ABSTRACT

In this paper we discuss an application of machine learning based methods to the identification of candidate AGN from optical survey data and to the automatic classification of AGNs in broad classes. We applied four different machine learning algorithms, namely the Multi Layer Perceptron (MLP), trained respectively with the Conjugate Gradient, Scaled Conjugate Gradient and Quasi Newton learning rules, and the Support Vector Machines (SVM), to tackle the problem of the classification of emission line galaxies in different classes, mainly AGNs vs non-AGNs, obtained using optical photometry in place of the diagnostics based on line intensity ratios which are classically used in the literature. Using the same photometric features we discuss also the behavior of the classifiers on finer AGN classification tasks, namely Seyfert I vs Seyfert II and Seyfert vs LINER. Furthermore we describe the algorithms employed, the samples of spectroscopically classified galaxies used to train the algorithms, the procedure followed to select the photometric parameters and the performances of our methods in terms of multiple statistical indicators. The results of the experiments show that the application of self adaptive data mining algorithms trained on spectroscopic data sets and applied to carefully chosen photometric parameters represents a viable alternative to the classical methods that employ time-consuming spectroscopic observations.

Key words: methods: data mining – survey – AGN – catalogs – photometry.

1 INTRODUCTION

Active galactic nuclei (AGNs) and their high redshift counterpart, quasars, are the most luminous long-lived discrete objects in the Universe and are therefore crucial to address a variety of astrophysical and cosmological problems. Individual multi-wavelength studies allow to investigate the physical conditions in the proximity of the central power source, a supermassive black hole with a surrounding accretion disk. The study of well defined samples of AGNs in various environments, both in the local universe and at high redshift, is needed to constrain the various mechanisms invoked to explain galaxy assembly and early evolution (Mahajan et al. 2010). It is also needed to explore the role of the environment in triggering or inhibiting nuclear activity (Kaufmann et al. 2004; Popesso & Biviano 2006).

In spite of the fact that the unified model (Antonucci 1993), may provide a unique physical explanation for the central engine and the surrounding regions, the observable phenomenology of AGNs (and quasars) is quite complex and encompasses a variety of objects (Seyfert galaxies, liners, quasars, blazars, etc.), which, for the large differences existing in their observed properties, have for a long time been considered to be different and independent species (Antonucci 1993).

This phenomenological complexity is also the reason why there cannot be a unique method equally effective in identifying all AGN phenomenologies (cf. Messias et al. 2010) in every redshift range. While it is clear that the most effective and the most used relies on X-ray emission properties (cf. Alexander et al. 2002), other types of indicators

can be effectively used such as mid-infrared fluxes (cf. Donley et al. 2007), color-color diagrams (cf. Hatziminaoglou et al. 2005) and even radio data both through peak emission and through unresolved radio emission (Seymour 2007). All these methods have their share of pros & cons and are more or less biased against the detection of specific sub-types.

The techniques developed to classify galaxies based on the presence and intensity of spectral emission features have received special attention in the astronomical literature. Emission lines are visible in the spectra of a large fraction of galaxies of different classes. The relative strengths of multiple emission lines have been successfully used to infer the class of galaxies observed spectroscopically (see, for example, the ground-breaking work discussed by Veilleux & Osterbrock 1987). Among emission line galaxies Seyferts, LINERs and starburst galaxies can be distinguished based on their characteristic positions in the diagrams generated by the ratios of the equivalent width of the $\beta$(5007), $\delta$ lines on the y-axis and $[^{3}P_{0}]/[^{3}P_{0}](6584)$, $\alpha$ lines on the x-axis (Veilleux & Osterbrock 1987). In this diagram, starburst galaxies are located in the lower left-hand region, narrow-line Seyferts are located in the upper right corner and LINERs tend to occupy the lower right-hand region. Different parametric models of the lines delimiting these different regions have been proposed, based on the growing availability of large samples of galaxies with spectra (Kewley et al. 2001, Lamareille 2010). Details on the most recent parametrization of the line ratio diagnostic diagram are given in Section 2. While such methods based on spectroscopic data provide efficient and reliable classification of line-emitting galaxies, they are applicable only to galaxies with measured spectra, which usually represent a small fraction of the total number of galaxies observed in the modern mixed (photometric and spectroscopic) digital optical surveys (e.g. the Sloan Digital Sky Survey - SDSS, see York et al. 2000).

