Abstract

The increase in the average lifespan and the consequent proportional growth of the elderly segment of society has furthered the interest in studying aging processes. Ageing may be considered a multifactorial process derived from the interaction between genetic and environmental factors including lifestyle. There is ample evidence in many species that the maximum age attainable (maximum lifespan potential, MLSP) is genetically determined and several mitochondrial DNA polymorphisms are associated with longevity.

Many studies have shown that most of the phenotypic characteristics observed in the aging process are the result of the occurrence, with age, of a low grade chronic pro-inflammatory status called “inflammaging”, partially under genetic control. The term indicate that aging is accompanied by a low degree of chronic inflammatory, an up-regulation of inflammatory response and that inflammatory changes are common to many age-related diseases. Therefore, the theory of oxidation-inflammation was proposed as the main cause of aging. Accordingly, the chronic oxidative stress that appears with age affects all cells and especially those of the regulatory systems, such as the nervous, endocrine, and immune systems and the communication between them. This prevents an adequate homeostasis and, therefore, the preservation of health. It was also proposed that the immune system plays a key role in the aging process, specifically in the rate of aging, since there is a relationship between the redox state and functional capacity of immune cells and longevity of individuals. Moreover, the role of the immune system in senescence could be of universal application. A confirmation of the central role of the immune system in oxi-inflamm-aging is that the administration of adequate amounts of antioxidants in the diet improves immune function, decreases their oxidative stress, and consequently increases longevity.

The present review was aimed to understand the molecular mechanisms underlying beneficial effects of Mediterranean diet on neuroinflammation and related diseases.

Introduction

In industrialised societies the average lifespan considerably lengthened during the past century, so that whereas in the early twentieth century life expectancy at birth was about 40 to 50 years, today it is almost twice as much and by 2050 it is expected to rise by another 10 years. Italy in particular turns out to be among the most elderly countries in the world thanks to, undoubtedly, improvements in nutrition, sanitation, and medical care. This increase in the average lifespan and the consequent proportional growth of the elderly segment of society has furthered the interest in studying aging processes [1,2].

Ageing may be considered a multifactorial process derived from the interaction between genetic and environmental factors, and lifestyle. Old age in human beings is characterised by the onset of several diseases which, although not unique to old age, are nonetheless rather strictly correlated to it, the physiological decline over time being a pivotal factor in the increase of the risk the elderly has of developing said diseases.

Over time, many studies have targeted the identification of biological events to which the progressive deterioration over time could be attributed. The view of ageing as a complex multifactorial process has superseded previous monofactorial theories which attributed the phenomenon of ageing to one single cause [3]. In fact, some of the phenomena which characterise physiological ageing can be explained by individual theories, but no one single theory is able to account for the ageing process in its entirety [4-44].

Inflammaging

The term inflammaging was coined by Claudio Franceschi [45] to indicate that ageing is accompanied by a low degree of chronic inflammation and an up-regulation of the inflammatory response, and that inflammatory changes are common to many age-related diseases [46-63]. Multiple persistent weak stimuli (endogenous and exogenous toxins) cause a prolonged commitment of body’s adaptive systems with multiple low-grade inflammatory responses, which tend to become chronic and often asymptomatic. Indeed, patients report vague and nonspecific signs and systemic order symptoms with complex diagnostic definition. Inflammaging is characterized by five conditions: low-grade, controlled, asymptomatic, chronic and systemic inflammation [64]. So inflammaging is the up-regulation of a variety of stress responses at the cellular and molecular levels. Inflammaging is the result of the body’s ability to adapt to and counter the effects of a variety of stress factors that cause the accumulation of molecular and cellular damage.

Physiopathogenesis

The relationship between chronic systemic inflammation and ageing is now widely accepted. Many studies have shown that most of the phenotypic characteristics observed in the ageing process are the result of the occurrence, with age, of a low grade chronic pro-inflammatory state, called "inflammaging", partially under genetic control. This state seems to be the result of continuous antigenic stimulation that continues beyond the reproductive age and therefore widely not expected by the evolution [52,65,66]. The resulting tissue damage appears to be related to death risk in elderly people and also appears to be deleterious to longevity [67]. Some studies have identified genetic, cellular, and serological markers of inflammaging, such as an immunophenotype characterised by a decrease of naïve T cells and an accumulation of memory cells, increased levels of pro-inflammatory cytokines, and significant alterations in the frequency of functional of pro- or anti-inflammatory polymorphisms [54,68,69].

