The climate of the Arabian Desert is not well documented during the past two millennia due to the scarcity of continuous and well-dated terrestrial archives in the region. Reliable interpretation from the climatic records from this region are pivotal for identifying periodicities of inter-annual to multi-decadal variability and trends driven by shifts in position of the Interropical Convergence Zone (ITCZ) and the strength of the monsoons. A high-resolution multiproxy approach is presented for a ∼3.3 m composite core, GBW, from a karst lake located in Ghayl ba Wazir, southern Yemen. Sedimentary proxies, including particle size distribution, coupled with magnetic susceptibility (MS) and geochemistry (XRF), provide a comprehensive picture of sediment depositional changes that may be linked to climate and environmental variability over the southern Arabian Desert. The chronology of the GBW core is provided by five radiocarbon (14C) dates from terrestrial macrofossils (wood and twigs) extracted from sediment samples and indicates the core extends to ∼900 CE. Our data indicates generally wetter conditions from 930 to 1400 CE corresponding to the “Medieval climate anomaly (MCA)” followed by arid phases during 1,410–1700 CE coinciding with the “Little Ice Age (LIA)”. Evidence for a drier LIA include high authigenic calcium precipitation [Ca/(Al + Fe + Ti)], decreased TOC/TIC values, and gypsum precipitation, whereas the wetter MCA is characterized by higher detrital element ratios (Ti/Al, K/Al, Rb/Sr), and increased TOC/TIC and deposition of finer sediments (EM1). Furthermore, end-member mixing analyses (EMMA) derived from the grain-size distribution (EM2 and EM3) corroborates the deposition of coarser silt sediment through wind erosion and production of carbonate sand during the LIA concurrently with low lake levels under generally dry conditions. Aridity during the LIA is consistent with evidence and theory for weakened boreal summer monsoons during intervals of northern hemisphere cooling.

Keywords: lake sediment, paleoclimate, late holocene, Indian Summer Monsoon, XRF, Yemen, medieval climate anomaly, little ice age

INTRODUCTION

Large sub-tropical desert belts on Earth are formed due to a drastic decline in the distribution of rainfall that results from changes in atmospheric circulation (Edgell, 2006; Warner, 2009). Continuous terrestrial records located near desert margins (e.g., lacustrine, fluvial, cave and aeolian) have provided valuable insights into past climate and hydrological changes, which were often linked to fluctuations in the strength and latitudinal penetration of the summer monsoons (Singhi and Kar, 2004; Sinha et al., 2006; Lespez et al., 2011; Wassenburg et al., 2016, among others). Lacustrine sediments, in particular, have provided valuable paleoenvironmental records from these regions (Abbott et al., 1997; Davies, 2006; Andersson et al., 2011) as they combine continuity with very high resolution. However, such records are only partially preserved or totally missing in the mid-and low-latitude desert belts.

Lakes situated near major global atmospheric circulation systems are likely to be highly susceptible to subtle changes in climate over time. The Arabian Peninsula is one of these locations as its northern areas are impacted by the Northern Westerlies Wind belt, while the southern margins are influenced by the Indian Summer Monsoon (ISM) circulation, with the latter linked to latitudinal changes in the Inter-Tropical Convergence Zone (ITCZ) position (Staubwasser et al., 2002; Gupta et al., 2003). Mechanisms influencing the current precipitation in the SW margins of the Arabian Peninsula are linked to shifts in the Red Sea Trough (RST), which is a low-pressure semi-permanent active zone over the Red Sea that generates local convective rainfall (Farquharson et al., 1996; Al-ameri et al., 2014). However, the precipitation pattern in the region is also modulated by the ISM, which brings moisture towards the southern Arabian Peninsula associated with northwards migrations of the ITCZ (Rodwell and Hoskins, 1996; Enzel et al., 2015). Holocene climate reconstruction from Yemen shows significant changes in the hydrological balance, probably as a response to the magnitude of monsoonal precipitation over time (Davies, 2006; Lézine et al., 2010; Berger et al., 2012). However, the existing lacustrine records are of relatively low temporal resolution. Other records, such as isotope data from speleothems, have proved to be valuable archives of climate change at high resolution, although with less continuity (Shakun et al., 2007; Fleitmann et al., 2011; Van Rampelbergh et al., 2013).

Hemispheric to global reconstructions have shown that warmth during the last two millennia reached a peak during the Medieval Climate Anomaly (MCA; from ~950 to ~1350 CE; Gayo et al., 2012), followed by increased cooling conditions during the Little Ice Age (LIA; ~1,500 to ~1800 CE; Matthews and Briffa, 2005; Miller et al., 2012), and anthropogenic post-industrial warming (Levitus et al., 2001). In fact, these two climate intervals (MCA and LIA) are defined in terms of temperature changes in the northern hemisphere; however, the temperature shifts in sub-tropical and tropical regions probably triggered changes in the moisture balance, which in turn gauged the amount and intensity of precipitation (Trenberth et al., 2003). The causes for the MCA and LIA have been widely discussed and linked to natural mechanisms, including solar and volcanic forcing as well as anthropogenic processes such as land cover decrease (Shindell et al., 2001; Ruddiman, 2013; among others). However, disagreement continues on the exact timing of both MCA and LIA intervals, which appear desynchronized worldwide (Crowley and Lowery, 2000; Broecker, 2001; Neukom et al., 2019), with many studies pointing to profound differences in temperature and precipitation gradients (e.g., Cronin et al., 2010; Jomelli et al., 2016). For example, while tropical East Africa experienced arid conditions during the MCA due to weak East African monsoons (Tierney et al., 2011), drier conditions associated with a positive phase of the North Atlantic Oscillation (NAO) characterizes the southern Levant during the same interval (Toker et al., 2012; Kushnir and Stein, 2019). Thus, there is a need to increase information density from climate archives around the globe to produce a reliable dataset for understanding the mechanisms and modalities of these two climate systems (MCA and LIA). The current study aims to enhance our understanding of the impact of these two climate phases by exploring sub-tropical hydrologic changes recorded in Gayal el Bazal, a lacustrine sedimentary sequence from southern Yemen, and its relation with tropical monsoonal circulation.

