Abstract It is now well established that European earthworms are re-shaping formerly glaciated forests in North America with dramatic ecological consequences. However, few have considered the potential invasiveness of this species assemblage in the European arctic. Here we argue that some earthworm species (Lumbricus rubellus, Lumbricus terrestris and Aporrectodea sp.) with great geomorphological impact (geoengineering species) are non-native and invasive in the Fennoscandian arctic birch forests, where they have been introduced by agrarian settlers and most recently through recreational fishing and gardening. Our exploratory surveys indicate no obvious historical dispersal mechanism that can explain early arrival of these earthworms into the Fennoscandian arctic: that is, these species do not appear to establish naturally along coastlines mimicking conditions following deglaciation in Fennoscandia, nor were they spread by early native (Sami) cultures. The importance of anthropogenic sources and the invasive characteristics of L. rubellus and Aporrectodea sp. in the arctic is evident from their radiation outwards from abandoned farms and modern cabin lawns into adjacent arctic birch forests. They appear to outcompete previously established litter-dwelling earthworm species (i.e. Dendrobaena octaedra) that likely colonized the Fennoscandian landscape rapidly following deglaciation via hydrochory and/or dispersal by early Sami settlements. The high geoengineering earthworm biomasses, their recognized ecological impact in other formerly glaciated environments, and their persistence once established leads us to suggest that geoengineering earthworms may pose a potent threat to some of the most remote and protected arctic environments in northern Europe.

Introduction

Hidden underfoot, earthworms are powerful ecosystem engineers and the best-known soil macrofauna. Earthworms are found on all continents except Antarctica, but non-native earthworm populations have drawn renewed scientific interest in recent years due to their large-scale invasive properties (Hendrix

et al. 2008). Introductions and ecological impacts of non-native earthworms are particularly well studied in the formerly glaciated forests of North America, where it is now established that earthworms were eradicated during the last glaciation (Gates 1982), but have since been reintroduced by farming, fishing, and other human activities (Cameron et al. 2007; Eisenhauer et al. 2007). Here, invasive European earthworm species (Lumbricidae) have resulted in dramatic transformations to forest soil morphologies (Alban and Berry 1994; Hale et al. 2005), inorganic nutrient availability (Resner et al. 2015), carbon cycling (Lyttle et al. 2015), understory plant communities (Hale et al. 2006), and overall ecosystem biodiversity and functioning (Craven et al. 2016). Earthworms dwelling within the organic soil horizons and the upper few cm of the mineral soil (epi-endogeic, i.e. Lumbricus rubellus), or those that burrow deeply (vertically or horizontally) into mineral soil (anecic Lumbricus terrestris and endogeic Aporrectodea sp., respectively) are recognized as the main ‘geoengineers’ and drivers of ecosystem change (e.g. Hale et al. 2005, 2006; Resner et al. 2015). These earthworms are henceforth in the text referred to as ‘geoengineering earthworms’.

In Fennoscandia, earthworms have historically not been viewed as invasive. One possible reason for this differing perspective is the five millennia longer European agrarian history, for instance in southern parts of Sweden (Skoglund et al. 2012), which with the North American examples in mind likely induced a much older migration history of geoengineering earthworms. However, the alpine region of Fennoscandia (the Scandes) represents one of the last European environments where earthworm dispersal by agrarian cultures has historically been very limited. As a result, this biome likely represents one of the last northern European landscapes where peregrine earthworm communities have yet to establish. That epi-endogeic and anecic Lumbricus sp and/or endogeic Aporrectodea sp. have the capacity to establish in the arctic climate of the Scandes is evident given that L. rubellus has been reported in similar climates within Fennoscandia (Terhivuo 1988) and Southeast Alaska (Costello et al. 2011), while various Aporrectodea sp. have also been documented in man-made biotopes at similar latitudes in Finland and Norway (Terhivuo 1988).