Inflammaging is characterised by the activation of macrophages and the expansion of specific T cells clones (megaclones) directed to common virus antigens such as the Cytomegalovirus (CMV) and the Epstein-Barr virus (EBV) [70-74]. In order to clarify the roles of CMV disease 121 subjects have been recently studied. The subjects were between 25 and 100 years old: 18 subjects were serum negative and 103 serum positive for CMV infection [75]. It was also observed that the age-related reduction of CD8+ naïve T cells was accelerated in CMV+ subjects. The reduction of naïve CD8+ cells was accompanied by a progressive increase in CD8+ effectors T cells, CD28-, in CMV+ subjects. Therefore, the CMV seropositivity seems to be associated with many phenotypic and functional alterations of T cell immunity considered biomarkers of ageing [75]. Another chronic infection that could play a key role in the immune-inflammatory response in the elderly is caused by Herpes Simplex Virus (HSV) that appears to play a role as cofactor in damages involved in Alzheimer’s disease [76,77]. A recent prospective study has shown an increased risk of AD in patients seropositive for IgM-HSV, probably responsible for progressive chronic damage [78]. Inflammaging is a complex inflammatory response to various endogenous and environmental stimuli due mainly to the increase in circulating levels of pro-inflammatory cytokines. Cytokines are a class of soluble proteins responsible for the communication between the different components of the immune system. Cytokines play an important role in inflammation by acting on the targeting, regulation, and termination of inflammatory processes. It has been determined that these molecules also play a central role in the ageing processes. During ageing there is a decrease, reversible, in the levels of IL2 cytokine, which is important in the development of Th1 and population in increased production of pro-inflammatory mediators such as IL1, IL6, and TNFalpha [40]. The increase in the age-related inflammatory markers (inflammaging) could be the basis of the reduced ability for elderly subjects to cope with various stressors. The inflammaging process may also generate reactive oxygen species (ROS) that cause oxidative damage and elicit an increase in the release of cytokines, perpetuating a vicious circle resulting in a chronic pro-inflammatory state where tissue damage and repair mechanisms proceed simultaneously. In this case the damage accumulates slowly and asymptptomatically over the years, resulting in ageing and in the development of age-related diseases [59-64]. Reactive oxygen species (ROS) are also capable of inducing profound effects on gene expression and are implicated in the pathogenesis of many age-related diseases such as atherosclerosis, type II diabetes, neurodegeneration, osteoporosis and osteoarthritis, all pathologies which share a strong inflammatory/immunological component. Moreover, oxidative stress and ROS are active inducers of apoptosis and may act as mediators influencing other transcription factors such as NF-kB and AP-1 [68]. Alterations in apoptosis due to ageing may therefore explain some of the most important aspects of immunosenescence [79], such as the accumulation of memory cells, expanded megaclones, the restriction of the repertoire of T lymphocytes, and the increase in the incidence of autoimmune phenomena. The cellular and molecular mechanisms related to the body’s ability to appropriately respond to a series of oxidative stresses and inflammations appear to play an important role in promoting human longevity and in avoiding/delaying the major age-related diseases. The participation of inflammatory cells and molecules in the pathogenesis of many age-related diseases such as atherosclerosis, Alzheimer, and Parkinson’s disease is well documented. Conversely the control of inflammations may allow successful ageing that can be better achieved as is evident in centenarians. They are the living example of successful ageing, the desirable type of ageing, free from chronic debilitating diseases, and which preserves physical self-sufficiency and mental health. These subjects are a highly selected group who have lived for over a hundred years without the onset of any major age-related diseases; the study of these subjects could detect the biological basis of ageing or the combination of genes and lifestyle that have allowed these people to avoid the aforementioned age-associated diseases. The “INCHIANTI Study”, concluded in 2004 [80], showed that elderly subjects have high levels of IL-6, CRP, and IL-1 compared to young subjects in good health. A further study on a group of Italian centenarians showed that subjects genetically predisposed to produce IL-6 in old age have a reduced ability to reach the outer limits of human life.