In this paper we investigate the possibility to: i) identify candidate AGNs and, ii) classify them in broad classes using optical photometric parameters only, by means of supervised classification techniques trained on samples of spectroscopically classified galaxies. This study was motivated by the growing number of planned and ongoing optical surveys covering with high accuracy and depth large portions of the sky, such as KIDS (de Jong et al. 2013), DES (Annis 2013), PANSTARRS (Tonry et al. 2012) etc., where the possibility to identify reliable AGN samples from optical data alone, would be very helpful in selecting well characterized statistical samples, and to identify candidates for subsequent spectroscopic validation and other follow-up studies.

The new digital surveys produce complex data with many tens or hundreds of parameters measured by automatic methods and carry much more information than in the past. This wealth of accurate data has opened the path to the use of data mining methods (typical of machine learning), in place of the usual statistical tools to perform all sorts of classification, regression and clustering.

An interesting attempt to tackle this problem was performed by Suchkov et al. (2005) who tried to reproduce the SDSS classification using only optical colors and reached the conclusion that SDSS colors feature prominently in the algorithm used to select AGN candidates for subsequent SDSS spectroscopy (Suchkov et al. 2005).

The work described here was performed using supervised machine learning methods offered to the community through the DAte Mining & Exploration Web Application REsource (DAMEWARE). For those who are not familiar with the topic, we shall just remind that supervised methods learn how to perform a given operation (for instance how to disentangle normal from active galaxies) using a set of well known examples (also known as a priori knowledge or knowledge base). The methods we used in this paper are, respectively. Support Vector Machines (SVM; Chang & Lin 2001) and the Multi Layer Perceptron (MLP) with different types of training rules: the Conjugate gradient (CG; Golub & Ye 1999), the Scaled Conjugate Gradient (SCG; Watrous 1987) and the Quasi Newton Algorithm (MLPQNA; Brescia et al. 2012) and are shortly summarized in Section 4.

The data set used for the experiments was obtained by joining three catalogues of objects (within the redshift range $0.02 < z < 0.3$), respectively from Sorrentino et al. (2006), Kaufmann et al. (2003) and D’Abrusco et al. (2007), as described in Sec. 2 The data set contains the photometric parameters (hereinafter named as input features), as well as flags describing the nature of the objects (in machine learning methods, this flag is also called target) to be used only in the training and test steps of any experiment. These flags constitute the Knowledge Base (or KB).

We performed three types of experiments. First of all the detection of candidate AGNs (AGN vs non AGN), which is the main experiment; then we tried to classify Seyfert I against Seyfert II type galaxies; finally we also tested the possibility to distinguish Seyfert galaxies against LINERs. The data sets used in the experiments and the spectroscopic parametrization used to train the classification methods are described in Section 2 while the detailed description of the different classes of algorithms used is given in Section 3. The results of the experiments and the performances of the four techniques to each different class of experiment are described in Sec. 4 and we discuss our findings in Section 5. Finally, we draw our conclusions in Section 6.

2 THE KNOWLEDGE BASE AND THE DATA

Supervised methods learn how to reproduce the desired knowledge using the already mentioned Knowledge Base, i.e. a collection of examples, that are patterns for which the right classification (target) is already known by independent means. It goes without saying that a biased, incomplete or poor KB will affect the classification efficiency. In other words, since one of the main drawbacks of the machine learning methods is the difficulty in extrapolating to regions of the input parameter space that are not well sampled by the training data, the KB needs to cover in a homogeneous way the whole parameter space with a local density which depends on the complexity of the knowledge to be reproduced.

For the reasons outlined in the previous paragraph, it is quite evident that, in the case of AGNs, the construction of a complete and unbiased KB is almost an impossible dream unless very conservative choices, such as those adopted in this paper, are made.

1 http://dame.dsf.unina.it/dameware.html
Our KB was obtained by merging two different samples (respectively, Sorrentino et al. (2006) and Kauffmann et al. (2003)), containing objects for which a classification based on spectroscopy was available.

Both samples were drawn from the SDSS DR4 PhotoSpecAll table which contains all objects for which both photometric and spectroscopic observations are available.

