99.1%. Moreover, the variation of Tafel slopes of the monomer solution (shown in Table 1 of SI) comparing with the control means that the inhibitors influence the anodic and the cathodic corrosion reaction on mild steel [19]. To sum up, the PP curves suggest that these coumarate based monomers mainly affect and suppress the anodic activity. The extensive noise observed in particular with the with the [p-OHcoum] MA monomer is...
suggesting that there is ongoing activity on the steel surface; for example, metastable pitting with the inhibitor suppressing pit growth which is also observed from the optical microscopy in Figure 1c (a) where deposits are spotted across the steel substrate. It appears that [p-O(CH$_3$)$_3$coum] MA providing the best inhibition in solution and a significant increase in the pitting potential, which again is evident in the optical microscopy image in Figure 1c (c) with an almost pristine surface. SEM images of these surfaces imaged for 24 hours show a similar trend (Figure S3).

Electrochemical Impedance Spectroscopy (EIS) measurements of different solutions to further understand the corrosion inhibition effect of the ionic monomers. Figure 2 and Figure S2 represent the impedance response of each monomer comparing to the control surface without monomer. The Bode plots shows the impedance response of stainless steel surfaces covered by [p-OHcoum] MA, [p-O(CH$_3$)$_2$coum] MA and [p-O(CH$_2$)$_3$coum] MA monomers during an immersion on 0.01 M NaCl aqueous solution for 24h. The control surface (figure 2, A and C) shows a decrease in the impedance and in the plateau of the phase angle in the low frequency range (10$^{-1}$ – 10$^1$ Hz) with time. Mild steel, after an immersion of 2h in [p-OHcoum] MA solution, presents an impedance of 10$^4.25$ Ω, this value increases until 10$^{5.5}$ Ω after 24 hours.

![Fig. 2 Electrochemical impedance spectra for AS1020 mild steel immersed in the control and the inhibited solutions up to 24 h: impedance modulus and phase angle plots for control (a, c); inhibited solution containing [p-O(CH$_2$)$_3$coum] MA (b, d)](Image)

These increasing low frequency responses with time indicates that the inhibitor adsorbs and creates a barrier over the whole surface forming a protective layer against corrosive NaCl environment [20]. In the case of the mild steel immersed in an aqueous solution containing the [p-O(CH$_3$)$_3$coum] MA monomer, the impedance value is 10$^5$ Ω in the low frequency range with a corresponding phase angle of 78º. The Bode plots for the [p-O(CH$_3$)$_3$coum] MA monomer presents an impedance of 10$^{5.7}$ Ω at the low frequency range, which is better than either [p-OHcoum] MA or [p-O(CH$_2$)$_3$coum] MA monomers. In the corresponding phase angle a plateau is observed at 78º is obtained, indicating that [p-O(CH$_3$)$_3$coum] MA inhibitor presents the highest capacitive behaviour consistent with the best anticorrosive performance also observed from immersion and PP studies. This data suggests that the presence of all monomers decreased the corrosion rate of mild steel AS1020 through the development of a passive film on the alloy surface. As a first conclusion, [p-O(CH$_3$)$_3$coum] MA having an hexyl chain presented the best corrosion inhibition effect among the three monomers [25, 26].

To further understand this corrosion inhibition behaviour, imaging of the surfaces using both optical and SEM techniques were undertaken. Figure 1c presents optical images of the samples immersed in control, [p-OHcoum] MA and [p-O(CH$_2$)$_3$coum] MA. The control samples are covered with red rust, while the inhibitor immersed surfaces present minor corrosive attack and a thin and adherent surface protective film, showing some inhibitor-based crystals attached to the surface. On the other hand, figures S3, S4, S5, S6 and S7 present surface analysis of the samples immersed in solutions with and without inhibitors characterized by SEM and EDS. In each sample, two main areas were selected for the EDS analysis: inhibitor crystals covered and uncovered areas. For the control sample surface analysis, the main deposits consist on a mixture of iron oxide, being the corrosion product precipitated on the surface. On the other hand, samples in contact with both inhibitor monomers ([p-OHcoum] MA, [p-O(CH$_2$)$_3$coum] MA and [p-O(CH$_3$)$_3$coum] MA) exhibit less corrosion products (as shown in the optical images, figure 1.C) and the crystals that are precipitated on the surface contain nitrogen, an atom that is present in the monomers. Therefore, it can be concluded that the inhibitor may deposit and create crystals on the surface in order to stop steel dissolution in form of corrosion pitting.

With respect to the corrosion inhibition mechanism, it can be said that the inhibition efficiency of inhibitors in mild steel is mainly determined by the length of the hydrophobic tails attached to coumarate anion the electrostatic interaction of the head groups with the metal substrate. It is reported that increasing the alky chain length facilitates the formation of a compact film at the steel/solution inter-face, resulting in a pronounced surface coverage and improved inhibition of corrosion [23]. Earlier work by Seter et al. proposed a similar effect with the position of the OH of different derivatives of coumaric acid affecting packing on the surface and inhibition [24]. Yousefi et al. demonstrated that the steel surface is covered with the aromatic ring and the alky chains present in the inhibitors. In our case, the positive charge on the nitrogen atom is delocalized, resulting in a low net positive charge on the whole structure. The charge delocalization of the nitrogen may show less repulsive force with the positive charge present on the steel surface [25], allowing a better interaction between inhibitors and mild steel. Moreover, the π-electrons of the
aromatic rings and the oxygen atom present in the coumarate anion accompanying a good distribution of the negative charge, can interact with the metal vacant d-orbital to prevent metal dissolution in order to generate a protective passive layer against corrosion (Figure 1.A).