STUDY AREA

Gayal el Bazal is located in the town of Ghayl Ba Wazir, at 85 m above mean sea level, in the southern part of the Hadhramawt province, between the base of the Jabal Hasusah mountain cliffs and the Arabian Sea (Figure 1A). The geology of the region includes the Ghabar Group, which consists of metamorphic to anchi-metamorphic units, namely sandstone, greywacke, conglomerate, rhyolite, and quartzite rocks (As-Saruri and Wiefel, 2012). The region is characterized by several karstic sinkholes developed as a result of the dissolution of gypsum and limestone units from the Cretaceous Rus Formation (Hehmeyer et al., 2002). Lake Gayal el Bazal has occupied one of these sinkholes until very recently when it was reduced to small residual pools (Figure 1D), likely resulting from human groundwater withdrawal and agriculture. Currently, the small lake area (0.1 km², Figure 1C) is utilized by local communities for agriculture, mainly tobacco and palm plantations. The hydrological balance of the Gayal el Bazal is primarily controlled by summer precipitation (with an estimated mean of ~56 mm/yr) that falls over the main feeding Wadi Huwairah watershed (Figure 1B) and by an unknown amount of groundwater infiltration from the local aquifers. This limited precipitation amount promotes conditions of extreme pluvial events, with flash floods leaving a dramatic effect on local social and economic sustainability (Llasat et al., 2010). As for the water output balance, evaporation accounts for the sole estimated water output with unknown rates.

The climate of the studied area is characterized by extremely hot and dry conditions, with a monthly average ranges from 40°C to 43°C during summer and 28°C–31°C during winter (Bakhlah and Hassan, 2012). A hyper-arid desert dominates the east and north of our site (Almazroui, 2012), while the south part is slightly more temperate due to the Arabian Sea proximity (Hadden, 2012). Some minimal moisture appears to pass...
across the Hadhramaut Mountains to the north (that reach ~1,300 m) as a consequence of local orographic uplift and to reach the Arabian Desert, although the rates of this humidity are mostly unknown (Fleitmann et al., 2007). Most of the seasonal precipitation (~60%) over the region of Gayal el Bazal occurs during the spring months of March-April-May (MAM) through RST (Figure 2B; Baseer et al., 2019). During the summer season June-July-August (JJA), the moisture (~30%) is contributed by the ISM (Figure 2C; Fleitmann and Matter, 2009), and limited moisture is provided in the form of the winter season as a result of increasing outbreaks of North Westerly (NW) circulation (Figure 2D; Hasanean and Almazroui, 2015).

MATERIALS AND METHODS

Sample Collection

Three sites were cored in the Gayal el Bazal paleo-lake system aiming to retrieve a spatial coverage of the different sedimentary facies. The cores named Yemen-GBW01-2A (IGSN: CDR0000GK), Yemen-GBW01-2B (IGSN: CDR0000GL), Yemen-GBW01-3B (IGSN: CDR0000GM) were retrieved during a field campaign in December 2001 using a Livingstone piston corer, and cores measured 271, 95, and 108 cm (respectively) and were transported to the LacCore repository facility in Minnesota (United States) for curation and preservation.

Lab Measurements

Once in the lab, the cores were submitted to a set of non-destructive measurements, including magnetic susceptibility using a Bartington loop mounted to a Geotek multi-sensor core logger at a 5 mm (2.5 mm up and down) resolution and the data smoothed over 50 data points. Following this step, the cores were cut lengthwise into two halves (working and archive). While the archive halves were used for lithological description, imaging, and measurement of the elemental content using an ITRAX μX-Ray Fluorescence (XRF) core scanner, the working halves were used for destructive measurements (physical sampling). XRF measurements were done at a 0.5 cm resolution with the Cr and Mo tubes for identifying lighter and heavier elements, respectively (Croudace et al., 2006). The scanner generates element-related X-ray fluorescence peaks, and intensity is expressed in counts per second (cps), reflecting each given elemental concentrations (Löwemark et al., 2011; Rothwell, 2015; Chawchai et al., 2016). A semi-
quantitative analysis of the elements can be performed by normalizing element counts with total counts or Al to make a better comparison within intervals. Considering the parameters used during the XRF measurements, Al counts were reliable and were selected for normalization.

