Redshift space correlations and scale-dependent stochastic biasing of density peaks

Desjacques, V; Sheth, R K

Abstract: We calculate the redshift space correlation function and the power spectrum of density peaks of a Gaussian random field. Our derivation, which is valid on linear scales $k \lesssim 0.1 h \text{Mpc}^{-1}$, is based on the peak biasing relation given by Desjacques [Phys. Rev. D81(6), 103503 (2010)]. In linear theory, the redshift space power spectrum is $P_{\text{pk}}(k, \theta) = \exp(-f^2 \sigma_{\text{vel}}^2 k^2)[b_{\text{pk}}(k) + b_{\text{vel}}(k) f^2] P(k)$, where $\theta$ is the angle with respect to the line of sight, $\sigma_{\text{vel}}$ is the one-dimensional velocity dispersion, $f$ is the growth rate, and $b_{\text{pk}}(k)$ and $b_{\text{vel}}(k)$ are $k$-dependent linear spatial and velocity bias factors. For peaks, the value of $\sigma_{\text{vel}}$ depends upon the functional form of $b_{\text{vel}}$. When the $k$ dependence is absent from the square brackets and $b_{\text{vel}}$ is set to unity, the resulting expression is assumed to describe models where the bias is linear and deterministic, but the velocities are unbiased. The peak model is remarkable because it has unbiased velocities in this same sense—peak motions are driven by dark matter flows—but, in order to achieve this, $b_{\text{vel}}$ must be $k$ dependent. We speculate that this is true in general: $k$ dependence of the spatial bias will lead to $k$ dependence of $b_{\text{vel}}$ even if the biased tracers flow with the dark matter. Because of the $k$ dependence of the linear bias parameters, standard manipulations applied to the peak model will lead to $k$-dependent estimates of the growth factor that could erroneously be interpreted as a signature of modified dark energy or gravity. We use the Fisher formalism to show that the constraint on the growth rate $f$ is degraded by a factor of 2 if one allows for a $k$-dependent velocity bias of the peak type. Our analysis also demonstrates that the Gaussian smoothing term is part and parcel of linear theory. We discuss a simple estimate of nonlinear evolution and illustrate the effect of the peak bias on the redshift space multipoles. For $k \lesssim 0.1 h \text{Mpc}^{-1}$, the peak bias is deterministic but $k$ dependent, so the configuration-space bias is stochastic and scale dependent, both in real and redshift space. We provide expressions for this stochasticity and its evolution.

We calculate the redshift space correlation function and the power spectrum of density peaks of a Gaussian random field. Our derivation, which is valid on linear scales $k \lesssim 0.1$ hMpc$^{-1}$, is based on the peak biasing relation given in Desjacques [Phys. Rev. D., 78, 3503 (2008)]. In linear theory, the redshift space power spectrum is

$$P_{pk}(k, \mu) = \exp(-f^2 \sigma_{vel}^2 k^2 \mu^2) \left[ b_{pk}(k) + b_{vel}(k) f \mu^2 \right]^2 P_\delta(k),$$

where $\mu$ is the angle with respect to the line of sight, $\sigma_{vel}$ is the one-dimensional velocity dispersion, $f$ is the growth rate, and $b_{pk}(k)$ and $b_{vel}(k)$ are $k$-dependent linear spatial and velocity bias factors. For peaks, the value of $\sigma_{vel}$ depends upon the functional form of $b_{vel}$. When the $k$-dependence is absent from the square brackets and $b_{vel}$ is set to unity, the resulting expression is assumed to describe models where the bias is linear and deterministic, but the velocities are unbiased. The peaks model is remarkable because it has unbiased velocities in this same sense – peak motions are driven by dark matter flows – but, in order to achieve this, $b_{vel}$ is $k$-dependent. We speculate that this is true in general: $k$-dependence of the spatial bias will lead to $k$-dependence of $b_{vel}$ even if the biased tracers flow with the dark matter. Because of the $k$-dependence of the linear bias parameters, standard manipulations applied to the peak model will lead to $k$-dependent estimates of the growth factor that could erroneously be interpreted as a signature of modified dark energy or gravity. We use the Fisher formalism to show that the constraint on the growth rate $f$ is degraded by a factor of two if one allows for a $k$-dependent velocity bias of the peak type. Our analysis also demonstrates that the Gaussian smoothing term is part and parcel of linear theory. We discuss a simple estimate of nonlinear evolution and illustrate the effect of the peak bias on the redshift space multipoles. For $k \lesssim 0.1$ hMpc$^{-1}$, the peak bias is deterministic but $k$-dependent, so the configuration space bias is stochastic and scale dependent, both in real and redshift space. We provide expressions for this stochasticity and its evolution.

