Bovine

ABSTRACT

The aim of this study was to evaluate the efficacy of treatment with estradiol benzoate (EB) at luteal phase prior to the ovum pick-up (OPU) during in vitro production of transferable embryos in Japanese Black cattle. A total of 15 cows were used as oocyte donors for OPU. Of those, four donors were randomly allocated (three times) into each of two treatment groups as a crossover study, and OPU session was carried out six times per one donor. Another eleven donors were used in a paired difference test by one crossover trial. Donors in the control group received no hormonal treatment; whereas, donors in the EB group received 1 mg of EB as a single injection. First, we observed dynamics of ovarian follicles and emergence of follicular wave after EB injection using transrectal ultrasonography. The number and proportion of medium-sized follicles with 4 to 6 mm in diameter increased gradually and achieved a peak at 72 and 96 hours after EB injection. The OPU was performed 88 hours after EB injection. The EB-treated donors had a higher proportion of follicles with 4 to 6 mm in diameters at the time of OPU. The stimulation with EB significantly increased the numbers of follicles aspirated, and the good quality cumulus-oocyte complexes per OPU. Furthermore, in the EB group, the percentage of transferable blastocysts was significantly greater than that in the control group (P < 0.05). In conclusion, a single EB injection before OPU increases the number of medium-sized follicles and can produce more transferable embryos.

1. Introduction

Embryo transfer (ET) of in vitro production (IVP) embryos enables cattle industries to enhance and accelerate the diffusion of production traits (Kruip, Boni, Wurth, Roelofs & Pieterse, 1994; Numabe, Oikawa, Kikuchi, & Horuchi, 2000; Numabe, Oikawa, Kikuchi, & Horuchi, 2001; Stringfellow, Givens, 2010). The transfer of IVP embryos from Japanese Black donors to Holstein recipients increases the number of beef calves from Japanese Black donors to Holstein recipients increases the number of beef calves (Kruip, Boni, Wurth, Roelofs & Pieterse, 1994; Numabe, Oikawa, Kikuchi, & Horuchi, 2000; Stringfellow, Givens, 2010). Another eleven donors were used in a paired difference test by one crossover trial. Donors in the control group received no hormonal treatment; whereas, donors in the EB group received 1 mg of EB as a single injection. First, we observed dynamics of ovarian follicles and emergence of follicular wave after EB injection using transrectal ultrasonography. The number and proportion of medium-sized follicles with 4 to 6 mm in diameter increased gradually and achieved a peak at 72 and 96 hours after EB injection. The OPU was performed 88 hours after EB injection. The EB-treated donors had a higher proportion of follicles with 4 to 6 mm in diameters at the time of OPU. The stimulation with EB significantly increased the numbers of follicles aspirated, and the good quality cumulus-oocyte complexes per OPU. Furthermore, in the EB group, the percentage of transferable blastocysts was significantly greater than that in the control group (P < 0.05). In conclusion, a single EB injection before OPU increases the number of medium-sized follicles and can produce more transferable embryos.
OPU improved the efficiency of embryo production in Holstein cows during early lactation (Ogata, Hidaka, Matzushige & Maeda, 2015).

Breeding techniques which utilize gonadotropin-releasing hormone (GnRH) to control the follicular wave and ovulation synchronization methods, such as Ovsynch, have been developed (Pursley, Mee & Wiltbank, 1995). Previously, we reported that GnRH-stimulation before OPU improved the efficiency of embryo production in Holstein cows (Evans et al., 2000, Macmillan, 2000, Pontes et al., 2009).

Ovarian follicular growth and development in bovines is characterized by two or three consecutive follicular waves per estrous cycle (Ginther, Knope & Kastelic, 1989, Sirois, 1988). Each wave involves the recruitment of a cohort of follicles and the selection of a dominant follicle. The growth of follicular waves is initiated by a rise in circulating FSH. All follicles growing as a cohort contain specific receptors for FSH and depend on this gonadotropin when growing. Whereas, estradiol secretion is inversely related to FSH secretion and closely regulate the emergence and growth of follicular waves (Evans, Komar, Wandji & Fortune, 1997). Ovarian estradiol secretion is important for proestrous development of ovulatory follicle (Burke, Day, Bunt & Macmillan, 2000, Martinez, Kastelic, Bo, Caccia & Mapletoft, 2005). Furthermore, the dynamics of ovarian follicular wave development during the estrous cycle can be manipulated by treating with estradiol benzoate (EB) to synchronize proestrous development of ovulatory follicle (Burke, Day, Bunt & Macmillan, 2000, Martinez, Kastelic, Bo, Caccia & Mapletoft, 2005).