X-ray diffraction (XRD) measurements were carried out using a Rigaku Miniflex X-ray Diffractometer for the mineralogical study of the sediments. The mineral identification was carried out using PDXL 2 software, which uses a profile- and peak-based search approach based on detailed peak information. The quantitative analysis using reference intensity ratio determined the relative abundance of individual minerals.

Further destructive measurements include total inorganic and total organic carbon (TIC and TOC, respectively) at a ~3 cm resolution using a Skalar Primacs Series Total carbon analyzer. The samples were freeze-dried, weighed, and homogenized before the measurement. TIC was determined by acidification in the IC compartment at low temperature (100°C), which releases CO₂ to measure the abundance of inorganic carbon in the sediments. For TOC, dried sediments were treated with 1N HCl in order to remove carbonates, followed by heating the sample in the TC compartment at 700°C in the presence of pure Oxygen resulting in CO₂ releasing and generation of the abundance of organic carbon in the sediments.

Granulometric analysis was conducted using a Beckman Coulter LS 13 320 mw laser diffraction particle size analyzer on the same sampling resolution (~3 cm; n = 139). The sediments were pretreated with 10 ml H₂O₂ (30%) for organic matter removal and followed by acidifying using 1N HCl for removal of carbonate from the sediments (Murray, 2002; Vaasma, 2008). The solution containing digested sediments was washed with distilled water several times to remove the extra oxidizing reagents. The solution was homogenized with an ultrasonic bath prior to measurement. The grain size distribution was calculated for 100 grain size classes (particles sizes between 0.04 and 2000 µm), and the analytical error was less than 1%.

The chronology was established using AMS radiocarbon (¹⁴C) dating carried out at Poznań Radiocarbon Laboratory, Poland, on

![FIGURE 2](image-url) | The proportion of rainfall (1970-2010) by seasons: (A) winter (Dec-Feb), (B) spring (Mar-May), (C) summer (Jun-Aug), and (D) fall (Sept-Nov) (Source: WorldClim 2021).
wood and plant remains. Samples were selected from 5 different layers representing the whole composite core and weighed between \( \sim 5-15 \) mg for sufficient precision of \(^{14}\)C dating. The raw AMS radiocarbon dates were calibrated using the OxCal program (Bronk Ramsey, 2009) with the most recent IntCal20 calibration curve (Reimer et al., 2020).

### Statistical Approaches

For XRF data interpretation, a statistical approach was applied to understand possible grouping and disentangle complex signals out of the dataset. Further statistical analyses of the data [such as calculation of the principal component analysis (PCA)] were carried out using princomp function in R-Studio software (Mardia et al., 1979; Venables and Ripley, 2002). PCA is an important tool used for reducing the multivariate data into fewer dimensions and can help aid the interpretation of multiple elements. PCA transforms an original set of \( N \)-variables into a new set of \( N \)-principal components, which are orthogonal to each other (Xue et al., 2011). Each component is weighted in light of a linear combination of the original variables.

End-member mixing analysis (EMMA) was applied on the grain size parameters to understand the sediment mixtures in a series of sedimentary components (end members) reflecting the transport mechanisms and sediment sources (Dietze et al., 2012, 2013; Mishra et al., 2019). End member mixing analysis is a statistical tool that can disentangle the modes of transport of the sediments from polymodal particle size distribution (Weltje, 1997). The number of modes of transportation was selected based on a best-fit model for grain size distribution, representing the relation between the number of end members and the coefficient of determination (\( r^2 \)). After optimizing all the parameters (\( n, q, l \)), the statistical analysis was performed using EMMA function based on EMMAgeo-package, in R-language (Dietze et al., 2012).

### RESULTS

#### Stratigraphy and Lithology

A composite core record was generated based on correlation of the different cores sequences and through a detailed identification of the same lithology units and layers in all sections. The composite core GBW reaches 3.26 m in length, and three different lithological units are established (LU-1 to LU-3) and distinguished by distinct sedimentary facies (Figure 3).

- **Unit LU-1** (326–191 cm) is characterized by clayey silt and sandy silt beds separated by minor erosional contacts. The
mineralogical composition is dominated by calcite which is the most abundant mineral (range 16–100%), followed by gypsum (0–38%) and quartz (0–26%). There are increases in quartz minerals at 217–208 cm, 267–250 cm, and 295–286 cm intervals; Figure 3. The MS values in LU-1 range from 2.78 to 11.57 × 10⁻⁷ SI and average ∼5.46 × 10⁻⁷ SI. MS decreases at 326–265 cm and 251–224 cm and increases from 205 to 200 cm, where the highest values are observed for this unit (Figure 3). TOC/TIC content in the LU-1 unit varies between 0.07 and 0.92, with higher values of TOC/TIC in specific layers (217–208 cm, 237–222 cm, 267–250 cm, and 295–286 cm) (Figure 3).

- **Unit LU-2** (191–71 cm) is marked by silty sand and sandy silt and the appearance of gypsum. The sediments in the unit mainly contain calcite (0.4–100%) and gypsum (0–100%) abundance minerals with a trace amount of quartz (0–36%). The MS values range from 2.5 to 11.2 × 10⁻⁷ SI with an average of 5.7 × 10⁻⁷ SI, and higher values are for intervals from 102 to 99 cm, 136–126 cm, and 29–1 cm. The higher value of MS is also marked by higher values of Ca counts, coarser grain size (silty sand layers), and increased gypsum abundance (Figure 3). TOC/TIC content in this unit varies between 0.23 and 0.57 and showing lower values of TOC/TIC are observed from 63 to 50 cm (Figure 3).