I. INTRODUCTION

While velocities are directly measured through their Doppler (red)shifts, accurate measurement of cosmological distances are only available for nearby cosmic objects, and even at these small scales they are plagued with observational biases. Therefore, most observational data is described in terms of redshifts, e.g. three-dimensional (3D) galaxy surveys provide the angular positions and redshifts of galaxies. Redshifts differ from distances by the peculiar velocities (deviations from pure Hubble flow) along the line of sight. These generate systematic differences between the spatial distribution of data in redshift and distance (or real) space which are commonly referred to as redshift distortions [1]. Kaiser [2] first derived an expression which describes the effect of linear peculiar motions on 3D power spectra. References [3] and [4] provide two very different derivations of this same expression. Whereas the original derivation made no assumption about the form of the density and velocity fields, the other two assume they are Gaussian distributed.

The Kaiser formula has been used to interpret observations of the redshift space clustering of galaxies. The angular dependence of the redshift distortions can be used to measure the logarithmic derivative $f = d\ln D/d\ln a$, or growth rate, at multiple redshifts and thus potentially constrain many of the dark energy or modified gravity models (For a review of these scenarios, see [5]). Essentially all analyses to date assume that i) galaxies are biased tracers of the underlying matter field, ii) the bias is linear, local and deterministic [2, 3, 4, 7, 9] and iii) the velocities of the tracers are unbiased. In fact, except on the largest scales, the relation between the dark matter and galaxy fields is almost certainly nonlinear, nonlocal, and scale dependent [10]. Our main goal in the present study is to explore what complexities one might expect on smaller scales where the bias relation is more complicated, and where the velocities may also be biased. We do so by investigating the impact of redshift distortions on the correlation function of density maxima in a Gaussian density field.

We have chosen to study density peaks because the statistics of Gaussian random density [11] and velocity fields [12] in a cosmological context, and of the peak distribution in particular, has already received considerable attention [13, 14, 15, 16, 17, 18, 19]. Some of these results
have been used in studies of the nonspherical formation of large-scale structures [20, 21, 22, 23]. Others, especially from peaks theory, have been used to interpret the abundance and clustering of rich clusters [24, 25, 26, 27]. Density peaks define a well-behaved point-process which can account for the discrete nature of dark matter halos and galaxies. On asymptotically large scales, peaks are linearly biased tracers of the dark matter field, and this bias is scale independent [13, 14, 25]. However, these conclusions are based on a configuration-space argument known as the peak background split. Extending the description of peak bias to smaller scales is more easily accomplished by working in Fourier space. It has been shown that peaks are linearly biased with respect to the mass, but this bias is k-dependent [10, 28].

The first part of this paper demonstrates that, in the large-scale limit, the configuration and Fourier-based approaches yield consistent results. This is important, because the first (and only other) study of the redshift space clustering of peaks, reference [19], reported that in redshift space peaks behave very differently from the deterministic, linear and scale independent biased tracers investigated in [2, 23, 5, 6]. Since the linear bias assumption that is extensively advocated to convert large scale redshift space measurements into information about the background cosmology [7, 30], the fact that peaks might behave very differently is potentially very worrying. In addition, peak velocities exhibit a k-dependent bias even though peaks locally flow with the dark matter [28]. This is remarkable given that one commonly refers to such flows as having unbiased velocities. We explain the origin of this effect and argue that it should be a generic feature of any k-dependent spatial bias model.

