Single superconducting energy scale in electron-doped cuprate superconductor

Pr$_{2-x}$Ce$_x$CuO$_{4-\delta}$

(Dated: May 26, 2009)

The tunneling spectra of the electron-doped cuprate Pr$_{2-x}$Ce$_x$CuO$_{4-\delta}$ as a function of doping and temperature is reported. We find that the superconducting gap, $\Delta$, shows a BCS-like temperature dependence even for extremely low carrier concentrations (studied here for the first time). Moreover, $\Delta$ follows the doping dependence of $T_c$, in strong contrast with tunneling studies of hole-doped cuprates. From our results we conclude that there is a single superconducting energy scale in the electron-doped cuprates.

PACS numbers: 74.50.+r, 74.62.Dh, 74.72.-h

In his pioneering experiment Giaever showed that when a simple metal and a classical superconductor are connected through an insulating barrier the tunneling conductance is proportional to the density of states in the superconducting electrode. He used this method to directly measure the energy gap, $\Delta$, in various superconductors.$^1$ Giaever found that $\Delta$ drops to zero at the critical temperature $T_c$. In addition, for various materials $\Delta/kT_c$ is approximately constant as earlier predicted by Bardeen, Cooper, and Schrieffer (BCS).

Their theory predicts a single energy scale that is both related to the onset of single particle excitations ($\Delta$) and the temperature, $T_c$, at which coherence is destroyed.$^2$

In the hole-doped high $T_c$ cuprates Renner et al.$^3$ showed that the spectra obtained by scanning tunneling spectroscopy exhibit no special temperature dependence at the temperature where macroscopic superconductivity, i.e. vanishing resistance and Meissner effect, ceases to exist. This behavior was interpreted as a signature of the pseudogap state, which can be detected in a variety of experiments.$^4$ The nature of this pseudogap and its relation to superconductivity are still a puzzle. It has been suggested that the pseudogap is precursor superconductivity,$^5$ a competing order parameter$^6$ or a phenomenon related to the range of the antiferromagnetic interactions.$^7$

Deutscher$^8$ has pointed out that for the hole-doped cuprates there are two energy scales that merge together at high doping levels: the lower one, which follows $T_c$, is the phase coherent energy scale, probed by Andreev-Saint-James reflections. The higher energy scale is related to single particle excitations. It increases monotonically with decreasing doping. More recent contributions have confirmed Deutscher’s observation of two energy scales for the hole-doped cuprates.$^9,10,11$

The electron-doped and the hole-doped cuprates share many structural and electronic properties,$^{12}$ they both comprise of copper oxygen planes, were $d$-wave superconductivity takes place.$^{13}$ The parent compounds are antiferromagnetic insulators, which become superconducting upon adding charge carriers (doping) in a dome shaped region in the temperature-doping phase diagram. For electron-doped cuprates the Fermi surface evolves from small electron pockets in the underdoped regime into a large hole-like Fermi surface on the overdoped side.$^{14,15}$ For hole doped cuprates possible evidence for electron pockets were found in underdoped YBa$_2$Cu$_3$O$_{6.5}$ in quantum oscillations measurements.$^{16}$ Similar measurements on the overdoped side were interpreted in terms of large hole-like fermi surface.$^{17}$

On the other hand, there are several differences between the two types of cuprates: while for hole-doped the antiferromagnetic phase dissapears rapidly with doping it is relatively extended on the electron doped side, possibly persisting into the superconducting dome.$^{18,19}$ The temperature dependence of the resistivity well above $T_c$ is very different for hole and electron-doped cuprates.$^{12}$

Finally, possible existence of higher harmonics in the order parameter for electron-doped superconductors has been reported by several groups.$^{20,21,22}$

For hole-doped cuprates the pseudogap and the superconducting gap coexist both in doping and momentum space, they intermix for many spectroscopic probes (an exception is Andreev-Saint-James reflections that are sensitive only to the superconducting state). The superconducting state may possibly be obscured by the pseudogap for underdoped samples for most momentum directions. By contrast, the superconducting gap is not obscured by the pseudogap for electron-doped cuprates. Therefore, the superconducting gap in electron-doped cuprates can be measured directly by tunneling spectroscopy.