- **Unit LU-3** (71–1 cm) consists of clayey silts and sandy silts with abundant quartz compared to the rest of the sequence. Specifically, the interval 29–1 cm is marked by a clayey silt bed with increased quartz mineral for that interval (Figure 3). The MS values fluctuate from 3.3 to 11.2 × 10⁻⁷ SI and average ∼5.34 × 10⁻⁷ SI. Lower values of MS are observed from interval 29–1 cm (Figure 3). TOC/TIC content in this unit varies between 0.23 and 0.57 and showing lower values of TOC/TIC are observed from 63 to 50 cm (Figure 3).

**Geochemistry and Statistical Analysis**

XRF analyses document considerable variations in the counts for major elements like Al, Si, S, Cl, K, Ca, Ti, Mn, Fe, Sr and minor elements like Rb and Zr, which we interpret to reflect...
relative abundance changes. Element abundance and ratios like Ca/(Al + Fe + Ti), S counts, Ti/Al, K/Al, and Rb/Sr show significant variability through the whole GBW composite core (Figure 4). The element ratios like Ti/Al, K/Al, and Rb/Sr exhibit similar stratigraphic patterns. Unit LU-1 records the higher values of Ti/Al, K/Al, and Rb/Sr from 217 to 208 cm, 237–222 cm, 267–250 cm, and 295–286 cm (Figure 4). Unit LU-2 also shows sharp spikes in Ti/Al, K/Al, and Rb/Sr from 90.5 to 87.5 cm and 125–121 cm (Figure 4). However, Ca/(Al + Fe + Ti) sharply increases at 98–93 cm, 146–126 cm, and 191–174 cm and higher values of S counts from 126 to 146 cm and 162–191 (Figure 4). In Unit LU-3, Ti/Al, K/Al, and Rb/Sr increases from 35 to 1 cm. Additionally, Ca/(Al + Fe + Ti) shows increase trend interval between 59–34 cm (Figure 4).

The principal component (PC) analysis reveals two components explaining ~69% variability in the dataset (Figure 5A). PC1 receives positive loading from Ti, K, Fe, Si, Rb, Al, and Zr and negative loading from Ca (Figure 5B). The PC2 has positive loading from S and Sr but negative loading from Cl (Figure 5C). The biplot of PC1 and PC2 shows elements like Ti, K, Fe, and Rb are oppositely associated with Ca, Sr, and S (Figure 5A).

Grain Size Distribution and Statistical Approach

The clastic grain size distribution of the GBW composite core is largely characterized by silt with minor variations of sand and clayey silt fractions. The mean grain size of the core ranges from 3.1 to 7.1 ϕ and the coarsest grain size fraction is found at 152–144 cm and finest fraction at 260 to 253 cm (Figure 6). The overlay of all grain size data from all samples revealed a polymodal distribution, and hence end-member analysis has been applied. The EMMA of grain size distribution in GBW core yielded an optimal model with five end members and explained 65% variability of the total dataset. End member 1 (EM1) represents the finest particle fraction in the core with the dominant modal grain size of 7.1 and is in the range of clayey silt. For EM2, the dominant modal grain size is 4.8 and lies in the range of medium to coarser silt. Furthermore, EM3 (mode = 3.2 ϕ), EM4 (mode = 1.4 ϕ) and EM5 (mode = 0.65 ϕ) are in the range of fine, medium and coarse sand, respectively. Unit LU-1 is marked by the increased relative abundance of EM1 from 216 to 209 cm and 269–265 cm and a higher abundance of EM2 between 278–276 cm and 305–296 cm (Figure 6). Unit LU-2 represents higher contribution from EM3, EM4 and EM5 for
intervals ~86–84 cm, 175–167 cm, 180–178 cm, 189–186 cm, and significant contribution from EM2 for 109–95 cm, ~118–115 cm, ~129–126 cm, and 161–158 cm (Figure 6). Unit LU-3 has pronounced contribution from EM1 from 29 to 1 cm and EM2 from 57 to 50 cm. For EM3, EM4, and EM5, representing coarser particle size fractions are higher for 41–35 cm in the unit (Figure 6).

Chronology
The age model for GBW is based on five accelerator mass spectrometry (AMS) radiocarbon dates on terrestrial fragments (wood, twig, and plant remain) picked from intervals 62, 112, 157, 242, and 325 cm depth of the GBW composite core. The radiocarbon dates can also be affected by the reservoir effect, which can skew results such that older radiocarbon ages can appear than the equivalent age of the sample (Philippson, 2013). However, in the GBW composite core, radiocarbon ages are based on the most reliable material, including terrestrial macrofossils (short-lived twigs remains) for younger sediments in the lake (Marshall et al., 2007). Calibration of obtained ¹⁴C dates was done with the IntCal20 calibration curve (Table 1; Reimer et al., 2020), and the age-depth model was carried out using a Poisson process model deposition (P_Sequence; Ramsey, 2008) (Figure 7).