In this study, we test the idea that Lumbricus and Aporrectodea sp. are non-native and invasive (i.e. occurring in abundances causing significant impact on the native environment) in the Fennoscandian arctic (Fig. 1). This overall hypothesis was tested by a series of sub-hypotheses stating that these geoengineering earthworms: (1) did not enter northern boreal and arctic ecosystems via natural dispersal with brackish waters (conditions mimicking those following deglaciation); (2) did not arrive to the Scandes with traditional Fennoscandian native (Sami) cultures—in the North American analog native agrarian populations did not involve tillage and animal husbandry in the glaciated regions (Pleasant 2011) that could have facilitated earthworm introduction; and (3) are currently spreading into Fennoscandian arctic birch forests from anthropogenic point sources such as abandoned farms, cabin yards, composts, and fishing sites.

Materials and methods

Field methods and site description

Possible historical dispersal routes for geoengineering earthworms to enter the Fennoscandian arctic (Hypotheses 1 and 2) were assessed by surveying earthworm populations in primary succession gradients largely resembling those following deglaciation of Scandinavia where water in the Baltic alternated between brackish and freshwater stages (Figs. 1, 2), as well as within ancient Sami cultural soils. Hypothesis 1 was tested using primary succession gradients forming along the shoreline of the weakly brackish Gulf of Bothnia in response to isostatic uplift rates of ~ 0.8 cm yr\(^{-1}\) (Fig. 2). These vegetation gradients are described in detail in Svensson and Jeglum (2003). In short, two distinct temporal vegetation zones (Alnus incana, soil age ~ 20–50 years; Picea abies, > 200 years) in undisturbed forests were surveyed for earthworms presumambly entering the landscape via water transport (i.e. hydrochory), even though migration from adjacent terrestrial sources cannot be fully excluded. Spatial gradients traversing the Alnus and Picea forest were divided into two types: (1) gradients (N = 3) with no evident human sources of earthworms adjacent (referred to as ‘natural’); and (2) anthropogenic gradients (N = 3) developing adjacent

忞 Springer
to human earthworm sources (cabins with flower beds, composts and lawns). In these gradients, earthworm populations were surveyed at six sites located along each gradient. Each site, located between ca 10–110 m apart, was surveyed using three replicated sub-plots (0.07 m$^2$). For each sampling, the common liquid mustard extraction technique (Gunn 1992) was coupled with hand sorting of the organic soil or humus (if present) down to 15 cm depth. Following sampling, earthworms were identified to the species level. Measured length (mm) was converted to ash-free dry biomass (g m$^{-2}$) using the allometric equations of Hale et al. (2004) to facilitate comparison with previously published studies. This unit conversion was repeated for all survey sites (described below). In addition to the natural gradients, three gradients within the same temporal zones were traversed adjacent to known anthropogenic sources (cabins with lawns, flower beds, gardens, composts) to test whether geoengineering *Lumbricus* and *Aporrectodea* sp. could migrate into and survive in this environment if introduced (i.e. serving as positive controls, Fig. 2c–e).