Again, however, peaks are remarkable because, in the high peak limit where their spatial bias is expected to be linear and scale independent, their velocity bias remains k-dependent.

The second part shows that, at the linear order, redshift space distortions for peaks can be recast in a way that retains the simplicity of the original Kaiser formulae [2] while generalizing them to tracers whose linear bias is k-dependent. Because the present derivation is based on a model which is supposed to be accurate at smaller scales, we can identify an important term which does not appear in [2]. Furthermore, our analysis reaches very different conclusions from that of [19]. Our peaks-based formula for redshift space distortions, which includes k-dependent linear bias factors for both the density and the velocity fields, has a rich structure. We hope it will serve as a guide for what one might expect in the case of more realistic (nonlinear, nonlocal, scale dependent) bias prescriptions.

In the last part of this study, we use the Fisher formalism to quantify the extent to which any k-dependent velocity bias of the peak type would degrade the uncertainties on the growth rate f. We also demonstrate the stochastic nature of the peak bias and discuss its evolution with redshift. The peak biasing is interesting because, although it is deterministic in Fourier space, it is stochastic in real space. A final section summarizes our findings and speculate on some implications of the peak model.

Throughout the paper we work in the "distant observer" limit, where the line of sight is oriented along the z direction. In all illustrative examples, we assume a flat ΛCDM cosmology with Ω_m = 0.279, Ω_b = 0.0462, h = 0.7, n_s = 0.96 and a present-day normalisation σ_8 = 0.81 [33]. It will also be convenient to work with scaled velocities v_i ≡ v_i/(aH f), where v_i is the (proper) peculiar velocity, H ≡ dh/a/dt, and f ≡ dlnD/dlna with D(z) the linear theory growth factor. At z = 0.5 this is aH f ≈ 61 km s^{-1} hMpc^{-1}. As a result, v_i has dimensions of length.

## II. PROPERTIES OF DENSITY PEAKS

We begin by reviewing some general properties of peaks in Gaussian random fields. We then discuss the biasing relation which is used in the calculation of the redshift space correlation of density maxima.

### A. Spectral moments

The statistical properties of density peaks depend not only on the underlying density field, but also on its first and second derivatives. We are, therefore, interested in the linear (Gaussian) density field δ(x) and its first and second derivatives, ∂δ/∂x and ∂²δ/∂x². In this regard, it is convenient to introduce the normalised variables ν = δ(x)/σ_0 and u = −∇²δ(x)/σ_2, where the σ_n are the spectral moments of the matter power spectrum,

$$\sigma_n^2 \equiv \frac{1}{2\pi^2} \int_0^\infty dk k^{2(n+1)\nu} P(k, R_S)^2. \tag{1}$$

Here, P(k, R_S) denotes the dimensionless power spectrum of the linear density field at redshift z, and W is a spherically symmetric smoothing kernel of length R_S (a Gaussian filter will be adopted throughout this paper) introduced to ensure convergence of all spectral moments. We will use the notation P(k, z) to denote P(k, R_S)^2. The ratio σ_0/σ_1 is proportional to the typical separation between zero-crossings of the density field [16]. For subsequent use, we also define the spectral parameters

$$\gamma_n = \frac{\sigma_n^2}{\sigma_{n-1}\sigma_{n+1}} \tag{2}$$

which reflect the range over which k^{2n+1}P(k, z) is large.