Another study by Lyons et al. [62] on a group of centenarians assessed the levels of two cytokines, the anti-inflammatory protein IL-10 and the TNF-alpha, a protein that promotes inflammation. The study showed that centenarians express genes encoding high levels of IL-10 and low levels of TNF-alpha compared to the control group of younger subjects. Studies on the elderly and centenarians have shown that the frequency of variants (polymorphisms) of key genes involved in immune response and low-grade inflammation are present with different frequencies in centenarians by comparison to the young [74,81,82]. The presence of an anti-inflammatory genotype in centenarians suggests that chronic inflammation is a key predictive marker of mortality and morbidity in senescence. Signs of inflammaging have also been found unexpectedly in healthy centenarians, together with an increase of inflammatory markers, such as IL10 and TGF-beta [83,84]. It seems that beside the existent inflammatory phenomena, anti-inflammatory phenomena (anti-inflammaging) are also present and are equally important for longevity, and that longevity is the result of balancing these two conflicting responses [85]. A long life, which exceeds 90 years of age seems to have a strong genetic basis, which explains why the almost-one-hundred-years-old and centenarians are grouped into families. Longevity seems to be greatly influenced by a complex genetic pattern and not by a few isolated genes. It is easy to assume that genes and genetic variants associated with strong immune responses and inflammation have been selected and this has helped to ensure survival in reproductive age.

It has been proposed that an effective inflammatory response useful for the resolution of infection in young age may become the cause of much pathology such as arthritis, diabetes, cardiovascular and neurodegenerative diseases in old age. The double biological role of inflammation, positive when young and negative when older, is consistent with the antagonistic pleiotropy theory that a gene can have opposite effects at different periods of life. Inflammation itself is not a negative phenomenon; indeed, in response to various stimuli, the
immune system implements a complex series of local and systemic reactions that prevent tissue damage, isolate and destroy any infectious agents and activate the repair process. The damage is related to the increase in life expectancy not anticipated by evolution. When life expectancy is prolonged it means that immune system continues to react against external agents for decades longer than expected. The increased antigenic load eventually establishes a chronic inflammation that contributes to the deterioration of various organs, becoming a risk factor for all typical chronic diseases of old age. Indeed, the elderly that have higher blood levels of an acute phase protein, the PCR, are subject to chronic inflammatory diseases.

The systemic consequences determine a pattern of changes that goes by the name of “fragility” (chronic inflammatory disease or frailty) and epidemiological studies suggest that low grade inflammation observed in the ageing process promotes an atherogenic profile that is related to other chronic inflammatory diseases typical of old age. Other genetic and environmental factors that promote the diseases keep all their importance and even determine what will be the principal organ affected; the differences in the inflammatory status help to explain why not all the subjects develop age-related disease, even under the same risk factors. The permanent exposure to a variety of infectious agents for a long period (chronic antigenic load) influences the ageing of the immune system (Immunosenescence) [58,86].

So the potential of our immune system, genetically determined, is gradually depleted over time, in relation with the pathogenic antigen aggression. The improved hygienic conditions typical of industrialized countries may have reduced significantly the antigenic overload, preserving longer the immune system and avoiding a rapid depletion. This factor, in addition to reduced mortality due to acute infectious diseases, may have contributed to an increased life expectancy and to the increase in the number of subjects who reach the extreme limit of life.

Related disorders

Inflammation is a chronic systemic cause of many age-related diseases such as atherosclerosis and cardiovascular illness, Alzheimer’s disease and cancer.

Recent research has shown that chronic systemic inflammation contributes to anxiety, depression, cognitive decline, insulin resistance and adult-onset diabetes, obesity, and Parkinson’s disease.

Cancer

Cancer is a disease that occurs mostly in elderly subjects. The average age for diagnosis in industrialized countries is approaching 70 years of age and it is expected to increase [87]. This may be due to various reasons such as increased duration of exposure to carcinogenic factors, stronger cell susceptibility to environmental carcinogens [88,89] or to the immunosenescence in elderly [90]. Over the past 15 years a strong link between chronic inflammations, induced by chemical, biological, mechanical or physical lesions, and cancer has been discovered. For example, bowel inflammatory disease, ulcerative colitis and Crohn’s disease are clinical conditions predisposing to the development of large intestine or terminal ileum cancer [91,92]. Helicobacter pylori is a microorganism associated with atrophic gastritis, mucosal dysplasia, gastric adenocarcinoma. Inflammation plays an important role in the development of solid tumours such as colon cancer. This was clearly demonstrated by a prospective case-control study of 22887 adults followed for 11 years, where 172 cases of colon cancer were identified. In these patients plasma concentrations of CRP were higher compared to control cases [93]. Cancer susceptibility and severity may be associated with functional polymorphisms of cytokine genes involved in regulating inflammation. In particular, polymorphisms affecting IL6 and IL10 genes may influence susceptibility and in some cases the prognosis of cancer. Many different mechanisms may also link inflammation to cancer:

1. Induction of angiogenesis by inflammatory factors promotes cancer progression [94].
2. Increased release of pro inflammatory factors and certain cytokines such as IL1, TNF alpha and interferon are both involved in inflammation and cancer development [94,95].
3. Free radicals production promotes carcinogenesis [94].

Inflammatory state is the crucial mediator of the intermediate stages of tumour development. In cancer, genetic damage is the fuse that triggers the fire and inflammation is the fuel that feeds it. In 1978 Alberto Mantovani observed that innate immunity cells tend to cluster around some tumours [96]. Then Pollard et al. showed that cancer cells “reeducate” macrophages, turning them into cytokines and growth factors factories that stimulate cancer growth by acting as tumour promoters [96]. Macrophages produce tumour necrosis factor (NFκ), which activates the nuclear factor NFκB in cancer cells. This nuclear factor triggers the production of proteins that stop apoptosis and activate cell proliferation. So, the precancerous tissue in chronic inflammatory cells uses the innate immune system to help the tumour grow. How this process starts remains unanswered for the time being [96].

Atherosclerosis

Almost the 50% of all deaths in the developed world and 25% of the deaths in developing countries are attributable to cardiovascular diseases. Atherosclerosis is the leading cause of heart disease and stroke. Atherosclerosis, considered in the past a disease of lipid accumulation, is now considered a chronic inflammatory disease of large and medium size vessels [97]. The lesions begin in childhood as lipid streaks (reversible), which in old age tend to become plaques proper that can narrow the arterial lumen or ulcer and complicate in thrombosis which can occlude the lumen. The clinical manifestations depend on the vessels involved, so it will be angina pectoris and heart attack during when the coronary arteries are involved, stroke if the arteries of the central nervous system are involved, and peripheral arterial disease if the peripheral circulation is concerned. It is clear that the seats that are more predisposed to the development of atherosclerotic lesions are the ramifications and the curvatures of the vessels of the blood stream due to friction on its surface (hemodynamic stress), an important factor for the intima thickening. The early lesion of atherosclerosis is identified in the functional/dysfunctional endothelial alteration by cardiovascular risk factors (smoking, hypercholesterolemia, hyperhomocysteinemia, hypertension, obesity and diabetes mellitus, and possibly infectious and immunological causes) and to the accumulation and subsequent oxidation of low density lipoprotein (LDL). The endothelial dysfunction is followed by adhesion and migration of monocytes and T cells to the intima in response to the surface expression of endothelial adhesion molecules such as selectins, VCAM-1, ICAM-1 and chemotactic signals (MCP-1). Recruited monocytes proliferate in the intima, and differentiate into macrophages that phagocyte infiltration and oxidized lipoproteins transforming them into foam cells that characterize striae lipid (fatty streak). The secretion of cytokines and growth factors, mainly derived from macrophages, induces migration of smooth muscle cells from the media to the intima, where they proliferate, differentiate in “synthetic” phenotype and synthesize extracellular matrix, resulting in the transformation of lipid streaks in advanced lesions: fibrous plaques.
cardiovascular events even in apparently healthy subjects as shown. Risk factors such as negative prognostic index for atherosclerotic myocardial damage. The reactive C protein adds to the most common outcome of patients with acute coronary syndrome regardless of fibrous cap that becomes less resistant to hemodynamic stress. Inflammatory cells and especially macrophages produce hydrolytic enzymes that would make the plate less resistant to the blood component. These molecules on leukocytes, stimulate the production of chemotactic factors for monocytes/macrophages and smooth muscle cells. In the endothelium they induce the expression of adhesive molecules to leukocytes, stimulate the production of chemotactic substances (which are partly related to the endothelial surface and are partly released in subendotelium) and promote the synthesis of growth factors for monocytes/macrophages and smooth muscle cells, stimulate the synthesis of PAI-1 (plasminogen activator inhibitor-1) and tissue factors for monocytes/macrophages and smooth muscle cells. In smooth muscle cells induce the transformation into foam cells, stimulate the production of cytokines, growth factors and metalloproteases. In smooth muscle cells induce the synthesis of MCP-1. Finally, oxidized LDL activates platelets and cause aggregation. The fibrous plaques may experience more complications (ulceration, bleeding, thrombosis, calcification) determining the third and most serious atherosclerotic stage: the complicated lesions. There are many factors responsible for plaque fissuring, in particular the great importance of plaque inflammation and abundant lipid component that would make the plate less resistant to the blood component. Inflammatory cells and especially macrophages produce hydrolytic enzymes such as metalloproteases able to lyse the collagen of the fibrous cap that becomes less resistant to hemodynamic stress.