DISCUSSION

Variability of Allochthonous vs Autochthonous Depositional Patterns in GBW
The elemental analysis documents a series of processes occurring in the lake environment, including changes in the origin and
in most geochemical environments, and thus reflect detrital input into the lake (Boës et al., 2011). Changes in the concentration of Ti and K can be related to either stronger catchment runoff, which reflects wetter conditions, or enhanced aeolian deposition, hence a low precipitation regime (Hou et al., 2017). In the studied core, we observe a direct association of Ti and K with the clayey silt or finer fraction (EM1) of the sediment (r = \sim 0.78, Figure 8) and hence these elements probably represent detrital origin. Many studies done in lakes dominated by the siliciclastic type of sedimentation have shown that Fe and Mn can originate from detrital input and catchment runoff, though they can often be related to redox conditions in the sediment/water interface (Davison, 1993). Therefore, interpretation of their temporal behavior in the depositional system should carefully be considered in light of variability occurring in the other measured elements. In GBW, PC1 data reveals that Fe is aligned with detrital elements (Ti, K); hence we estimate that it also represents an allogenic provenance (Figures 5A,B). Although many studies use Si to estimate diatom blooms (Schettler et al., 2006), which may occur during episodes of increase in nutrient input from aeolian transport or volcanoclastic materials (Peinerud, 2000) however, our statistical analysis shows a close association of Si with Ti and K, which is carried by the silicate fraction and may indicate a terrigenous source for Si (Figures 5A,B).

Rb appears to be associated with fine-grained siliciclastic rocks (Kylander et al., 2011). In our core, this element shows a positive correlation with Al and K (Figures 5A,B); hence can be used to measure the amount of siliciclastic material depositing in the basin. The Rb/Sr ratio is often associated with the chemical weathering of catchment rock and can be interpreted as the changes in fluxes of dissolved materials within from catchment (Miriyala et al., 2017). This behavior suggests positive loading on PC1 indicates detrital influx into the lake system. Ca is on the negative axis of PC1, and hence we estimate that it shows a non-detrital origin; therefore, it indicates authigenic processes occurring in the lake (Figures 5A,B) (Zhao et al., 2010). We, accordingly, suggest that the elemental ratios of Ti/Al, K/Al, and Rb/Sr (or PC1 score) are well suited for estimating changes in the terrestrial sediment supply through time and can hence be used to reconstruct past fluvial discharge (Neugebauer et al., 2016).

PC2 is defined by positive loading of Sr and S and negative loading of Cl (Figure 5C); hence this principal component appears to indicate in-situ precipitation of carbonates. Moreover, Ca indicates authigenic origin due to its negative loading with PC1 (Figure 5B) and has no major correlation with S and Sr (Figure 5C). However, there is a possibility of allogenic sources of Ca to the lake basin cannot be omitted, and could consist of both fluvial and aeolian origins. Detailed XRD

provenance of particles (e.g., allochthonous vs autochthonous), oxidation/reduction conditions in the lake bottom, water velocities and depth variabilities through time (Engstrom and Wright, 1984; Zolitschka et al., 2002; Boyle, 2005; Weltje and Tjallingii, 2008; Löwemark et al., 2011). These can in turn, reflect changes in climatic and limnological conditions. We interpret that the inorganic geochemical compositions of the GBW core are primarily controlled by both alloogenic processes (fluvial (wadi) discharge and aeolian input) coupled with authigenic processes (i.e. precipitation of evaporite minerals).

The statistical analyses of the elemental record (PC1) carried out on the XRF data show that Ti, K, Si, Rb, and Zr follow the same behavior, with elements like Mn and Fe partially following the same positive axis (Figures 5A,B). Previous studies carried out on similar settings points that Ti and K are geochemically stable lithogenic elements, which are hosted by resistant minerals and are conservative

*FIGURE 7 | Age-depth model for the GBW core with grey lines indicating confidence limits and blue curve showing age-depth interpolation.*
measurements reveal that the GBW core contains calcite and gypsum, with the occasional appearance of quartz. The studies also show that calcite might constitute a major percentage of dust particles in the Arabian desert (Al-Dousari and Al-Awadhi, 2012; Al-Dousari et al., 2013). In general, Ca represents an arid environment; hence, to estimate the authigenic deposition of Ca, the ratio between Ca/(Al + Fe + Ti) might represent a reliable proxy of precipitation changes in the region (Mueller et al., 2009). Higher values of this ratio can imply an increase in lake water salinity coupled with lower runoff from the catchment, which might point to dry conditions. S counts show a good correlation with gypsum abundance (r = 0.73, Figure 8), and their down-core shifts in the sediment can be associated with lower lake levels or shallow water depths, indicating dry climatic conditions in the region.