Catalogue by Sorrentino et al. (2006): This catalogue contains objects in the redshift range (0.05 < z < 0.095). It provides a classification as Type 1 (Seyfert I and LINER I), Type 2 (Seyfert II and LINER II) and non-AGN for 24293 objects. The data were extracted from the Sloan Digital Sky Survey Data Release 4 (Adelman-McCarthy et al. 2006), and the selection was performed using the traditional approach based on the equivalent width of specific emission lines. In particular, objects classification was originally performed by Sorrentino et al. which assumed to be bona fide AGN sources that lay above one of the so called Kewley’s lines, (Kewley et al. 2001):

\[
\log \frac{[OIII]_{\lambda 5007}}{H_{\beta}} = 0.61 \log \frac{[NII]_{\lambda 6583}}{H_{\alpha}} - 0.47 + 1.19
\]

(1)

\[
\log \frac{[OIII]_{\lambda 5007}}{H_{\beta}} = 0.72 \log \frac{[SII]_{\lambda 6717,6731}}{H_{\alpha}} - 0.32 + 1.30
\]

(2)

\[
\log \frac{[OIII]_{\lambda 5007}}{H_{\beta}} = 0.73 \log \frac{[OII]_{\lambda 3727}}{H_{\alpha}} - 0.59 + 1.33
\]

(3)

Furthermore, AGNs were classified as Seyfert I if:

\[
FWHM(H_\alpha) > 1.5 FWHM([OIII]_{\lambda 5007})
\]

(4)

or

\[
FWHM(H_\alpha) > 1200 \text{Kms}^{-1}
\]

(5)

and

\[
FWHM([OIII]_{\lambda 5007}) < 800 \text{Kms}^{-1}
\]

(6)

All the other AGNs were classified as Seyfert II. The final catalogue comprises 22464 objects recognized as non-AGN, 725 Seyfert I, and 1105 Seyfert II (see their figure 2 and 3).

Catalogue by Kauffmann et al. (2003): This catalogue contains spectra lines and ratio for 88178 galaxies (0.02 < z < 0.3). Since this is a purely spectroscopic catalogue, in order to divide objects in different classes, we followed Kauffmann et al. (2003) prescriptions, defining a region populated by AGNs above the Kewley’s line, (Kewley et al. 2001), and a second region populated by objects which are likely not to be AGN below the Kauffmann’s line (Kewley et al. 2006):

\[
\log \frac{[OIII]_{\lambda 5007}}{H_{\beta}} = 0.61 \log \frac{[NII]_{\lambda 6583}}{H_{\alpha}} - 0.05 + 1.3
\]

(7)

The intermediate region is heavily contaminated by non-AGN and, in what follows, we shall refer to it as the mixed zone.

Finally, as in the previous case, we used the following Heckman’s line (Heckman 1980; Kewley et al. 2006):

\[
\frac{[OIII]_{\lambda 5007}}{H_{\beta}} = 2.145 \frac{[NII]_{\lambda 6583}}{H_{\alpha}} + 0.465
\]

(8)

to further divide the sample in Seyferts and LINERs.

The resulting five areas in the plane defined by the equivalent widths line ratios (Fig. 1), are populated by objects from the Kauffmann sample classified according to the Baldwin, Phillips and Terlevich (BPT; Baldwin et al. 1981), diagram diagnostics. In the diagram it is evident that this catalogue contains few object below the Kauffmann line (surely non-AGN), although other non-AGN objects are present in the mixed zone and in the catalogue by Sorrentino et al. (2006).

Catalogue by D’Abrusco et al. (2007): This catalogue contains photometric redshifts for all SDSS-DR4 with z < 0.4, matching the following selection criteria: dereddened magnitude in r band, r < 21; mode = 1 which corresponds to primary objects only in the case of de-blended sources.