We will also need the analogous quantities to σ_n^2 but for non-zero lag:

$$\xi_{f}^{(n)}(r) = \frac{1}{2\pi^2} \int_0^\infty dk k^{2(n+1)} P(k, z) j_n(kr), \tag{3}$$
where \( j_l(x) \) are spherical Bessel functions. As \( \ell \) gets larger, these harmonic transforms become increasingly sensitive to small-scale power.

Finally, we note that the auto- and cross-correlations of the fields \( v_i, \delta, \partial_\delta \) and \( \partial_i \partial_\delta \) can generally be decomposed into components with definite transformation properties under rotations. Reference [28] gives explicit expressions for the isotropic and homogeneous linear density field.

**B. Smoothing scale and peak height**

The peak height \( \nu \) and the filtering radius \( R_S \) could in principle be treated as two independent variables. However, in order to make as much connection with dark matter halos (and, to a lesser extent, galaxies) as possible, we assume that density maxima with height \( \nu = \delta_{sc}(z)/\sigma_0(R_S) \) identified in the primeval density field smoothed at scale \( R_S \) are related to dark matter halos of mass \( M_S \) collapsing at redshift \( z \), where \( \delta_{sc}(z) \) is the critical density for collapse at \( z \) in the spherical model [31, 52]. In the background cosmology we assume, the linear critical density for (spherical) collapse at \( z = 0.5 \) is \( \delta_{sc} \approx 1.681 \). The Gaussian smoothing scale at which \( \nu = 1 \) is \( R_\nu \approx 1.3 \, h^{-1} \text{Mpc} \), so the characteristic mass scale is \( M_\nu \approx 6.5 \times 10^{11} \, M_\odot/h \).

While there is a direct correspondence between massive halos in the evolved density field and the largest maxima of the initial density field, the extent to which galaxy-sized halos trace the initial density maxima is unclear. Therefore, we will only consider mass scales \( M_S \) significantly larger than the characteristic mass for clustering, \( M_\nu \), for which the peak model is expected to work best. We will present results at redshift \( z = 0 \), for which the peak model is expected to be very good. For a more comprehensive discussion, see reference [31].

The peak height \( \nu \) and the filtering radius \( R_S \) could be defined as the convolution

\[
(b_{pk} \ast \delta) (x) \equiv \left( b_\nu - b_\zeta \nabla^2 \right) \delta_S (x),
\]

so it has the same functional form as Eq. (57) in reference [10] who approximated density peaks by density extrema (our coefficients agree with those of [10] only in the limit \( \nu \gg 1 \)).

This bias relation is distinct from either linear [13] or nonlinear [37, 38, 39] biasing transformations of the density field for which \( b_\zeta = 0 \). Note in particular that Eq. 4 shows that local bias schemes can generate \( k \)-dependent bias factors if the bias relation involves differential operators. Furthermore, when \( \nu \gg 1 \), then \( \bar{u} - \gamma_1 \nu \), so that \( \sigma_0 b_\nu \rightarrow \nu \) and \( \sigma_0 b_\zeta \rightarrow 0 \) [29]. This is clearly seen in Fig. 1 where the biasing factors are plotted as a function of the peak height. Thus, the spatial bias of the highest peaks is expected to become scale independent, approaching the local deterministic relation of linearly biased tracers for which there is no \( k \)-dependent bias. However, notice that the \( k \)-dependence in the velocity bias remains. We will return to this point shortly.

**C. Biasing**

The large-scale asymptotics of the two-point correlation \( \xi_{pk}(r) \) and line of sight mean streaming \( \bar{v}_{12}(r) \) for peaks of height \( \nu \) can be thought of as arising from the nonlinear bias relation [28]

\[
\delta n_{pk} (x) = b_\nu \delta_S (x) - b_\zeta \nabla^2 \delta_S (x),
\]

\[
\bar{v}_{pk} (x) = \bar{v}_S (x) - \frac{\sigma_0^2}{\sigma_1^2} \nabla \delta_S (x),
\]