Moreover, elevated levels of some inflammatory markers predict the outcome of patients with acute coronary syndrome regardless of myocardial damage. The reactive C protein adds to the most common risk factors such as negative prognostic index for atherosclerotic cardiovascular events even in apparently healthy subjects as shown by Ridker. It is now commonly accepted that the cardiovascular risk increases for PCR levels in serum above 5 mg/l, but some authors have shown that subjects with PCR levels greater than 3.6 have a risk for cardiovascular events 2 times higher than the rest of general population.

Alzheimer’s disease

Alzheimer’s disease is the most common neurodegenerative disease in Western Europe and an important public health problem as the number of cases is increasing with the aging of the population. It manifests with progressive decline in memory and intellectual abilities, impoverishment of language, disorientation and behavioral skills. The characteristic neuropathological aspects of Alzheimer’s disease (AD) are senile plaques (SP), neuro fibrillar clusters (NFT) and amyloid angiopathy. The NFT are accumulations of dystrophic neurites containing double helix filaments whose main component is the phosphorylated form of tau protein encoded by chromosome 17, associated with microtubule. Amyloid beta deposits are observed both within the cerebral vessel wall and, more typically, as SP represented by a central core of beta amyloid fibrils surrounded by a ring of dystrophic neurites, reactive astrocytes and microglia. The beta amyloid protein originates from the cleavage of a precursor consisting in two fragments of 40 (Abeta1-40) and 42 amino acids (Abeta1-42). About AD it is known a familial form (FAD) with autosomal dominant. In more than 50% of cases of this type have been identified mutations in the amyloid precursor protein (APP) on chromosome 21 [98], presenilin 1 gene (PS-1) on chromosome 14 [99] and presenilin 2 gene (PS-2) on chromosome 1 [100]. These changes are associated with increased production of amyloid beta fragment 1-42 (Abeta), highly toxic for neurons and main component of the plaques observed in AD. However, the role of genetic factors in the sporadic AD pathogenesis is not completely clear and is likely involved multiple risk factors. The presence of epsilon 4 allele (ε4) in the gene for apolipoprotein E (APOE) is the major genetic risk factor associated to the development of sporadic AD. Subjects carrying respect to non-carrying ε4 allele has a developing AD risk by three (in heterozygote’s) to eight (in homozygote’s) times greater. The ε4 promotes the deposition of Abeta in extraneuronal plaques. The annual incidence rate is estimated about 1% in subjects over 65 years old to more than 3% in patients over eighty. Immune responsiveness in AD appears to be altered [101,102]. In the brain of these patients there are some acute phase proteins and elements of the immune system, although there are the classic inflammation signs such as oedema and neutrophil invasion. Alterations of this type found in the brains of patients affected by AD, but not in age-matched healthy controls, include a greater number of receptors for immunoglobulin and for the complement, increased microglial expression of major histocompatibility complex, increased production of cytokines (like IL-1β, IL-6), increased acute phase proteins alpha-1-antichymotrypsin (ACT) and infiltration of T lymphocytes in the tissues [103-106]. A case-control study (103) showed that plasma levels of ACT are related to the degree of cognitive impairment in AD patients and that peripheral markers of inflammation or altered immune response could be used to monitor disease progression. The role of inflammation is further underlined by epidemiological studies showing that the long-term use of NSAIDs may protect against AD [107]. From the immunohistochemical prospecive microglia is shown that related to monocytes, which replaces in phagocytic role in brain. It also expresses a number of important marker of immune function including major histocompatibility antigens type I and II, which facilitates interaction with T lymphocytes. It is shown by numerous studies the increased concentrations of some cytokines and their receptors that regulate and amplify immune responses, conversely lymphocytic infiltration does not seem to be an important
Beneficial effects of Mediterranean diet in neuroinflammation and related diseases