The first two catalogues were merged together and, in the case of overlapping entries, we retained the Type 1 and Type 2 information from Sorrentino et al. (2006) and all other types from Kauffmann et al. (2003). The resulting merged catalogue included a total of 108162 objects. The two catalogs have ~ 2000 common objects. In principle it could be possible to perform the same classification done by Sorrentino et al. (2006) on the Kauffmann et al. (2003) catalogue. The choice has been driven by considering their divergent and specific goal: Sorrentino et al. (2006) tried to investigate the AGN environment, by following a very conservative approach; on the other side, the prescriptions of Kauffmann et al. (2003) and Kewley et al. (2006) are more general-purpose. It was finally cross matched with the third catalogue, containing photometric redshifts (photo-z) provided by D’Abrusco et al. (2007), having a very low standard deviation of residual error (σ = 0.02), which further reduced the number of objects to 100,069.

Not a Number

For these objects we extracted the following parameters from the SDSS archive and for each band (see SDSS web site for details):

- fiberMag, flux in 3 arcsec diameter fiber radius;
- petroMag, petrosian flux;
- petroR50, radius containing 50% of petrosian flux;
- petroR90, radius containing 90% of petrosian flux;
- dered, dereddened magnitude, corrected for extinction.

Therefore the number of initial parameters is 26 (i.e. the five SDSS parameters listed above for each of the five SDSS ugriz bands plus the photometric redshift). We also used derived parameters such as colors and concentration index. Finally, all objects with undefined values for some of their parameters (named also as Not a Number or NaN) were removed and this reduced the final number of objects to 84885. In this case with the term undefined values we mean undefined numerical values underlying either non detection or
contaminated measurements. This last step is crucial in machine learning methods since the presence of such unknown data might affect their generalization capabilities (Marlin 2008).

This final catalogue, summarized in Tab. 1, was then used to create three different data sets to be used for the three distinct classification experiments described in Sec. 4. Namely:

(i) KB data set for the AGN vs non-AGN experiment: the whole (Kauffmann + Sorrentino) catalogue;
(ii) KB data set for the Seyfert I vs Seyfert II experiment: just the pure AGN objects belonging to the data set of Sorrentino et al. (2006), resulting into 1570 objects;
(iii) KB data set for the Seyferts vs LINERs experiment: pure AGN objects, belonging to the catalogue of Kauffmann et al. (2003), divided into LINERs and Seyferts, obtaining 30380 objects.

3 THE METHODS

DAMEWARE, (cf. Brescia et al. 2010), is among the main products made available through the DAME (Data Mining & Exploration) Program Collaboration. It provides a web application, able to configure and execute data mining experiments through machine learning models on a distributed computing infrastructure. More recently some of these machine learning algorithms were offered in a parallel version which exploits the computing possibilities offered by Graphical Processing Unit (GPU) technology (Cavuoti et al. 2013). From the models available in DAMEWARE we selected four supervised classifiers, the Support Vector Machines (SVM) and three variants of the Multi Layer Perceptron (MLP), a standard neural network trained by different types of self-adaptive learning rules, respectively, the Conjugate Gradient (CG), the Scaled Conjugate Gradient (SCG) and the Quasi Newton Algorithm (MLPQNA).

Support Vector Machines (Chang & Lin 2001): SVM are supervised learning models with associated learning algorithms that analyze data and recognize patterns, which are mostly used for classification and regression analysis. The basic SVM takes a set of input data and predicts, for each given input, which of two possible classes forms the output, making it a non-probabilistic binary linear classifier. Given a set of training examples, each marked as belonging to one of two categories, an SVM training algorithm builds a model that assigns new examples into one category or the other. An SVM model is a representation of the examples as points in space, mapped so that the examples of the separate categories are divided by a clear gap that is as wide as possible. New examples are then mapped into that same space and assigned to a category depending on which side of the gap they fall on. In addition to performing linear classification, SVMs can efficiently perform non-linear classification using what is called the kernel trick, implicitly mapping their inputs into high-dimensional feature spaces. Among different types of such kernel function, we used the radial basis function type (Chang & Lin 2001).

The SVM training experiments over large data sets have huge computational cost (about one week per experiment on a single CPU for a data sample of about 80000 input patterns), thus, in order to be able to perform the hundreds of experiments described in what follows (see Sec. 4), it was needed to exploit the SCoPE\(^5\) GRID infrastructure resources (Brescia et al. 2009).

Multi Layer Perceptron (Bishop 1995): Neural Networks (NNs) have long been known to be excellent tools for interpolating data and for extracting patterns and trends and since a few years they have also carved their way into the astronomical community for a variety of applications (see the reviews Tagliaferri et al. 2003a,b and references there in).