where \( \bar{v}_S \) is the dark matter velocity smoothed at scale \( R_S \) (so as to retain only the large-scale, coherent motion of the peak), and the bias parameters \( b_\nu \) and \( b_\zeta \) are

\[
b_\nu = \frac{1}{\sigma_0} \left( \frac{\nu - \gamma_1 \bar{u}}{1 - \gamma_1^2} \right),
\]

\[
b_\zeta = \frac{1}{\sigma_2} \left( \frac{\bar{u} - \gamma_1 \nu}{1 - \gamma_1^2} \right) = \frac{\sigma_0^2 (\nu - \sigma_0 b_\nu)}{\sigma_1^2 - \sigma_0}. \tag{5}
\]

Here, \( \bar{u} \) denotes the mean curvature of the peaks. Furthermore, \( b_\nu \) is dimensionless, whereas \( b_\zeta \) has units of (length)$^2$. Note that \( b_\nu \) is precisely the amplification factor found by [16] who neglected derivatives of the density correlation function (i.e. their analysis assumes \( b_\zeta \equiv 0 \)).

Strictly speaking, the bias relation [4] is nonlocal because of the smoothing. In configuration space, the peak bias \( b_{pk} \) could thus be defined as the convolution

\[
(b_{pk} \ast \delta) (x) \equiv (b_\nu - b_\zeta \nabla^2) \delta_S (x),
\]

so it has the same functional form as Eq. (57) in reference [10] who approximated density peaks by density extrema (our coefficients agree with those of [10] only in the limit \( \nu \gg 1 \)).

There is another route for estimating large scale bias of peaks [25] which utilizes the peak background split argument [16, 41, 42, 43]. This approach which is very different from ours, because it is based on configuration space counts-in-cells statistics. In particular, it makes no mention of the bias in Fourier space.
The large scale bias predicted by this approach is

\[ b_{\text{pkbs}} \equiv -\frac{1}{\sigma_0 \nu} \frac{\partial \ln [\bar{n}_{\text{pk}}(\nu)]}{\partial \ln \nu} \]  

(8)

where

\[ \bar{n}_{\text{pk}}(\nu) = \frac{1}{(2\pi)^2 R_1^2} e^{-\nu^2/2} G_0(\gamma_1, \gamma_1 \nu) \]  

(9)

is the differential averaged number density of peaks in the range \( \nu \) to \( \nu + d\nu \). Here \( R_1 = \sqrt{3} \sigma_1 / \sigma_2 \propto R_S \) characterizes the typical radius of density maxima, and \( G_0 \) is given by setting \( n = 0 \) in our equation \( A10 \). Therefore,

\[ b_{\text{pkbs}} = \frac{\nu^2 + \gamma_1}{\sigma_0 \nu}, \]  

(10)

where

\[ g_1 \equiv \frac{\partial \ln G_0(\gamma_1, y)}{\partial \ln y} \bigg|_{y=\gamma_1 \nu}. \]  

(11)

Performing the derivative yields

\[ g_1 = -\gamma_1 \nu \frac{G_1(\gamma_1, \gamma_1 \nu) G_0(\gamma_1, \gamma_1 \nu) - \gamma_1 \nu}{1 - \gamma_1^2}. \]  

(12)

where \( G_1 \) is given by equation \( A10 \) with \( n = 1 \). However, \( G_1/G_0 \equiv \bar{u} \) (see the discussion immediately following equation \( A10 \)), so

\[ g_1 = -\gamma_1 \nu \left( \frac{\bar{u} - \gamma_1 \nu \gamma_1}{1 - \gamma_1^2} \right) = -\gamma_1 \nu \sigma_2 \bar{b}_\zeta. \]  

(13)

The last equality follows from the definition of \( \bar{b}_\zeta \) (Eq. 3). Equations \( \Box \) and \( \Box \) eventually imply that

\[ -\gamma_1 \nu \sigma_2 \bar{b}_\zeta = -\nu (\nu - b_\nu \sigma_0), \]  

(14)

so

\[ b_{\text{pkbs}} = \frac{\nu^2 - \nu(\nu - b_\nu \sigma_0)}{\sigma_0 \nu} = b_\nu. \]  

(15)

This demonstrates that the large-scale, constant, deterministic bias factor returned by the peak background split approach is exactly the same as in our approach, when one considers scales large enough such that the \( k \)-dependence associated with the \( \bar{b}_\zeta \) term can be ignored.