Administration of exogenous estradiol-17β (E2) in progesterone-implanted cattle suppressed the dominant follicle and resulted in the consistent emergence of a new follicular wave, on average 4.3 days later, regardless of the stage of development of the dominant follicle (Araujo et al., 2009, Bo et al., 1995). Therefore, the dynamics of ovarian follicular wave development during the estrous cycle can be manipulated by treating with estradiol benzoate (EB) to synchronize proestrous development of ovulatory follicle (Burke, Day, Bunt & Macmillan, 2000, Martinez, Kastelic, Bo, Caccia & Mapletoft, 2005).

These data suggest that treatment with progesterone and E2, in combination, can be used to effectively control and synchronize follicular wave development. However, in OPU, there are few reports of treatments with EB alone, without the combination with progesterone source.

In this study, we hypothesized that the administration of EB prior to OPU would improve embryo production by OPU-IVF. We report here on the effectiveness of treatment with a single administration of EB prior to OPU for increasing the number of good quality embryos.

2. Materials and methods

2.1. Animals and Experimental design

Animal experiments in this study were approved by the Institutional Animal Experimental Committee of Hiroshima Prefectural Livestock Technology Research Center, where the experiments were performed. A total of four Japanese Black cows were used as donors for experiments. They were kept in stalls and fed grass silage and water.

Experiment 1 was designed to evaluate dynamics of ovarian follicles over time and emergence of follicular wave after one-shot EB (1 mg; estradiol benzoate, ASKA Animal Health Co., Ltd, Tokyo, Japan) intramuscular injection. In this experiment, four donors at luteal phase were stimulated with EB injection. At 0, 24, 48, 72, 96 and 120 hours after EB injection, ovarian follicles were visualized using a real-time ultrasound scanner (SSD-1000 type, Aloka Co. Ltd., Tokyo, Japan) equipped with a 7.5 MHz convex array transducer (UHT-9106 type, Aloka) and the number of follicles in ovaries were counted on ultrasound video images. All visible follicles were quantified and classified according to their diameters (small follicles: 2 to 3 mm, medium follicles: 4 and 6 mm and large follicles: more than 7 mm).

Experiment 2 was designed to evaluate effects of EB injection on the number and quality of oocytes aspirated by OPU. In this experiment, four donors were randomly allocated three times into each of two treatment groups (OPU without hormones as control group or with EB injection as experiment group). The experimental design was both group crossover study, and the OPU sessions were carried out total six times per one donor (Fig. 1A and B). The OPU was performed about 88 hours after EB injection according to the results of Experiment 1. Each OPU session was performed at more than four weeks intervals to avoid effects from repeated OPU and EB injection. In the preliminary study, we found that the number of COCs recovered decreased with the shorter intervals at less than 3-weeks.

Immediatly before the OPU session, both ovaries were examined by transrectal ultrasonography. All visible follicles were quantified and classified according to the criteria shown as above in experiment 1 for control and EB groups. Furthermore, we examined the number of cumulus-oocyte complexes (COCs) recovered, classified the quality of COCs, and then cultured them.

Then, using in vitro-matured oocytes obtained from living cattle by OPU in control and EB groups, we examined the embryo production following IVF. Embryo development and transferable blastocysts were evaluated under an inverted microscope according to the International Embryo Transfer Society (IETS) manual (4th Edition IETS, IL, USA) (Stringfellow, 2010). Evaluation of the quality of the embryo was based on its morphological integrity. Embryos classified as transferable were all of code 1(excellent/good).