Table 1. The final data set (knowledge base) composition. Empty fields stand for the unused typology. The separation between class 0 and class 1 are referred to the target vector (used during training).

ranging from star-galaxy separation (Donalek 2006), spectral classification (Winter et al. 2004), and photometric redshifts evaluation (Cavuoti et al. 2012, Brescia et al. 2013). In practice a neural network is a tool which takes a set of input values (input neurons), applies a non-linear (and unknown) transformation and returns an output. The optimization of the output is performed by using a set of examples for which the output value (target) is known a priori. Performances of a MLP are greatly affected by the choice of the learning rule, i.e. by the mathematical expression used for the optimization of its internal weights. In this paper we tested three different rules, namely, the Conjugate Gradient (CG), the Scaled Conjugate Gradient (SCG), and the Quasi Newton Algorithm (MLPQNA). In essence, the learning process of a MLP consists of two phases through the different layers of the network: a forward pass and a backward pass. In the forward pass, an input vector is applied to the input nodes of the network, and its effect propagates through the network layer by layer. Finally, a set of outputs is produced as the actual response of the network. During the backward pass, on the other hand, the weights are all adjusted in accordance with the error-correction rule. The training of NNs like MLP implies to find the more efficient among a population of NNs differing in the hyper-parameters controlling the learning of the network, in the number of hidden nodes, etc. The most important hyper-parameter (usually called $\alpha$), is related to the weights of the network and allows to estimate the dependency of the training performance on the different inputs and the selection of the parameters for a given task. In fact, a larger value of $\alpha$ implies a less meaningful corresponding weight (Bishop 1995). The three variants of learning rules discussed here differ basically in the way to calculate the $\alpha$ parameter.

All these algorithms found the minimum of a square error function, but the computational cost of each step is high, because in order to determine the values of $\alpha$, we have to refer to the Hessian matrix $H$ of the error, which is highly expensive in terms of calculations. But fortunately, the coefficients like the parameter $\alpha$ can be obtained from analytical expressions that do not use the Hessian matrix explicitly. The method of Conjugate Gradients reduces the number of steps to minimize the error up to a maximum of $|w|$ (where $|w|$ is the cardinality of network weights), because there could be almost $|w|$ conjugate directions in a $|w|$-dimensional space (Golub & Ye 1999). The Scaled Conjugate Gradients method differs from the CG by imposing that the Hessian matrix $H$ is always positive (Nocedal & Wright 1999). This can be done by adding to $H$ a multiple of identity matrix $\lambda I$, where $I$ is the identity matrix and $\lambda > 0$ is a scaling coefficient (Watrous 1987). Finally the Quasi Newton Algorithm does not calculate the $H$ matrix, but an approximation in a series of steps. A famous implementation of the QNA, which offers good performance even for non-smooth optimizations, is known as BFGS, by the names of its inventors (Broyden 1970, Fletcher 1970, Goldfarb 1970, Shanno 1970), and it was our choice. This approach generates a sequence of matrices $G$ which are subsequent more and more accurate approximations of the Hessian matrix by using only information related to the first derivative of error function (Brescia et al. 2012).
In what follows we outline the standard data mining procedure which was adopted in all the AGN classification experiments performed with the machine learning models described above.

### 3.1 Feature extraction

The first step is the pruning of the input parameters. Most machine learning methods are in fact quite demanding in terms of computing time, which may scale badly with the number of input parameters (features). It is therefore necessary to optimize the number of input features by performing what is usually called the feature selection or pruning phase, aimed at identifying the subset of features carrying the highest amount of information for a specific task.

In order to perform the pruning of input features, the initial 26 features have been organized by replacing the five magnitudes $dered$ for each band with the corresponding colors plus the $r$ $dered$ magnitude as reference, due to their capability to improve the performance, as revealed after some preliminary experiments. The improvement carried by colors can be easily understood by noticing that even though colors are derived as a subtraction of magnitudes, the content of information is quite different, since an ordering relationship is implicitly assumed, thus increasing the amount of information in the final output (gradients instead of fluxes).