Hypothesis 2 was tested at meadows (historical milking grounds) generated by nomadic Sami peoples within Padjelanta national park (Figs. 1, 3a, e), where nomadic Sami cultures gathered reindeer for milking for centuries (1600–1900). The more nutrient (nitrogen) rich soils in the historical milking grounds are likely to be suitable for soil-dwelling *Lumbricidae*; thus, if Sami cultural practices facilitated their dispersal to the landscape, these geoengineering species should be present in these areas. The unique vegetation and soils of these milking grounds are described in detail elsewhere (Egelkraut 2017). Milking ground sites ($N = 4$), were surveyed for earthworms (methods as described previously) using 3–4 subplots (0.07 m$^2$) per site. At each site we used a similar set of control sites ($N = 4$) representing the adjacent tundra and sub-alpine birch (*var. tortuosa* and *Betula pubescens*, respectively) forest soils to allow quantification of the impact of anthropogenic disturbances on earthworm communities.
To test hypothesis 3, we surveyed potential anthropogenic point sources situated in alpine environments within the Abisko area and Padjelanta national park during the summer and autumn (July through September) of 2016 and 2017. In 2016, three presumed earthworm invasion gradients extending from farms established by homesteading farmers in the late nineteenth century (Kopparäsen and Jierpen, Fig. 3b-d respectively) as well as a modern compost (Staloloukta, Padjelanta) (Fig. 3a) were surveyed for earthworms (methods as described previously). Here, at a subjectively chosen distances from the point source, earthworm populations were surveyed using one to three replicates per distance. The gradient at Jierpen was surveyed again in 2017 to cope with eventual between-year differences. During this survey, an additional control gradient was established running in parallel to the gradient intersecting with the anthropogenic source (farm), but separated from this former gradient by a stream restricting species unable to migrate via hydrochory. In these two surveys (summer 2017), we also sorted mineral soils down to a depth of 25 cm following the liquid mustard extraction, to cope with eventual under-selecting for endogeic (i.e. Aporrectodea) species.

Site selective surveys of earthworm species introduced from potential anthropogenic sources were also conducted (sampled as described earlier) along parts...
of the hiking trail Kungsleden (the King’s trail), at abandoned farms and station homes along the Kiruna-Narvik railway line, and in the villages of Abisko (lawns and composts) and Staloloukta (lawns and helicopter landing ground) (Fig. 1b). The validity of hypothesis 3 was tested statistically using a regression analysis (data normal distributed) between distances from the point source versus total biomass of geoengineering (epi-endogeic, endogeic, and anecic) earthworm species for the three gradients sampled in detail (Jierpen, Kopparåsen and Staloloukta).

Results and discussion

Our earthworm surveys from primary succession gradients along the Gulf of Bothnia (Fig. 2a–e) and Sami cultural soils (milking grounds) in Padjelanta (Fig. 3a, e) revealed only the epigeic earthworm species Dendrobaena octaedra (and on some occasions Dendrodrilus rubidus in the primary succession gradients); hence, our findings support hypotheses 1 and 2. The most parsimonious explanation for the absence of Lumbricus and Aporrectodea sp. in the indigenous cultural meadows is that geoengineering species did not migrate along with the traditional Sami cultures. We cannot fully exclude the possibility that geoengineering species were once present in the Sami milking grounds, but dissipated due to natural soil acidification processes following cessation of the reindeer milking culture (late nineteenth century). However, we find this scenario very unlikely as: (1) current soil pH around 4.3 (in KCl) is above the critical pH of 2.5 noted for L. rubellus (Heggström and Terhivuo 1979) and is comparable to other sites where geoengineering species are present (Table 1); and, (2) Lumbricus sp and Aporrectodea sp. species were present only in the acidic \((\text{pH}_{\text{CaCl}_2} = 3.3)\) anthropogenic primary succession gradients (Fig. 2c–e) and not in naturally formed succession soils (Fig. 2b), suggesting that the absence of geoengineering species is more likely a result of their inability to be dispersed by indigenous cultural practices rather than by soil acidity.