**Correlation of Magnetic Susceptibility, Total Inorganic Carbon/Total Organic Carbon With Elemental Proxies**

The magnetic susceptibility (MS) properties of sediments are influenced by the presence of Fe-bearing ferromagnetic minerals and serve as a proxy to disentangle the abundance of paramagnetic and diamagnetic minerals, such as carbonates, quartz, and clays (Bareille et al., 1994; Schnurrenberger et al., 2003). Previous studies have shown that MS can be a reliable indicator of both external processes (e.g., weathering magnitude and volcanism) and internal chemical cycling in the lacustrine environment, particularly the oxidation state in the sediment-water interface that can influence magnetite dissolution or formation (Rawat et al., 2021). In GBW, MS values are relatively low (averaging ∼5.6 × 10⁻⁷ SI) compared to carbonate rich lakes (Wünnemann et al., 2010; Pleskot et al., 2018), which can be associated to an increase in the presence of diamagnetic minerals or due to presence of negative magnetic susceptibility values of rocks in the catchment area (e.g. sandstone, greywacke, conglomerate, quartzite and carbonates). The MS values in the GBW sediments are mainly controlled by the minerals of Ca in the sediment as a high correlation is observed between Ca counts and MS values (r = 0.82, Figure 3 and Figure 8). Our GBW core is highly enriched in calcite (a typical diamagnetic mineral) with frequent intercalations of gypsum (least diamagnetic mineral), and we find that the layers enriched by gypsum have relatively higher values of MS compared with those enriched by calcite (Ivakhnenko et al., 2015). Furthermore, studies have shown that sediment consisting of higher carbonate or organic matter can dilute the concentration of magnetic minerals, also leading to low MS values.
(Hounslow and Maher, 1999). In several previous studies, MS values have been shown to increase with decreasing grain-size fraction (Thompson and Morton, 1979; Dessai et al., 2009). However, in GBW high values of MS are not necessarily associated with changes in the grain size distribution. The MS values are also lower for higher detrital influx events where quartz is found due to its diamagnetic properties, however it doesn’t show any significant variation throughout the GBW core.

The Total Carbon (TC) budget of a lake is primarily controlled by chemical and biochemical processes associated with the balance between the water input and the evaporation of lake water (Håkanson and Jansson, 1983). TIC is primarily controlled clastic sediment input or precipitation/evaporation processes, depending on whether carbonate minerals are allogenic or autogenic. In turn, TIC can serve as a proxy for temperature and precipitation changes (Yanhong et al., 2007). We estimate that TIC values increases during drier conditions due to the increased carbonateous dust influx as it correlates quite well with calcite mineral abundance (r = 0.7). Hence for those intervals, lower values of TOC/TIC reflect intervals with sandy silt units. TOC indicates the productivity of the lake,oxic state of the bottom waters and can also be used to track changes in the organic deposition conditions through the sedimentary sequence (Chen et al., 2001; Xu et al., 2007). The organic matter in the lake can be derived from the allochthonous input through catchment runoff or wadi influx and from authochthonous sources. However, in general, low productive lakes get the significant contribution of organic matter from the allochthonous terrestrial sources (Dean and Gorham, 1998). Hence, the primary source of TOC for the paleo-lake Gayal el Bazal is the terrigenous sediment supply during the relatively wetter condition in the region. The TIC and TOC data thus are complex to interpret due to uncertainty in the sources of these materials to the sediment through time. Nevertheless, the TOC/TIC data used in conjunction with other proxies (e.g., Ti/Al, K/Al, and Rb/Sr or PC1 score) provide information about different sedimentary processes, such as fluvial vs. aeolian input to the lake, and thus reflect rainfall changes. We further suggest that the high preservation conditions of the organic matter result from relatively fast burial processes, which in turn might indicate deposition during intense floods.

Deposition and Transport Mechanism of Sediments

The depositional patterns of lake sediment are controlled by sediment transport mechanisms such as fluvial inflows, aeolian transport, and turbid inflows (Solohub and Klovan, 1970; Sly, 1994; Lou et al., 2000; Stuut et al., 2002). These different transport mechanisms and depositional conditions can yield high variability in grain size distribution and grain morphology (e.g., sphericity and roundness; Håkanson and Jansson, 1983; McLaren and Bowles, 1985; Sun et al., 2002; Last, 2005; Vandenberghhe, 2013). Processes like these can create complex distributions in the particle size variation; thus, disentangling the sources is a must. To un-mix the modes of deposition into the lake system, end-member mixing analysis (EMMA) is applied to provide meaningful end members associated with various depositional processes. This approach, applied on the GBW core, resulted in five particle populations of modes attributed to different transport mechanisms. EM1 is the finest grain size fraction (7.1 ϕ), which a large majority falls under the clayey silt class and reflects the fluvial or wadi influx into the lake. Previous studies have shown that during pluvial events in arid environments, clayey silt is deposited in the basin, mostly due to surface runoff (Lézine et al., 1998, 2007). Furthermore, heavy elements (e.g., Ti, K, and Rb) and PC1 score are closely associated with EM1 variation, which are introduced to the basin also through surface runoff (r = ~0.8, Figure 8). Hence, finer fraction EM1 along with other proxies (detrital elements and PC1) are interpreted as increased precipitation in the region. EM2 consists of medium to coarse silt (4.8 ϕ) and reveals the aeolian mode of transport of sediments into the basin. It is consistent with available records showing that the southern Arabian Peninsula is highly influenced by aeolian processes (Khalaf and Al-Hashash, 1983; Al-Dousari et al., 2013). The greater abundance of EM2 reflects coarser aeolian dust advected from proximal sources, as it is larger in size than the dust particles from distal source (Crouvi et al., 2008). EM3 is situated around a fine sand fraction (3.1 ϕ) which would have formed due to the lowering of lake level or shallow near the shore. Hence, this end member, along with increased authigenic Ca precipitation (Ca/(Al + Fe + Ti)) in the lake, represents dry episodes with shallow water conditions, characterized by higher hydraulic energy conditions and deposition of coarser sediments in the lake. The greater abundance of EM3 is attributed to lower lake stands that probably resulted from periods of increased aridity and decreased water supply from the wadi catchment. EM4 (mode = 1.4 ϕ) and EM5 (mode = 0.65 ϕ) represent the coarsest sediment fraction and indicate extreme erosional events. Those intervals with a high abundance of EM4 and EM5 are followed by a higher abundance of EM1 (clayey silt). Hence we suggest that these two end members are indicative of coarser erosional material from the catchment.