The additional reference magnitude instead removes the degeneracy in the luminosity class for a specific galaxy type (Brescia et al. 2013).

Then a leave-one-out cyclic method has been used to test the contribution of each single feature to the classification training performance and to remove each time the worst resulting. This cyclic procedure is stopped when the performance does not increase by removing any further feature.

The leave-one-out procedure was performed according to the following top-down strategy:

(i) perform one experiment with all the features and store the performance;
(ii) perform $N$ experiments, where $N$ is the whole number of features in the data set, by removing each time one of the features;
(iii) find the set of features achieving the best performance;
(iv) if the achieved performance is better or equal than the previous one, remove the feature from the set, store the result and go back to point ii, otherwise stop the procedure.

At the end the feature extraction phase produced the following subset of 7 selected input features, candidates to perform the final classification experiments:

- the 4 SDSS colors $(u-g), (g-r), (r-i), (i-z)$, dereddened for galactic absorption;
- the dereddened magnitude in the $r$ band;
- $f_{iber}mag_{r}$ the fiber magnitude in the $r$ band;
- the photometric redshift derived from D’Abrusco et al. (2007).

All these features have been used in all the experiments in order to maintain the coherence along the overall classification process.

### 3.2 Model architecture selection

The second step consists in identifying for each model, via a trial-and-error procedure, the best architecture, which, for instance, in the case of MLP would mean to find the optimal number of neurons in the hidden layer, the optimal learning function, etc. Since there is no way to define it a priori, it is necessary to perform many experiments changing every time the parameters defining the model.

In each experiment, the KB is randomly split into two parts, namely the training set (70% of the data set) to be used by the model to learn the classification rule and the test set (the remaining 30%), used exclusively to evaluate the results. Due to the supervised nature of the classification task, the system performance can be measured by means of a test set during the testing procedure, in which unseen data are given to the system to be labeled. The overall performance thus integrates information about the classification accuracy (i.e. in terms of output correctness). Moreover, the results obtained from the unseen data are also important to evaluate the learning robustness, i.e. the generalization capability of the network in presence of data samples never used during the training phase.

Furthermore, it is important to stress that, in order to ensure a proper coverage of the KB in the Parameter Space (PS), the data objects were indeed divided up among the training and blind test datasets by random extraction, and this process minimizes the possible biases induced by statistical fluctuations in the coverage of the PS, namely small differences in the class distribution of training and test samples used in the experiments.

### 3.3 Evaluation of performances

Performances were evaluated on the test set using a standard set of statistical indicators defined in this section. We wish to stress that the test were performed by submitting to any given model the photometric data alone and then by comparing the predicted value with the target. For a given confusion matrix:

| TARGET | OUTPUT |
|-------|--------|
| Class A | $N_{AA}$ | $N_{AB}$ |
| Class B | $N_{BA}$ | $N_{BB}$ |

We can define the following statistical quantities:

- total efficiency: $te$. Defined as the ratio between the number of correctly classified objects and the total number of objects in the data set. In our confusion matrix example it would be:

$$te = \frac{N_{AA} + N_{BB}}{N_{AA} + N_{AB} + N_{BA} + N_{BB}}$$

- purity of a class: $pcN$. Defined as the ratio between the number of correctly classified objects of a class and the number of objects classified in that class, also known as efficiency of a class. In our confusion matrix example it would be:

$$pcA = \frac{N_{AA}}{N_{AA} + N_{BA}}$$

$$pcB = \frac{N_{BB}}{N_{AB} + N_{BB}}$$
4 EXPERIMENTS AND RESULTS

We performed three different kinds of experiments: (i) AGN detection; (ii) Seyfert I vs Seyfert II classification and (iii) Seyferts vs LINERs classification. In all the experiments were approached with two kinds of machine learning models, respectively, SVM and MLP, the latter in three different versions, by changing the internal learning rule (i.e. CG, SCG and QNA), as described in Sec. 3.

4.1 AGN classification

Concerning the classification of AGN against non-AGN, the MLP models were trained using a target vector whose values where set to 1 for each object above the Kewley’s line (i.e. pure AGN) and to 0 for object below it (which therefore includes the mixed zone objects which are non-AGN). The KB included 84885 objects after the removal of the patterns affected by NaNs. According to the mentioned strategy, the training set (70% of the whole data set) contained 59419 patterns while the test set (30% of the data set) contained 25466 patterns.