Next the ionic liquid monomers were introduced into polymeric coatings by UV-photopolymerization. A typical UV-photopolymerization formulation (see ESI and Scheme 3) was chosen as a reference to which a given amount of ionic monomer was introduced (20 wt%). The monomer liquid mixture was deposited onto mild steel and UV photopolymerize, forming a crosslinked polymer coating on top of the steel substrate, as shown in Figure 3. The UV photopolymerization was observed optically with the appearance of a transparent coating and the acrylic bond dissappearance was confirmed by FTIR (Figure S10, S11 and S12).

As a result, a cross-linked polymer network is obtained in which the ammonium cation is covalently attached whereas the coumarate free anions are interacting ionically. EIS measurements of different coated mild steels (coating thickness 60 micrometers) samples were carried out in order to represent an impedance response of each coating containing the ionic monomer inhibitors in comparison to the control polymer coating without ionic monomer. Figure 3.A showed polymer coatings on AS1020 mild steel containing 20% of [p-OHcoum] MA, 20% of [p-O(C4H9)coum] MA and 20% of [p-O(C6H13)coum] MA inhibitors. The impedance then reduces over 24 hours to $10^4$ $\Omega$ while the phase angle peak reduces to around 32$^\circ$. [p-O(C6H13)coum] MA based polymer has the biggest arc of 40$^\circ$ is observed. The impedance then reduces over 24 hours to $10^4$ $\Omega$ while the phase angle peak reduces to around 32$^\circ$. [p-O(C6H13)coum] MA based coating shows an impedance of $10^4$ $\Omega$ at the low frequency range. The coating containing 20% [p-O(C6H13)coum] MA monomer, presents an initial impedance value of $10^4$ $\Omega$ at the low frequency range. For the corresponding phase angle a peak of 40$^\circ$ is observed. The impedance then reduces over 24 hours to $10^4$ $\Omega$ while the phase angle peak reduces to around 32$^\circ$. [p-O(C6H13)coum] MA based coating shows an impedance of $10^4$ $\Omega$ at the low frequency range after 2h of immersion in NaCl aqueous solution for 24h. The control coating (fig. S9.B) shows a decrease in the impedance and in the plateau of the phase angle in the low frequency range with time. The initiation of corrosion can be the main factor for this variation (fig. S9.A). Mild steel coated with [p-OHcoum] MA polymer shows an almost constant impedance value ($10^{1.8}$ $\Omega$) and phase angle (27$^\circ$) throughout the 24 hours at the low frequency range. The coating containing 20% [p-O(C6H13)coum] MA monomer, presents an initial impedance value of $10^4$ $\Omega$ at the low frequency range. For the corresponding phase angle a peak of 40$^\circ$ is observed. The impedance then reduces over 24 hours to $10^4$ $\Omega$ while the phase angle peak reduces to around 32$^\circ$. [p-O(C6H13)coum] MA based coating shows an impedance of $10^4$ $\Omega$ at the low frequency range. The coating containing 20% [p-O(C6H13)coum] MA monomer, presents an initial impedance value of $10^4$ $\Omega$ at the low frequency range. For the corresponding phase angle a peak of 40$^\circ$ is observed. The impedance then reduces over 24 hours to $10^4$ $\Omega$ while the phase angle peak reduces to around 32$^\circ$. [p-O(C6H13)coum] MA based coating shows an impedance of $10^4$ $\Omega$ at the low frequency range after 2h of immersion in NaCl 0.005 M aqueous solution. This impedance is reduced to $10^2$ $\Omega$ after 9h and it remains constant until 24h. In the corresponding phase angle of the time constant (fig. 3B. h) various peaks can be seen, in contrast to what was observed when the monomer was added to the solution (as discussed above). The multiple phase angles represent different processes and are not simply related to the coating barrier properties or inhibition. Previous work with sol-gel coatings has also reported multiple time constants and these relate to water absorption in the coating as well as porosity in addition to the inhibition processes [26 – 29]. Furthermore, all the coatings present a depressed semicircle in the Nyquist plot (fig. S8) where the sample coated with [p-O(C6H13)coum] MA based polymer has the biggest arc consistent with the largest impedance observed in the Bode plot. As with the complex phase angle behaviour, the depressed Nyquist plots are indicative of multiple processes and a detailed analysis of these processes is beyond the scope of this paper. However, combining the impedance values with the observations of the coated specimens post immersion, it is very evident that the coatings with 20% [p-O(C6H13)coum] MA provides significantly more protection than any of the other
coatings, consistent with the behaviour of the monomer in solution.

Conclusions

In this communication, we report new coumarate containing polymerizable ionic compounds which show great potential as corrosion inhibitors. Potentiodynamic polarisation, electrochemical impedance spectroscopy experiments and surface analyses were made in order to verify the corrosion inhibition performance of the monomers and coatings on the mild steel AS1020 surface. Experiments show that the coumarate ionic monomers reduced mainly the anodic corrosion reaction. Among them, the \( [\text{p-O(C}_6\text{H}_{13})\text{coum}] \) MA monomer which is the most hydrophobic one presents the best inhibitor profile with the highest inhibition efficiency of 99.6% in solution. The monomers were easily incorporated into polymer coatings by UV-photopolymerizations. The incorporation of the ionic monomers into the commercial polymer coatings formulation significantly improved their corrosion inhibition properties suggesting this is a promising route forward to improve corrosion protective coatings for metal substrates. Further work is being carried out to explain the anticorrosion mechanism of the coumarate based organic ionic compounds.