Experiment 3 was designed to evaluate effects of EB injection on the number and quality of oocytes aspirated by OPU as a paired difference test by one crossover trial using eleven donors. The OPU was performed about 88 hours after EB injection according to the results of Experiment 2.
Follicular needle. The aspiration rate and vacuum pressure were 20 mL/min and than 2 mm in diameter were punctured using an aspirator (K-MAR- described (De loos, Van, Vliet, Van, Maurik & Kurip, 1989). Brie

from the follicular aspirates.

collection medium was kept in a warm water bath at 35 °C. Lactate

2.2. Follicle aspiration

Prior to follicular aspiration, all cows received a single dose of 80 mg Procaine hydrochloride (4 mL Adosan, Riken K.K., Tokyo, Japan) as epidural anesthetics to prevent abdominal straining and to relax the rectum, which was necessary for palpation of the ovaries for a long time. During the follicular aspiration, follicles were visualized using a real-time ultrasound scanner (SSD-1000 type, Aloka Co. Ltd., Tokyo, Japan) equipped with a 7.5 MHz convex array transducer (UHT-9106 type, Aloka). A 17-gauge disposable single lumen needle (COVA Needle, Misawa Medical, Tokyo, Japan) connected to a 50-mL conical tube via Teflon tubing was used for follicular puncture. Follicles greater than 2 mm in diameter were punctured using an aspirator (K-MAR-5115 type, Cook Medical Technology, Australia) equipped with a needle. The aspiration rate and vacuum pressure were 20 mL/min and 115 mmHg, respectively. Follicular fluids were collected in 50-mL conical centrifuge tubes (Sumitomo Bakelite, Tokyo, Japan). The collection medium was kept in a warm water bath at 35 °C. Lactate Ringer’s Solution (Haruzen V, Zenoaq, Fukushima, Japan) supplemented with 0.3% fetal calf serum (FCS, Funakoshi, Tokyo, Japan), 10 units/mL heparin (Neotube, Nipro, Osaka, Japan) and 0.1 mg/mL kana- mycin was used as the collection medium. The COCs were collected from the follicular aspirates.

2.3. Oocyte evaluation

The quality of COCs was graded according to morphologic criteria as described (De loos, Van, Vliet, Van, Maurik & Kurip, 1989). Briefly, grade A COCs had compacted and more than four layers of cumulus cells with a homogenous ooplasm, grade B had a compacted and three or four layers of cumulus cells with a homogenous ooplasm, grade C had a less compact cumulus cell layer with irregular ooplasm containing dark granules, grade D had denuded oocytes with no cumulus cells, and grade E had oocytes with expanded cumulus and a jelly-like matrix.

2.4. In vitro maturation (IVM), in vitro fertilization (IVF) and embryo culture

All COCs graded as A, B and C, were matured in IVM medium, as described by Kani et al. (Kani, Kuwahata, Ochi & Horiiuchi, 2011) with minor modification. The IVM medium was tissue culture medium (TCM) 199 supplemented with pyruvate (0.25 mM), gentamicin sulfate (50 µg/mL), 10%FCS, 50 ng/mL epidermal growth factor (EGF, E-1264, Sigma-Aldrich, St. Louis, MO, U.S.A.), 10 µM dibutyryl-cyclic AMP (dbcAMP, D0260, Sigma-Aldrich) and 1 IU/mL FSH (0.12 Amour Unit/ mL, Antrin 10, Kyoritu Seiyaku, Tokyo, Japan). Ten to 15 COCs were cultured in each 100-µl droplets of IVM medium under a layer of paraffin oil (Nacalai tesque, Kyoto, Japan) for 22 to 24 hours in a humidified atmosphere of 5% CO2 at 38.5 °C.

Frozen semen of the same lot of one bull was used in six OPU-IVF sessions of four donors in Experiment 2 to avoid effects from variations between different bulls. On the other hand, frozen semen of the same bull by one of six bulls was used in two OPU-IVF sessions of eleven donors in Experiment 3. The COCs were washed five times in fertili- zation medium (IVF-G, IFF, Yamagata, Japan) before being transferred to 10- to 50-µL droplets of IVF-G under mineral oil. They were co-in-cubated with spermatozoa at a concentration of 1.2×10⁶ sperm/ml for 6 hours, and then the cumulus cells were removed (Ogata et al., 2015).

The presumptive zygotes were cultured in 50-µL droplets of modi-fied synthetic oviduct fluid (m-SOF) medium supplemented with 6 mg/ mL bovine serum albumin (BSA), 0.25 mg/mL linoleic acid albumin (L-8384, Sigma-Aldrich), 0.12 mg/mL glycine (G7126, Sigma-Aldrich), 0.25 mg/mL taurine (T8691, Sigma-Aldrich) and 10 µL/mL ITS (5 µg/ mL Insulin, 5 µg/mL Transferrin and 5 ng/mL Selenium; I1884, Sigma) under a layer of paraffin oil (Nacalai tesque) in a humidified atmo-sphere of 5% O2, 5% CO2 and 90% N2 at 38.5 °C.