Findings of D. octaedra in the Padjelanta alpine soils (milking grounds and control sites) and on about 68% of the surveyed tundra and alpine birch forest sites (Table 2) is consistent with North American studies implicating this litter dwelling species as the prime colonizer of pristine soils (e.g. Gundale et al. 2005). Results from the primary succession gradients (Fig. 2b) provide a mechanistic explanation for their early arrival to the Fennoscandian landscape, as these surveys indicate that D. octaedra and D. rubidus are effectively dispersed by brackish waters (i.e. hydrochory): a mechanism previously suggested for these species (Terhivuo 1988; Terhivuo and Saura 2006). We note that the driftwood zone within these successional gradients appears to be the main habitat for these earthworms, and possibly also the main sources of cocoons. The likelihood of L. rubellus establishing via hydrochory in the post-glacial Fennoscandian landscape seems more improbable given that this species reproduces only biparentally (Muldal 1952). That is, the probability that viable L. rubellus cocoons from continental Europe traversed the brackish Baltic water and were deposited adjacent to each other on post-glacial Fennoscandian shorelines seems very low. The same holds true for Lumbricus terrestris and most of the Aporrectodea sp., although Aporrectodea rosea and Aporrectodea trapezoids are believed to be parthenogenetic (Jaenike and Selander 1979) and therefore may be exceptions. Nonetheless, based on this reasoning, and on the absence of geoengineering species in Sami cultural soils (Fig. 3e) and primary succession coastal gradients not strongly affected by human disturbance (Fig. 2b), we argue that geoengineering Lumbricus and Aporrectodea sp. are unlikely to have entered the Fennoscandian arctic biome by non-human mediated migration transport processes or with early native human cultures. Their modern presence in the arctic is likely the result of human introductions in recent centuries.

In all of the arctic gradients studied in detail, composts, fishing sites, and historic farmlands are the apparent sources of geoengineering earthworms, and their biomasses decrease significantly with increasing distance from the anthropogenic point sources into the surrounding sub-arctic birch forests (Fig. 3a–f). The invasive character of these anthropochorous geoengineering earthworms is also apparent in these gradients, as they become far more abundant than the native epigeic macrofauna, namely D. octaedra. In the arctic birch forest near the abandoned farms of Jierpen and Kopparåsen, we found a diverse geoengineering earthworm species assemblage including L. rubellus.
(epi-endogeic) and various endogeic Aporrectodea sp. including Aporrectodea calignosa complex, Aporrectodea rosea, and Aporrectodea trapezoides. At Jierpen, the control gradient showed none of these species as long as the two gradients were separated by a stream, further stressing that dispersal from the farmland is the main explanation for the observed spatial trends. Similarly diverse communities were identified in a modern compost from the Sami village of Staloluokta in the heart of Padjelanta national park. Local Sami residents informed us that earthworms were absent until their introduction by fishermen at the end of the 1970s (Sven-Ingvar Blind, personal comm.), further supporting our interpretation of a
non-native origin. Interestingly, *Lumbricus terrestris*, which is thought to have more strict environmental constraints with respect to climate and soil quality, was found in low densities within the compost at Staloluokta, making this one of the few reported occurrences of this species above the Arctic Circle in Fennoscandia (Terhivuo 1988; Nieminen et al. 2011). The between-site difference in the length of the geoengineering earthworm migration front seems to largely reflect differences in anthropogenic introduction, i.e. late 1970s in Padjelanta, ca 1900s at Kopparäsen (timing of railroad construction from Kiruna, Sweden to Narvik, Norway), and ca 1850s at Jierpen when agriculture first arrived to the interior of northern Sweden (Andersson et al. 2005). We also note that the estimated dispersal rates at these sites, inferred using our estimated arrival times, are directly comparable to North American analogues were migration rates have been estimated to be on the order of ~ 5 m per year (e.g. Hale et al. 2005). The importance of man-made biotopes as the primary sources of geoengineering earthworms was further supported by our more general survey indicating multiple lawns, gardens and abandoned farms as sources of geoengineering earthworm species across the Scandes (Table 2).

Our exploratory surveys stress that *Lumbricus* and *Aporrectodea* sp. are likely earthworm species that should be treated as non-native and invasive in the Fennoscandian arctic biome. In contrast to some other arctic countries where European earthworms are considered invasive (i.e. USA and Canada), the Nordic countries have no strategy regarding the dispersal of these earthworm species to sensitive environments. We call for immediate attention to the potential invasiveness of this species assemblage and list four
main reasons for our concern. First, the observed
g eoengineering earthworm species are known to be
drivers of dramatic environmental changes in other
formerly glaciated environments, including negative
effects on native plants and preferential selection for
non-native plants and graminoids (Roth et al. 2015;
Craven et al. 2016), increased greenhouse gas emis-
sions (Lubbers et al. 2013) and depletion of key
nutrients in surface soils (Resner et al. 2015). We
also note that the earthworm-driven modifications to
soil morphologies appears to largely resemble