We make use of the absence of a pseudogap phase in the electron-doped cuprates to directly measure the full doping and temperature dependence of the superconducting gap. We show that for these compounds there is a single superconducting energy scale, $\Delta$, which follows the same doping dependence as $T_c$ for the entire phase diagram,
even for the heavily underdoped region (samples with \( T_c \) as low as 6K). Assuming that the two types of cuprates share the same mechanism responsible for superconductivity, our results may imply that the pseudogap state in the hole-doped cuprates is a competing order to the superconducting one.

We fabricated superconductor/insulator/superconductor (SIS) junctions using \( \text{Pr}_2-x\text{Ce}_x\text{CuO}_4 \) (PCCO) and lead as described elsewhere.\[22, 23\] The advantage of planar tunnel junctions is the ability to measure the SIS tunneling conductance at various temperatures and magnetic fields without changing the properties of the junction. This is in strong contrast with scanning tunneling microscopy measurements where a change in temperature or magnetic field may result in junction resistance variation due to its exponential dependence on tip-sample distance. At high magnetic fields, \( \mu_0H=14\text{T} \), superconductivity in the PCCO is muted and the normal state is revealed. This enables us to normalize the data as was done by Giaever.\[1\] This eliminates spurious barrier and normal state effects. This procedure is impossible for hole-doped cuprates due to its inaccessible upper critical field.

The conductance versus voltage for a typical very underdoped \( x=0.125 \) junction is shown in figure 1. The strong phonon structure of the lead (at \( \pm5\text{meV} \) and at \( \pm10\text{meV} \)), and the relatively low conductance at zero bias are indicative of the high quality of the junctions. The insert of figure 1 presents the differential conductance as a function of voltage at zero field and at an applied field of 14 Tesla. At high magnetic fields a small reduction in the zero bias conductance is revealed. This behavior has been reported in other tunneling measurements on electron-doped cuprates.\[23, 24, 25, 26\]

We fit the data using a Blonder-Tinkham-Klapwijk\[27\] model extended for anisotropic order parameters.\[28\] We used a modified \( d \)-wave gap, which was suggested for electron-doped cuprates.\[21, 29\] This modified \( d \)-wave gap better fits the Raman,\[21\] ARPES,\[20\] and tunneling\[22\] spectra. In this model the gap has a maximum away from the \((\pi, 0)\), at an angle \( \theta_{(\text{max})} \). We used \( Z, \Delta, \theta_{(\text{max})} \) and \( \Gamma \) as free parameters, with \( Z \) being the barrier strength and \( \Gamma \) a lifetime broadening.\[30\] More details on the fitting procedure are described elsewhere.\[22\]

We emphasize that the gap amplitude, which is the main focus of this contribution, is independent of the details of the order parameter chosen for the fit. The gap amplitude is determined predominantly by the energy at which the coherence peaks appear at low temperatures.

In figure 2 we show the temperature dependence of the gap maximum as found from fitting the tunneling spectra at various temperatures for the PCCO \( x=0.125 \) sample. We point out that all fitting parameters are determined at the lowest temperature, leaving the gap amplitude as the only temperature dependent fitting parameter. For comparison the BCS prediction is shown. This result is similar to the temperature dependence reported for higher dopings.\[22, 31\]

In figure 3 we present the obtained gap amplitude at low temperatures as a function of doping. This is the main result of this paper. We note that the gap decreases when decreasing the doping towards the underdoped regime.