Despite during recent years many theories about aging have been developed we are still far from a full explanation of the mechanisms underlying the aging process. It has not yet been found an answer to the question that always arises from the man: “why grow old?”, “what do we live longer?”. Great strides have been made by immunological-inflammatory research, but it is still waiting for effective and validated therapeutic strategies. It has great consensus the hypothesis that aging is multifactorial and complex process, produced by the interaction between genetic, environmental and lifestyle. According to the latest scientific understanding our genes are programmed to make us live 120 years. But we know that longevity is not only written in the genes, but for a good 70% must conquer day by day with healthy lifestyles. So from the earliest years of life is essential for healthy nutrition, physical exercise constant, constant mental activity, a limited use of tobacco and alcohol, a life away from polluted environments, with limited sun exposure and most importantly it is necessary to lead a life animated by many interests [124-138].

Epidemiological studies have shown an inverse association between adherence to the Mediterranean diet and the risk of chronic and neurodegenerative diseases, the most frequent causes of mortality in industrialized countries. Greater adherence to the Mediterranean diet is associated with a reduction in the incidence of cardiovascular mortality (10%) and a reduction of all-cause mortality (8%) [124-138].

The paternity of research on the Mediterranean Diet is to be attributed to the nutritionist Lorenzo Piroddi (1911 - 1999), who in 1939 hypothesized the connection between eating habits and the onset of the diseases of the exchange. To cure his patients, Piroddi developed a first version of the Mediterranean Diet, which limited the consumption of animal fats favoring the vegetable ones.

But the first scholar who brought the concept of “Mediterranean Diet” to the attention of science was Ancel Keys (1904 - 2004) [124-138].

The indicators of adequacy to the most used Mediterranean Diet are:

1) Mediterranean Adequacy Index (MAI), created by Albert-Fidanza, is built on the Mediterranean Diet of reference, i.e that taken in 1960 in Nicotera (which was then designated in the Seven Countries Study as the third Italian rural area), dividing the percentage of energy deriving from the consumption of typical Mediterranean foods for that deriving from foods of a typically non-Mediterranean diet. The MAI of the men of Nicotera of 40-50 years amounted to 7.5. Analyzing the MAI it was possible to see how the diet of population groups examined in Italy in the last four decades has changed, progressively abandoning the nutritional characteristics of the Italian-Mediterranean diet. Even the diet of the subjects of Nicotera, has undergone profound changes in quality over time, in fact after 42 years the MAI has fallen to 3.5 for men [124-138].

2) The Mediterranean Diet Score (MDS), created by Antonia Trichopoulou, is a scale that indicates the degree of adhesion through 9 components and determines a score from 0 to 9 (from the minimum grade to the maximum degree of adherence to the Mediterranean diet [124-138].

3) The Mediterranean Diet Score, created by Panagiotakos, evaluates the consumption of 11 categories of food products with a score from 0 to 5 depending on the portions taken weekly [124-138].

The Mediterranean diet foods

The undisputed protagonists of the Mediterranean diet are: olive oil, whole grains, fresh fruit, vegetables, fish, legumes, a moderate number of dairy products and meat, red wine [124-138].

Olive oil

It is the heart of the Mediterranean diet, and determines its taste. It is the most used fat, and this is good: it is rich in monounsaturated fatty acids and in particular of oleic acid (70-86%), thanks to this particular feature is one of the best condiments to keep under control the serum concentrations of lipoproteins very low density rich in LDL cholesterol which tends to remain in the blood and to settle on the walls of the arteries. Furthermore, the relatively high concentration of oleic acid in the membrane phospholipids, makes the cell less susceptible to oxidation, reducing the formation of pro-inflammatory molecules [124-138].
It is rich in polyphenols, substances that in addition to having antioxidant characteristics, stimulate the expression of genes that protect us from cancer. Some of these compounds, in particular flavonoids and secoiridoids, have shown significant effects in the prevention of chronic diseases such as cardiovascular diseases, some types of tumors, premature aging and degenerative diseases of the nervous system, so they could help to explain the health effects of extra virgin olive oil in addition to the oleic acid content [124-138].