2.5. Statistical analyses

All statistical analyses were performed using GraphPad Prism soft-ware, Version 5.0 (GraphPad Software, Inc., San Diego, California, USA). Data were presented as means ± SEM in Table 1. Differences between two groups in the numbers of follicles, COCs, oocytes, and embryos were compared using student’s t-test. Evaluation of COCs grade, distribution of follicle size and embryos development in Tables 2 to 4, and Figs. 2 and 3 were analyzed by Chi-square test. Significant differences were defined when P value was less than 0.05.

3. Results

3.1. Dynamics of ovarian follicles and emergence of follicular wave after EB injection

The mean number of follicles in ovaries increased gradually over time after one-shot EB injection (Fig. 2A). At 72 and 96 hours after EB

‡‡ Values with different superscript letters in the same column are significantly different by chi-square test (P < 0.05).
The results of the present study showed that stimulating bovine donors with EB had a positive effect on the efficiency of embryo production in the OPU-IVF technology. The number of follicles in the ovaries increased gradually after EB injection. Furthermore, the number of blastocysts and transferable embryos were significantly greater in the EB group compared with the control group (43.0 vs. 34.3%, P < 0.05). In addition, the number of transferable embryos was significantly higher in the EB group compared with the control group (50.5 vs. 34.3%, P < 0.05, Fig. 4).

### 3.3 Embryo development and transferable embryos produced by OPU-IVF

As shown in Table 3, the numbers of oocytes cleaved after IVF was not significantly different between the EB and the control groups. However, the number of blastocysts in the EB group was significantly higher than that in the control group (50.5 vs. 34.3%, P < 0.05). In addition, the number of transferable embryos was significantly greater in the EB group compared with the control group (32.7 vs 15.6%, P < 0.05).

Furthermore, at a paired difference test by one crossover trial, the numbers of blastocysts and transferable embryos were significantly higher in the EB group compared with the control group (43.0 vs. 33.9% and 30.3 vs. 15.7%, P < 0.05, Fig. 2B).

### 4. Discussion

The mean number of follicles aspirated by OPU was significantly greater in EB group than in control group without hormone injection (36.6 ± 3.0 vs. 27.8 ± 1.8, P < 0.05, Table 1). Then, the mean numbers of COCs recovered and cultured, that is grade A to C were significantly higher in the EB group than in the control group (28.9 ± 2.9 vs. 21.8 ± 1.4, and 23.4 ± 2.4 vs. 15.0 ± 1.1, P < 0.05). As shown in Fig. 3, the proportion of medium follicles with 4–6 mm in diameter in the EB group increased remarkably compared with the control group (49 vs. 15%, P < 0.05). Therefore, the percentage of grade B COCs in the EB group was significantly higher compared with the control group (77.2% vs. 62.4%, P < 0.05, Chi-square test). Follicles were observed using a real-time ultrasound scanner at the time of OPU (n=12 OPU session in each group).

### 3.2 The number and the quality of cumulus oocytes aspirated by OPU

The mean number of follicles aspirated by OPU was significantly greater in EB group than in control group without hormone injection (36.6 ± 3.0 vs. 27.8 ± 1.8, P < 0.05, Table 1). Then, the mean numbers of COCs recovered and cultured, that is grade A to C were significantly higher in the EB group than in the control group (28.9 ± 2.9 vs. 21.8 ± 1.4, and 23.4 ± 2.4 vs. 15.0 ± 1.1, P < 0.05). As shown in Fig. 3, the proportion of medium follicles with 4–6 mm in diameter in the EB group increased remarkably compared with the control group (49 vs. 15%, P < 0.05). Therefore, the percentage of grade B COCs in the EB group was significantly higher than that in the control group (P < 0.05, Table 2).

Furthermore, at a paired difference test by one crossover trial using eleven donors, the mean numbers of follicles aspirated and COCs recovered were significantly higher in the EB group than in the control group (28.9 ± 2.9 vs. 21.8 ± 1.4, and 23.4 ± 2.4 vs. 15.0 ± 1.1, P < 0.05). As shown in Fig. 3, the proportion of medium follicles with 4–6 mm in diameter in the EB group increased remarkably compared with the control group (49 vs. 15%, P < 0.05). Therefore, the percentage of grade B COCs in the EB group was significantly higher than that in the control group (P < 0.05, Table 2).