This is very reassuring for two reasons. First, recall that our expressions for \( b_\nu \) and \( \bar{b}_\zeta \) only agree with those given in \( \Box \) in the limit \( \nu \gg 1 \) (in which extrema are almost certainly peaks). The analysis above shows that our \( b_\nu \) is the appropriate generalization to lower \( \nu \). And second, the peak background split approximation has been shown to provide an excellent description of large scale peak bias in simulations \( \Box \). Since our expressions reproduce this limit, we have confidence that our approach will provide a good approximation on the smaller scales where the peak-background split fails (i.e., where the bias \( b_{\text{pk}} \) becomes scale dependent).

**E. Power spectra and correlation functions**

Using the bias relations \( \Box \), it is straightforward to show that the real space cross- and auto-power spectrum are

\[ P_{\text{pk}, \delta}(k) = (b_\nu + b_\nu k^2) P_{\delta}(k) W(k, R_S) \]  

(16)

\[ P_{\text{pk}}(k) = (b_\nu + b_\nu k^2)^2 P_{\delta}(k). \]  

(17)

We have omitted the explicit redshift and \( \nu \)-dependence for brevity. The corresponding relations for the correlation functions are

\[ \xi_{\text{pk}, \delta}(r) = b_\nu \xi_{0}^{(0)}(r) + b_\zeta \xi_{0}^{(1)}(r) \]  

(18)

\[ \xi_{\text{pk}}(r) = b_\nu^2 \xi_{0}^{(0)}(r) + 2 b_\nu b_\zeta \xi_{0}^{(1)}(r) + b_\zeta^2 \xi_{0}^{(2)}(r) \]  

\[ \equiv b_\nu^2 \xi_{0}^{(0)}(r) \]  

(19)

where the final expression defines the (scale dependent) peak bias factor in configuration space. As shown in \( \Box \) (for \( \xi_{\text{pk}}(r) \)) and in Appendix A (for \( \xi_{\text{pk}, \delta}(r) \)), these expressions agree with those obtained from a rather lengthy derivation based on the peak constraint, which involves joint probability distributions of the density field and its derivatives. It is worth noticing that, while expressions \( \Box \) and \( \Box \) are only valid at leading order, the cross-correlation functions \( \Box \) and \( \Box \) are exact to all orders.

**F. Velocities**

In what follows, we will be interested in redshift space quantities, for which the velocity field also matters. The bias of peak velocities is particularly simple in Fourier space. Taking the divergence of Eq. 4, we find

\[ \theta_{\text{pk}}(x) \equiv \nabla \cdot \mathbf{v}_{\text{pk}}(x) = \nabla \cdot \mathbf{v}_S(x) - \frac{\sigma_0^2}{\sigma_1^2} \nabla^2 \delta_S(x). \]  

(20)

The linear continuity equation stipulates that \( \theta_S(x) \equiv \nabla \cdot \mathbf{v}_S(x) = -\partial \Sigma(x) \), so the result of Fourier transforming the expression above implies that

\[ \theta_{\text{pk}}(k) = \left( 1 - \frac{\sigma_0^2}{\sigma_1^2} k^2 \right) \hat{W}(k, R_S) \theta(k) \equiv b_{\text{vel}}(k) \theta(k). \]  

(21)