Olive oil is not only important for its intrinsic properties, but also because it replaces other fats widely used in non-Mediterranean kitchens, such as those of animal origin (lard or butter) or from lower quality vegetable oils. Let’s not forget, however, that it is still a fat and that all fats, regardless of other nutritional characteristics, have the same caloric intake [124-138].

**Whole grains**

They are representative of the Mediterranean Diet, in fact they occupy the base of the food pyramid with vegetables and fruit. Cereals are a group of foods that include corn, barley, rice, wheat (soft and hard wheat) and spelled. They are an important source of nutritive energy and provide this energy in the form of starch, polysaccharide from which glucose is obtained after the digestive process, and are also a good source of protein. Whole grains are those that keep intact bran and germ and are rich in iron, B vitamins and fibers that facilitate intestinal transit and limit the contact of some harmful elements with the gastrointestinal mucosa. Many cereals can be ground to make different types of flour, which may have retained the original composition for the entire production path or have been reconstituted. These flours are then used for the production of pasta, bread and other baked goods [124-138].

Current epidemiological evidence indicates that whole grains have a beneficial effect on health. Whole grain foods substantially reduce the risk of cardiovascular disease, diabetes and cancer and also play a part in body weight management and digestive health. Essential macro and micronutrients with phytoneutrients present in whole grains contribute synergistically to their beneficial effects. The inverse association between whole grain intake and cardiovascular disease was demonstrated by a meta-analysis that evaluated seven cohort studies highlighting that the increased total grains intake (2.5 portions compared to 0.2 per day) was associated with a 21% lower risk of cardiovascular events. On the contrary, there was no correlation with the intake of refined cereals, in which the relative concentration of starch is higher because most of the bran and some parts of the germ are removed in the refining process [124-138].

A recent intervention trial showed a greater reduction of fat mass without any change in body weight, in the group that took whole grains compared to that with refined grains. Also for the risk of type 2 diabetes mellitus has been demonstrated an inverse association with the intake of whole grains; the beneficial effects may be due to the structure of whole grains and nutrients present in whole grains, such as magnesium and antioxidants such as vitamin E, phytic acid and selenium [124-138].

A recent meta-analysis of 25 prospective observational studies confirmed the reduction in colorectal cancer risk, resulting in an increase of 3 portions per day of whole grains. The nutritional components of whole grains, which exert their action in improving health by preventing chronic-degenerative diseases, include tocochromenols, lignans and phenolic compounds, and anti-nutrients such as phytic acid, tannins and enzymatic inhibitors [124-138].

**Fresh fruit and vegetables**

They are foods with reduced caloric power, rich in fiber, water, vitamins and minerals. The dietary fiber present in fruits and vegetables increases the distension of the stomach with an increase in the sense of satiety which consequently leads to not exceeding the consumption of other types of foods with higher caloric power. The portions of fruit and vegetables consumed per day must be five. Always choosing seasonal fruit and vegetables limits the risk of using harmful substances used in agriculture with them, helps to preserve biodiversity and also the organoleptic qualities are superior [124-138].

**Fish**

It is a food that has shaped and determined the history of the countries bordering the Mediterranean. It is an excellent source of protein, vitamin D, of omega-3 long-chain polyunsaturated fatty acids and some mineral salts such as selenium, phosphorus and potassium that regulate the exchange of substances through the cell membrane and therefore affect the normal functioning of all the cells of our body. Particular attention is given to the presence of omega-3 fatty acids, which include eicosapentenonic acid and docosahexaenoic acid, defined as essential because our body is not able to produce them, and must therefore necessarily be taken with the diet. Consumption of omega-3 protects the cardiovascular system, decreasing the risk of coronary heart disease, hypertension, atherosclerosis, thrombosis [124-138].

They have antithrombotic effects as they inhibit the platelet aggregation, substituting arachidonic acid to produce the thromboxane A3 without any aggregating and weak vasoconstrictor effects and antidyslipidemic effects, as they reduce the expression of ApoB100 of LDL [124-138].

**Legumes**

Often called the “meat of the poor”, they have a dual function, both for the presence of slow-absorbed carbohydrates and for the good protein content they possess. The association of cereals and legumes is complete from the protein point of view, as it provides the body with all the essential amino acids we need. Legumes have a fair amount of mineral salts, some vitamins and dietary fiber, which helps to reach a sense of satiety. They also help to modulate the glycemic response of the meal [124-138].