Furthermore, at a paired difference test by one crossover trial using eleven donors, the mean numbers of follicles aspirated and COCs recovered were significantly higher in the EB group than in the control group (49 vs. 15%, P < 0.05). Therefore, the percentage of grade B COCs in the EB group was significantly higher than that in the control group (P < 0.05, Table 2).

### 3.3 Embryo development and transferable embryos produced by OPU-IVF

As shown in Table 3, the numbers of oocytes cleaved after IVF was not significantly different between the EB and the control groups. However, the number of blastocysts in the EB group was significantly higher than that in the control group (50.5 vs. 34.3%, P < 0.05). In addition, the number of transferable embryos was significantly greater in the EB group compared with the control group (32.7 vs 15.6%, P < 0.05).

Furthermore, at a paired difference test by one crossover trial, the numbers of blastocysts and transferable embryos were significantly higher in the EB group compared with the control group (43.0 vs. 33.9% and 30.3 vs. 15.7%, P < 0.05, Table 4).
OPU had a greater numbers of COCs suitable for culture with grade A to C. In addition, the numbers of blastocysts and transferable embryos were higher with EB stimulation than without the hormone treatment.

Many techniques have been evaluated for their ability to increase the mature follicle populations of bovine ovaries in OPU (Chaubal, 2007, De Roover et al., 2008, Presicce et al., 2011, Vieira, 2014). A number of studies have attempted to establish the most cost-effective procedure for retrieving the higher number of good quality oocytes, via OPU, that produce more blastocysts. The numbers of follicles observed by ultrasound and the COCs obtained by OPU were greater after GnRH treatment in the previous report (Ogata et al., 2015). These results suggested that OPU at 48 hours after GnRH administration, the presumed time for a new wave of follicular development, led to the increased number of COCs recovered.

As another approach, treatment with a combination of progestogen and E2 can effectively regulate and synchronize follicle wave development (Bo, Adams, Nasser, Pierson & Mapletoft, 1993, 1995). In these studies, a wave of follicular development has been defined as a synchronized development of a large number of follicles with 4 to 6 mm in diameter, followed by selection and growth of the dominant follicle and suppression of the subordinates. The net result was that the interval for a new wave of follicular development, led to the increased number of COCs recovered.

Fig. 4. A paired difference test using 11 donors: Effect of pre-treatment with estradiol benzoate on the number of follicles aspirated and COCs recovered at each paired-donor.

When considering parameters related to embryo development in this study, the number of oocytes cleaved in the EB group is the same as in the control group. The positive effect of EB stimulation might be related to a remarkable increase in the number of medium follicles with 4 to 6 mm in diameter (Fig. 3).

The outcome of IVP programs has also been associated with the stage of follicular growth at which OPU is performed (Blondin & Sirard, 1995, Fair, Hyttel & Greve, 1995, Hagemann et al., 1999, Hendriksen et al., 2004). The developmental potential of oocytes has been associated with follicular growth development and continues to be enhanced as the follicular diameter increases toward the luteinizing hormone (LH) surge (Chaubal, 2007, HumbLOT et al., 2005). EB treatment can manipulate the dynamics of dominant follicle during the estrous cycle and synchronize proestrous development of the ovulatory follicle (Burke et al., 2000). It was shown that the mean number of all counted follicles and all usable oocytes recovered per donor were similar, but the mean number of embryos per donor and the development rate of oocytes into blastocysts were higher in the growth phase than in the dominant phase (Maachatova, Krausova, Jokesova & Tomanek, 2005). Moreover, synchronization of the follicular wave using
progesterone implant and estradiol benzoate prior to OPU showed positive effects on in vitro embryo production as well as on pregnancy rates (Cavalieri et al., 2017). In this study, at the time of OPU, the number of medium-sized follicles with a diameter of 4–6 mm increased markedly, which is considered to be in the follicular growth phase. Therefore, EB injection prior to OPU induced a follicle growth phase, which is a new wave of follicular development and as a result, the number and quality of OCs recovered were improved, and the number of oocytes capable of developing to blastocysts was considered to have increased.

In conclusion, the results of our present experiments indicate that EB pretreatment prior to OPU to synchronize follicular wave emergence promotes blastocyst yield and the number of transferable embryos. Further studies should be conducted to optimize the timing and dose of EB injection.