The MLP output may be interpreted as the probability for a given object to belong to a specific class and a threshold needs to be assumed in order to classify the objects. With the standard choice of such threshold to 0.5, for instance, an object above the threshold is considered to belong to the class of AGNs. Such threshold represents the median point of the probability to assign the MLP output to a class or another in a two-class classification problem. As it can be seen from the Tab. 2, which summarizes the results coming from all the experiments, the best result was obtained by the MLP with the Quasi Newton learning rule.

In the best experiment, the SVM reached a comparable result, 75.8%, obtained with $C = 32768$ and $\gamma = 0.001953125$, where $C$ is a penalty parameter and $\gamma$ the internal parameter of the radial basis function kernel (Chang & Lin 2001). The Tab. 2 reports the complete results by using the three MLP learning rules and the SVM.

\begin{table}
\centering
\begin{tabular}{|c|c|c|c|c|c|}
\hline
model & cmpAGN & cmpMIX & pcAGN & cntAGN \\
\hline
CG & 75.5\% & 55.6\% & 86.3\% & 68.5\% & 31.5\% \\
SCG & 75.7\% & 55.1\% & 86.2\% & 68.4\% & 31.6\% \\
QNA & 76.5\% & 58.6\% & 86.5\% & 70.8\% & 29.2\% \\
SVM & 75.8\% & 55.4\% & 86.2\% & 70.6\% & 29.4\% \\
\hline
\end{tabular}
\caption{AGN vs non-AGN: the first column is the model used, while the others give, respectively, the total efficiency, the AGN completeness, the non-AGN completeness, the AGN purity and the AGN contamination. These percentages are calculated by considering only the results on the 25466 objects of test set (i.e. not including training set results).}
\end{table}

\begin{table}
\centering
\begin{tabular}{|c|c|c|c|c|}
\hline
excluded & te & cmp & pc & cnt \\
\hline
features & & & & \\
photo-z & -0.4\% & -0.8\% & -0.6\% & +0.6\% \\
fibermag_r & -0.9\% & -2.8\% & -1.7\% & +1.7\% \\
dered_r & -0.6\% & -2.5\% & -0.3\% & +0.3\% \\
all except colors & -0.9\% & -1.6\% & -3.7\% & +3.7\% \\
\hline
\end{tabular}
\caption{AGN vs non-AGN: comparison among the 7 features of the test set in terms of their amount of information given to the classification performance. The first column reports the excluded features from the training set for each pruning experiment. The others are respectively, total efficiency, completeness, purity and contamination. The values are expressed in terms of percentage variations in respect to the best values (QNA) reported in Tab. 2.}
\end{table}

4.2 Seyfert I vs Seyfert II classification

In the classification between type I and type II Seyfert objects, the ML models were fed using a target vector whose values were set to 1 for objects classified as Seyfert I in the catalogue by Sorrentino et al. (2006) and to 0 if classified as Seyfert II, resulting in 1830 objects and 1570 after the usual removal of the patterns affected by NaN values. So, the training set contained 1256 patterns while the test set 314 patterns.

In this case, the main parameter of interest that quantifies the ability to distinguish the two classes is the efficiency; the MLPQNA model produced a total efficiency of 72\%, while using the SVM, the best result produced a total efficiency equal to 81.5\%. As it can be seen the results are promising, even more if we take into account the small number of patterns used for the training.

4.3 Classification of Seyferts vs LINERs

Concerning the last experiment, namely the classification between Seyfert and LINER objects, the ML models were fed using a target vector with values labeled as 1 for objects laying below the Heckman’s line, and 0 for objects above the line. This resulted in a total of 30380 objects after the removal of the patterns affected by NaN presence. The training set (70\% of the whole data set) contained 21266 patterns and the test set 9114 patterns.