**Dairy products and meat**

As for meat, we tend to prefer white to red. It is rich in proteins, fats whose quota depends on the type of breeding and origin of the animal, vitamins and mineral salts. Milk is an excellent source of protein, minerals and vitamins [124-138].

**Wine**

Attention goes to the presence of antioxidants such as resveratrol and quercetin. These substances are important because they have the power to protect the proteins, lipids and nucleic acids of the cells from the attack of free radicals. Obviously, it is not possible to pursue an anti-radical or completely protective objective, because it would coincide with an excessive amount of alcohol. The concept therefore remains that a good glass of red wine can help to exercise positive actions not only for the reduction of cardiovascular risks, but also for the improvement of the lipid pattern, of the hemostatic balance, of blood pressure, of insulin sensitivity, of cholesterol level. HDL [124-138].

Each food, therefore, has beneficial effects on health, when the consumption of these is adequate and proportionate in the right
amounts, to meet the energy and nutrient needs of the body. It is essential to stress that all the meals of a day, starting from breakfast, lunch, dinner and snacks, must be balanced, that is to contain all the nutrients we need, a goal that can be reached easily with a diet as varied as possible as the Mediterranean diet indicates to us [124-138].

Always pay attention to the quantity, but above all to the balance of the nutrients that bring energy, respecting in particular the following proportions: 55-60% of the energy from the carbohydrates, 12-15% from the proteins, 25-30% from the fats. We can also say with certainty that the Mediterranean diet can be a useful tool for reducing body weight, with moderate caloric restriction associated with physical activity [124-138].

**Conclusions**

While nutritional strategies that reduce inflammation and oxidative stress appear to hold promise for preventing neurodegenerative disease, it’s important to note that some nutritional factors may actually enhance brain inflammation. Obesity seems to be on the top of the list of concerns. Studies have shown that people with higher levels of adiposity are at higher risk for both future PD and AD and that central adiposity is related to cognitive decline and dementia. Body fat promotes inflammation. Body fat may store toxins. A fatter person even has a smaller hippocampus, says Perlmutter of links between obesity and neurodegeneration. Diabetes is linked with a higher risk of dementia and AD as well. Brain inflammation may also be bolstered by advanced glycosylation end products (AGEs), molecules formed during a nonenzymatic reaction between proteins and sugar residues called the Maillard reaction. AGEs produce a “fifty-fold increase in free radicals and increase the risk of AD by 400%,” according to Perlmutter. AGEs can create adverse effects on tissues and cells, including the activation of intracellular signal transduction pathways leading to the upregulation of cytokine and free radical production [124-138].

It may seem strange, but the much-publicized Mediterranean Diet, which we should all follow to be better and prevent diseases of well-being and which represented the basis of eating habits until the middle of the twentieth century in all the countries of the area, is progressively disappearing from the Mediterranean countries, from Italy, from Greece, from Spain and also from the Middle East and from North Africa, because of the wide diffusion of the western economy, of the urban and technological culture and of the globalization of production and consumption. The food choices are oriented towards what the market offers, depending on the efficiency and speed of transport, distribution networks and the effectiveness of conservation technologies and become increasingly disconnected from seasonality and tradition [124-138]. In the last years, the Mediterranean style has undergone a profound change: the diet has progressively been enriched with foods high in protein, saturated fats and simple sugars because they have become more frequent both meals outside the home (for necessity and for laziness) that the consumption of ready-made foods (very different qualitatively from those consumed in the 60s) and also the portions of Italians have increased by 30-40% (from 2,500 to 3,300 kcal / day), with a progressive impoverishment of plant origin and complex carbohydrates. This increase in the calorie intake did not follow an adequate energy expenditure because the lifestyle has become more sedentary as it is linked to transport and work more and more to the machines, thus resulting in a significant reduction in daily energy expenditure [124-138].

We live, therefore, in an era of “apparent well-being”, where the growth of overweight and obesity and of all the related pathologies is also registered when life expectancy is prolonged. The Mediterranean food model should not be abandoned, but rediscovered, re-evaluated and proposed daily in the tables of all the people [124-138]. The smart lesson to be learned about health and function? Don’t neglect Mediterranean diet.