Our result is in strong contrast with scanning tunneling spectroscopy data on hole-doped cuprates.\[32\] To better
understand the similarities and differences between the two types of cuprates we shall now discuss the various gap spectroscopies on hole-doped cuprates, and compare their findings to our results on the electron-doped PCCO. Following Deutscher and the recent ARPES measurements, the various results fall into two classes: The first class of experiments includes probes that are mostly sensitive to the (0, π) or anti-nodal direction. The second class includes experiments that are sensitive to the nodal direction (π, π). Experiments that belong to the first class such as: Raman scattering in the B_{1g} channel, most scanning tunneling spectroscopies and most angle resolved photoemission spectroscopy experiments report a gap that increases with decreasing doping on the underdoped side. This is the k direction at which the pseudogap is maximal. Scanning tunneling spectroscopy experiments in their common configuration, i.e. the tip perpendicular to the CuO$_2$ plane, are mostly sensitive to the antinodal momentum direction. In this configuration, at zero bias one can tunnel only into the nodal direction in which the gap (and the pseudogap) is zero. As the energy is increased the momentum cone opens up and the measurement is dominated by momenta away from the nodal direction. For this reason the gap features in scanning tunneling spectroscopy arise mainly from the anti-nodal direction in momentum space. It is therefore not surprising that for the hole-doped cuprates the gap amplitude measured by scanning tunneling spectroscopy increases with decreasing doping on the underdoped side, as observed for all measurements that probe momenta along the antinodal direction. One should therefore bear in mind that for the hole-doped cuprates a measurement of the gap by tunneling or ARPES is not necessarily a measurement of the superconducting order parameter.

On the other hand Raman B_{2g} channel and the slope of the penetration depth as a function of temperature are both mostly sensitive to the nodal direction. Such nodal sensitive measurements show a gap that follows the doping dependence of T_c on the hole-doped side of the phase diagram.

We can therefore conclude that for hole-doped cuprates probes exciting single particles such as Raman scattering, Angle resolved photoemission spectroscopy or tunneling can probe the superconducting gap depending on their momentum selectivity, i.e. the superconducting gap is observed for the nodal direction, while the pseudogap dominates for the anti-nodal one. This picture is consistent with recent ARPES measurements focusing on the nodal region of Bi$_2$Sr$_2$CaCu$_2$O$_{8+δ}$. Andreev-Saint-James reflections exhibit similar doping dependence as the nodal sensitive probes, and can therefore be associated with the second class.

Indeed, a tunneling study into the nodal direction of the hole-doped cuprate YBa$_2$Cu$_3$O$_{6−δ}$ showed a gap that decreases with doping on the underdoped side. This is consistent with the idea that when probing the nodal direction, one is sensitive solely to the superconducting energy gap. Such measurements that are sensitive to nodal momenta give similar doping dependence for the gap as Andreev-Saint James reflections that are only sensitive to the coherent state.

Our results in electron-doped cuprates of an order parameter that follows a BCS temperature and doping dependence are therefore in line with nodal gap measurements in hole doped cuprates. This suggests that the energy scale relevant for superconductivity measured in our experiment by simple tunneling experiment is related to the nodal energy scale found in hole doped cuprates.

In Summary, we present tunneling spectra measurements on Lead/Insulator/Pr$_{2−x}$Ce$_x$CuO$_{4−δ}$ over the entire doping range where superconductivity is observed. From these spectra we extracted the gap amplitude for each doping and at various temperatures. Our results show a BCS like temperature dependence for the superconducting gap even in the very underdoped regime. We show that the gap amplitude follows the doping dependence of the critical temperature T_c. This is in strong contrast with the celebrated doping dependence of the pseudogap for the hole-doped cuprates. Our results are therefore consistent with a single superconducting energy scale.

We can further assume that the hole and electron doped cuprates share the same mechanism for superconductivity. In addition, one can note that for hole-doped cuprates the gap probed by Andreev-Saint-James reflections or by spectroscopy sensitive to the nodal direction follows the same doping dependence as our tunneling gap. We therefore conclude that for hole-doped cuprates the nodal gap is related to superconductivity, while the pseudogap may be a competing order.
We are indebted to Guy Deutscher, Shay Hacohen-Gourgy for fruitful discussions, to M. Karpovski for evaporating Lead electrodes.