The MLPQNA model produced a total efficiency of 73.8\%, while using SVM we reached the best total efficiency equal to 78.18\%.
5 DISCUSSION OF THE EXPERIMENTS

In general terms, in the main experiment (i.e. the classification AGN vs non-AGN), the MLP with QNA learning rule performs better than all other methods, both in terms of performance and robustness. This is not completely a surprise since already in other cases, the MLPQNA has been proven (Brescia et al. 2012) to be quite effective in optimizing the poor information introduced by a small or incomplete KB, due to its fine approximation of the Hessian of the training error (Broyden 1970, Fletcher 1970, Goldfarb 1970, Shanno 1970). We obtain a good overall efficiency, of about 75% with a good purity (70%) while all methods performed badly in terms of completeness reaching about 58% even though it must be stressed that if a high level of purity is needed for specific applications, MLPQNA can be fine tuned to do it by varying the threshold at which an object is recognized as AGN, but this can be done at the price of a loss in completeness. The low completeness may be partly explained by the ambiguities introduced by template patterns in the mixed zone. We therefore investigated the possibility to increase the purity at a relative price of completeness by changing the threshold level. The optimal value has been obtained for the threshold 0.87 which leads to a purity of 88% and a level of completeness of 9%. It goes without saying that the balancing between purity and completeness can be performed according to the needed from the specific application.

By considering the data set which gives the best results, obtained with the MLPQNA model, we performed a series of experiments to evaluate the contribution of each feature of training objects to the test performance, in terms of information given to the classification during training. This set of tests has been done by alternately excluding some of the features for all training objects. The resulting variation percentages for all used statistical indicators are shown in Tab. 3. We emphasize that in our methods perform fairly (77\% and 81\% in the case Seyfert I vs Seyfert II and the classification of Seyfert from LINERs. In more fine classification of Seyfert vs LINERs are \sim 78\% and \sim 81\% in the case Seyfert I vs Seyfert II.

Concerning the experiment related to the classification of AGN vs non-AGN, while the difference between Seyfert and LINER is somehow very small, and this must be considered very encouraging since the ambiguities in the knowledge base, introduced by unrecognized AGN in the mixed zone, can only lower this already very small percentage.

Concerning the classification Seyfert vs LINER (hereinafter experiment 3), the contamination in the lower region near to the Heckman’s line confuses the machine learning techniques, leading, in turn, to reduced performances of the photometric classification. This is also partially true in the first experiment (AGN vs non-AGN), where a contamination is also present in the mixed zone, i.e. between Kauffmann and Kewley lines.

Hence, a clear result of our experiments is that an unambiguous KB is required to successfully train and apply any classification method. This can be brought back to the fact that Seyfert I and Seyfert II, from the optical photometry point of view, show substantially different behavior, while the difference between Seyfert and LINER is somehow more vague; this situation is even worse in the AGN vs non-AGN experiment where the whole mixed zone confuses the network. This is also evident in the spectroscopic parameter space where the so called seagull wings move away far from the Kewley line. By considering the Seyfert I and II alone, it results evident a quite sharp spectroscopical separation (Sorrentino et al. 2006).

6 CONCLUSIONS

The production of large and accurate AGN catalogues is an important topic that will become crucial with the advent of the future photometric only digital surveys that will map large fractions of the sky to unprecedented depth in the different wavelengths.

We have applied four distinct classification methods, based on self-adaptive classification techniques, to the problem of the classification of emission line galaxies using only optical photometric parameters. The methods have been applied to three classification problems, specifically the separation of AGNs from non-AGNs, Seyfert I from Seyfert II and the classification of Seyfert from LINERs. In terms of classification efficiency, the results indicate that our methods perform fairly (\sim 76\%) when applied to the problem of the classification of AGNs vs non-AGNs, while the performances in the more fine classification of Seyfert vs LINERs are \sim 78\% and \sim 81\% in the case Seyfert I vs Seyfert II.

From a methodological standpoint, the results of our experiments indicate how sensitive the performances of the photometric classification of line-emission galaxies are to the size of the spectroscopic data sets used to train the
method, and to the uncertainty affecting the spectroscopic classification of the training set sources.

It is important to stress that, even with a completeness of about 58%, the possibility to use photometric data alone would lead to a catalogue of candidate AGN about 200 times larger than existing ones, still retaining a purity of about 70%. This work, that should be interpreted as a feasibility study, is hence just a first step and encourages the possibility to proceed further with more fine classifications of the different families of line emission galaxies by exploiting their multiband photometry.