Unraveling the Medieval Climate Anomaly and Little Ice Age in Yemen

The sedimentary record from the GBW core reveals the past 1,200 years’ climatic changes in the southern Arabian Peninsula and is divided into three stages based on the down-core variation (Figure 9).

Unit LU-1 (~920–1400 CE)

Unit LU-1 is dominated by detrital influx to the lake, as is marked by a higher PC1 score and an increase in TOC/TIC interpreted as resulting from augmentation in catchment runoff during pluvial episodes (Figure 9). The intervals from 930–1000 CE, 1,060–1110 CE, 1,140–1200 CE, 1,220–1280 CE, and ~1,330–1400 CE are sustained periods of wetness as represented by increased catchment erosion and augmentation of the clayey silt fraction (EM1 score) (Figure 9). These periods coincide with the Medieval Climate Anomaly (MCA; ~900–1350 CE; Gayo et al., 2012), which is an interval characterized by a shift in atmospheric circulation in the northern hemisphere that has left signals in sedimentary archives around the globe (Graham et al., 2011;
The synchronicity and extent of the climate pattern during this period are debated (Mann et al., 2009), yet it is widely recognized as a relatively warming interval in the northern hemisphere. However, it appears that the MCA interval in our record does not uniformly represent wet conditions but shows the inception of a major wet interval probably associated with increase warmth and humid conditions. Enhanced precipitation in the region during the MCA is consistent with regional records (Gupta et al., 2003; Fleitmann et al., 2004). The possible causes of the MCA are debatable as different forcing mechanisms, such as solar, volcanic, greenhouse gases, and land cover/use changes, occurred individually, and their combination all likely influenced this climatic shift. The simulation provided by Community Earth System Model-Last Millennium Ensemble (CESM-LME) captures globally warmer conditions during the MCA due to weaker volcanic forcing relative to radiative forcing that characterized the Little Ice Age (LIA; ∼1,500–1800 CE, Otto-Bliesner et al., 2016). Fluctuations in the regional climate during the MCA can also be attributed to changes in the intensity of solar irradiance and thus inducing enhanced wet conditions in the region, which led to an increase in the input of allogetic materials into the lake (Figure 9). We estimate that this anomaly could have been triggered by the northward migration of the ITCZ linked to increased solar forcing (Broccoli et al., 2006; Kuhner and Mulitza, 2011), which led to an increase in humidity in the southern margins of the Arabian Peninsula during the MCA.

Unit LU-2 (∼1,400–1720 CE)
The LU-2 unit is defined by increased Ca/(Al + Fe + Ti), gypsum abundance, and higher EM2 abundance, which we believe represent an increase in the evaporite formation and aeolian influx to the lake basin. During 1,410–1450 CE, 1,500–1580 CE, and 1,640–1690 CE, higher values of Ca/(Al + Fe + Ti) and increased abundance of gypsum indicate periods of decline in lake level, which exemplify for dry climatic conditions in the region (Figure 9). In fact, the EM2 abundance from 1,430 to 1670 CE significantly increases due to drier conditions. These dry episodes appear to prevail during the LIA when coarser silt sediments were brought into the lake and were consequently winnowed under lower lake levels. Aridity during the LIA is consistent with regional evidence (Felis et al., 2018) and follows proposed theories for weakened boreal summer monsoons during an interval of northern hemisphere cooling (Feng and Hu, 2008; Figure 9).

Conversely to the MCA interval, with a southward migration of the ITCZ during the inception of the LIA, an increase in the interhemispheric temperature contrast and enhanced high-latitude ice cover resulted in arid climatic conditions on the southern margins of the Arabian Peninsula (Schneider et al., 2014). Hence precipitation changes in Yemen during both the MCA and LIA anomalies were possibly driven by changes in the mean position of ITCZ. However, we infer that the LIA was not extremely dry, as we do not see evidence for compete desiccation of the lake and formation of soils.

Unit LU-3 (∼1720–2000 CE)
This unit consists of post-LIA sediments and is defined by higher detrital input to the lake post-1900 CE. These intervals are defined by higher values of PC1 score and finer sediment (EM1 score) fraction but lower values of TOC/TIC (Figure 9). The unit is also marked by a higher aeolian influx due to an increase in the abundance of EM2 (Figure 9). However, uncertainty in our age-depth model is high for this section, as it is difficult to accurately constrain the timing of initial influx of detrital material to the lake. However, it occurred after the LIA and is marked by the inception of wetter conditions. Several
studies have reported warm and wet conditions following the LIA (Kotlia et al., 2012; Lüning et al., 2019), and our GBW record follows a similar trend. We suggest that this pattern is promoted by an active Red Sea Trough system that enhances precipitation over the southern Arabian Peninsula (Almazroui, 2012; Baseer et al., 2019).