observations from North American forests (Fig. 4a,
b), wherein thick organic soil horizons (O horizon)
diminish after the establishment of geoengineering
earthworms while the underlying organic rich mineral
soil (A horizon) expands (Lyttle et al. 2015). Second,
measured earthworm biomasses in Fennoscandian
arctic birch forests adjacent to anthropogenic source
areas are comparable to biomasses in North American
temperate and boreal forests where invasive earth-
worms are recognized as a potent threat (e.g. Hale
et al. 2006; Eisenhauer et al. 2007; Resner et al. 2015).

### Table 1 pH values of humus and mineral soil for Fennoscandian boreal (Bothnian coastlines) and arctic environments surveyed for earthworms in this study

| Site type | Vegetation type | Sample matrix | Sample pHa |
|-----------|----------------|---------------|-------------|
| Bothnian coastlines | | | |
| Successional gradients | Spruce—*Picea abies* | Humus (n = 14)c | (3.9, 3.3) |
| | Alder—*Alnus incana* | Humus (n = 17) | (5.0, 4.5) |
| | Driftwood (thick litter) | Litter/Humus (n = 9) | (5.8, 5.5) |
| Padjelanta national park | Sami cultural soils | Milking ground | Humus (4.3)d |
| | Controls | *Vaccinium* tundra | Humus (3.8)d |
| Arctic invasion gradients (near Abisko) | Jierpen Birch forest | Humus (n = 20)e | (5.2, 4.6) |
| | (Pre-invasion) (> 341 m from source) | Mineral soil (n = 18)f | (5.5, 4.7) |
| | Jierpen Field/Birch forest | Humus (n = 4) | (5.1, 4.8) |
| | (Invaded)g (< 341 m from source) | Mineral soil (n = 20) | (6.4, 5.5) |
| | Kopparåsen Birch forest | Humus (n = 8) | (4.8, 4.4) |
| | (Pre-invasion) (> 171 m from source) | Mineral soil (n = 6) | (5.4, 4.1) |
| | Kopparåsen Field/Birch forest | Humus (n = 2) | (5.2, 4.9) |
| | (Invaded) (< 171 m from source) | Mineral soil (n = 8) | (5.6, 5.1) |

aStandard error (σ) for all sites and matrix types was in the range of ± 0.1–0.4
bPH was measured in 0.02 M CaCl2 following pH determination in water
cHumus was sampled in bulk to 20 cm depth. When humus thickness < 20 cm, the entire depth profile was collected
dPH values for Padjelanta cultural soils and adjacent control plots were collected during a study by Egelkraut (2017) by extracting 2 g fresh soil in 50 ml 1 M KCl solution. Samples were shaken for 2 hours and left to settle overnight before measuring pH
eAt the arctic gradients, humus was sampled to 10 cm depth (when present). If humus thickness < 10 cm, the entire depth profile was collected
fThe upper 10 cm of the mineral soil profile was collected, either beginning at the base of the humus layer (when present) or at the ground surface in the absence of an organic horizon
gWe defined (Invaded) as the stage along our invasion gradients where the forest floor displays a (relatively) continuous humus layer. Fields and birch forests with diverse, well-established geoengineering earthworm communities are typically devoid of an organic horizon
Third, we know from previous studies that earthworms are almost impossible to eradicate once they have invaded a system. Finally, the limited historical impact from humans on the Fennoscandian alpine environment makes this area one of the few remaining northern European biomes where anthropogenic spreading of earthworms is likely still limited. Thus, there is an urgent need for further assessment of this on-going earthworm invasion that can aid decision-making as to whether measures should be taken to restrict the spread of geoengineering earthworm species to the Fennoscandian arctic, before they have become fully established.