This defines the peak velocity bias factor, \( b_{\text{vel}}(k) \), which depends on \( k \) but not on \( \nu \). As seen in Fig. 1, the ratio \( \sigma_0/\sigma_1 \) increases monotonically with the filtering scale such that, even in the limit \( R_S \rightarrow \infty (\nu \rightarrow \infty) \) where the spatial bias is linear (\( b_\zeta(r) \approx b_\nu \)), the peak velocities remain \( k \)-dependent. Therefore, the linear bias approximation \( \delta \theta_{\text{pk}} = b_\nu \delta_S \) with unbiased velocities \( \mathbf{v}_{\text{pk}} = \mathbf{v}_S \) never provides a good description of the large-scale properties of density peaks.

The three-dimensional velocity dispersion of peaks is known to be smaller than that of the dark matter \( \Box \): \( \Box \) and \( \Box \): \( \Box \)

\[ \sigma_{\text{vpk}}^2 = \sigma_{\text{vel}}^2 (1 - \gamma_0^2). \]  

(22)
spatial bias will lead to $k$-dependence of $b_{vel}$ even if the tracers flow with the dark matter. Note, however, that this is not a necessary condition since, for the highest peaks, the velocity bias remains scale dependent even though the spatial bias has no $k$-dependence.

The equality $\langle b_{vel} \rangle = \langle b_{vel}^2 \rangle$ does not uniquely constrain the velocity bias. For instance, the choice $b_{vel}(k) = 1 - (\sigma_{v,1/2}/\sigma_0^2) k$ also has $\langle b_{vel} \rangle = \langle b_{vel}^2 \rangle$. However, if we think of the velocity bias as a real space operator $b_{vel}(\mathbf{x})$ that maps a vector (velocity) field onto another vector field, then for homogeneous and isotropic random fields $b_{vel}(\mathbf{x})$ must transform as a scalar under rotations. Hence, it must be built from powers of the Laplacian $\nabla^2$, and this brings down a factor of $k^2$ upon a Fourier transformation. Therefore, we generically expect the lowest order $k$-dependence to scale as $b_{vel}(k) \equiv 1 - R_{vel}^2 k^2$ (for some constant $R_{vel}$), at least for tracers whose spatial bias relation can be expressed as a local mapping of the (smoothed) density and its derivatives.

FIG. 1: Bias parameters $\sigma_{0b}, \sigma_{2b}$ and ratio of spectral moments $\sigma_0/\sigma_1$ as a function of the filtering scale. Results are shown for density maxima of height $\nu = \delta_{vel}/\sigma_0$ at redshift $z = 0.5$. Dotted curves denote negative values. The linear spatial bias of peaks becomes scale independent in the limit $\nu \to \infty$. However, the $k$-dependence of the velocity bias, which is controlled by $\sigma_0/\sigma_1$, remains and even increases with the peak height.

Notice that Eq. (21) for the peak velocity bias yields the same number,

$$\sigma_{vel}^2 = \frac{1}{2\pi^2} \int_0^\infty dk P_{vel}(k) b_{vel}^2(k),$$

as it should, but that

$$\sigma_{vel}^2 = \frac{1}{2\pi^2} \int_0^\infty dk P_{vel}(k) b_{vel}(k)$$

also! If we regard the integral over one power of $b_{vel}$, say $\langle b_{vel} \rangle = \langle b_{vel}^2 \rangle$ indicates that, at the position of the peak, the velocities of the peak and the mass are the same. This can also be seen in the average bias relation, Eq. (1): at the position of the peak the gradient of the density vanishes (by definition), and so $\mathbf{v}(\mathbf{x}_{pk}) = \mathbf{v}(\mathbf{x}_{pk})$. The peak velocity dispersion is lower than that of the mass because large scale flows are more likely to be directed towards peaks than to be oriented randomly. This illustrates an important point that has not been appreciated before: peaks are biased tracers which move with the dark matter flows – so the conventional wisdom would say their velocities are unbiased – but their spatial bias (which follows from the discrete nature of maxima) implies that $b_{vel}$ is $k$-dependent. This is almost certainly true in general: $k$-dependence of the