Climate Variability in the Region

Based on the multiproxy approach of this study, high rainfall intervals were identified during ∼930–1400 CE, with lower magnitudes occurring during ∼1,410–1700 CE (Figure 9). A similar precipitation trend is witnessed in other well-dated sites from NW Arabia and eastern Africa, suggesting warm and humid conditions during the MCA followed by a cold and dry condition during the LIA (Lüning et al., 2017). A late Holocene study from Shuaiba Lagoon, Saudi Arabia, reveals high paleo-tidal elevation as shown by enrichment in δ¹³C and δD of Sorites orbiculus indicating wet climatic condition during 1,000–1550 CE followed by aridity from 1,550 to 1850 CE due to MCA and LIA influence in the region (Figure 10A; Abu-Zied and Bantan, 2015). Furthermore, marine records retrieved on the Arabian Sea also report increased monsoonal activity 750–1150 CE and a weaker monsoon during 1,350–1550 CE (Figures 10D,E), which correlate well with two large temperature excursions during the late Holocene (Anderson et al., 2010). Additional records from Mount Kenya (Figure 10C) and Lake Turkana (Figure 10F) report cooler on average temperatures during the LIA but no indication of the MCA (Fastook et al., 1999; Berke et al., 2012). In contrast, a study based on sea surface temperature (SST) reconstruction from the Gulf of Aden using GDGTs shows no major indication for substantial temperature change during the MCA and LIA (Figure 10G; Tierney et al., 2015). This pattern can potentially be argueable due to major cold upwelling in the Arabian Sea that results from stronger Indian Summer Monsoons (SW winds) that brings colder, nutrient-rich waters from the Indian Ocean. The relationship between cold upwelling conditions during higher solar irradiance was already established by a previous study from the Oman margin (Figure 10E; Gupta et al., 2005), showing strong SW monsoons during the MCA (equivalent to a solar maxima interval) and weaker strengths during the LIA (solar minima). Hence, both climatic anomalies are well documented in many segments of East Africa, Saudi Arabia, and the Arabian Sea which most likely are triggered by changes in solar and volcanic forcing and ocean cycles.

CONCLUSION

This study integrated magnetic susceptibility, geochemical, and TOC/TIC analyses, coupled with end-member mixing analysis derived from particle size measurements carried out on a ∼3.3 m long core retrieved from Gayal el Bazal (southern Yemen) utilized to understand the late Holocene climatic fluctuations in the region. The current study shows that sediment accumulating in the lake comprises of allochthonous material (derived during pluvial events through surface runoff), precipitation of authigenic evaporite minerals (formed following changes in water composition and inflow strength during dry intervals), and aeolian activity (indicated by an increase in EM2 and calcite minerals). The multiproxy investigation displays enhanced precipitation during the MCA, marked by an increase in

detrital elements, higher TOC/TIC content, and dominance of EM1 (clayey silt fraction), which represent higher surface runoff in the lake watershed. Additionally, the higher contribution of EM2 (coarser silt fraction) appears to indicate aeolian input, coupled with increased gypsum production during the LIA, which indicate drier conditions. Our results show that the evolution of the Gayal el Bazal Lake has been mainly controlled by climatic factors (Solar and volcanic forcing), as the MCA and LIA are well imprinted in the sedimentary record. We further suggest that the Gayal el Bazal sedimentary archive has reliably responded to centennial-scale latitudinal variability of the ITCZ and associated with ISM. Comparison with other marine and terrestrial records from the Arabian Peninsula and Eastern Africa shows a similar variability of the ITCZ and associated with ISM.

We conclude that this work documents, for the climate pattern during the LIA and MCA intervals. We directed to the corresponding author. The original contributions presented in the study are included in the article/Subplementary Material, further inquiries can be directed to the corresponding author.

The original contributions presented in the study are included in the article/Subplementary Material, further inquiries can be directed to the corresponding author.

**AUTHOR CONTRIBUTIONS**

SP, JR, and NW designed the study. JR collected the samples, SP performed the measurements and carried out analysis on the samples, drafted the manuscript, and designed figures. NW and JR supervised the project made a substantial contribution to the concept or design of the article. All authors provided critical feedback and helped shape the research, analysis, and manuscript.

**FUNDING**

This research was supported by grants from PBC Fellowship program for International PhD students offered by the Council for Higher Education of Israel to SP.

**ACKNOWLEDGMENTS**

We are thankful to LacCore (National Lacustrine Core Facility), Department of Earth Sciences, University of Minnesota, for providing the sediments for the project. The authors acknowledge assistance with fieldwork from Douglas Schnurrenberger, who led fieldwork, and Prof. Juris Zarins. The American Institute for Yemeni Studies is thanked for their assistance with field logistics and project permitting. The authors warmly thanks Nimer Taha for assistance with grain size, XRD, and TOC/TIC measurements. This project was partially funded by Israel Science Foundation grant number 3413/21.