III. REDSHIFT SPACE CLUSTERING OF DENSITY MAXIMA

We derive three estimates of the redshift space clustering of peaks. The first generalizes the formulation of [2] based on linear theory of gravitational instability; it furnishes a simple estimate of the power spectrum. The second extends the probabilistic interpretation of (3,44); it provides an expression for the correlation function. Reference (45) has emphasized that, within the context of linear theory, this description of the correlation function is exact whereas that of (2) is only approximate. Analytic approximations based on a probabilistic treatment lead to terms which, upon Fourier transforming to obtain the power spectrum, are lacking in the approach of (2). This has recently been emphasized by (46). Finally, our third estimate shows that if one Fourier transforms at an earlier stage in the analysis, one obtains a slightly more intuitive expression for the redshift space power. We examine in detail the implications of this approach for density peaks, despite the fact that much of this was already done by (19), for the reasons stated in the Introduction.

A. Simple estimate of redshift space clustering

The redshift space coordinate (also in $h^{-1}\text{Mpc}$ since velocities are in unit of length) is given by $s = (s_\parallel, s_\perp)$,

$$s = \mathbf{x} + f [\mathbf{v}(\mathbf{x}) \cdot \hat{z}] \hat{z},$$

where $\hat{z}$ is the unit vector along the line of sight. Therefore, at the lowest order, the redshift space density contrast is related to that in real space by

$$\delta^s(k, \mu) = \delta(k) + f \mu^2 \theta(k)$$
where $\mu$ is the cosine of the angle with the line of sight $\ell$. For peaks, this becomes

\[
\delta n_{pk}(k, \mu) = \delta n_{pk}(k) + f \mu^2 \theta_{pk}(k) = b_{vel}(k) \delta(k) + f \mu^2 b_{vel}(k) \delta(k) = \left[1 + \frac{b_{vel}(k)}{b_{pk}(k)} f \mu^2\right] \delta n_{pk}(k) \quad (27)
\]

upon insertion of the peak bias relation (4). Note that $f \mu^2$ is now multiplied by a $k$-dependent factor.

Using the former relation, the calculation of the redshift space power spectra at leading order is straightforward and yields

\[
P_{pk,0}(k, \mu) = (b_{pk}(k) + [b_{vel}(k) + b_{pk}(k)]) f \mu^2 + b_{vel}(k) f^2 \mu^4 P_b(k) \quad (28)
\]

\[
P_{pk}(k, \mu) = (b_{vel} + b_{\perp} k^2 + b_{vel} f \mu^2)^2 P_b(k) \quad (29)
\]

(30)

Parameter constraints are then derived from the angular dependence of $P_{pk}$, under the assumption of linear scale independent bias, for which $b_{\perp} = 0$ and $b_{vel} = 1$, so the term which multiplies $\mu^2$ is $f/b_{\nu}$, and $b_{\nu}$ is assumed to be a constant. Our analysis shows that, for peaks, this prefactor is $k$-dependent, and it depends on peak height. The window functions cancel out, leaving us with

\[
\frac{b_{vel}(k)}{b_{pk}(k)} \approx \frac{1}{b_{\nu}} \left[1 - k^2 \left(\frac{\nu}{\sigma_{0} b_{\nu}}\right) \frac{\sigma_0^2}{\sigma_1^2}\right] (k \ll 1)
\]

\[
\approx - \left(\frac{\nu}{\sigma_0} - b_{\nu}\right)^{-1} \left[1 - \frac{1}{k^2} \left(\frac{\nu}{\sigma_0 b_{\nu}} - 1\right) \frac{\sigma_0^2}{\sigma_1^2}\right] (k \gg 1).
\]

Hence, unless care is taken, this will lead to constraints which depend on $k$ even in the limit $\nu \gg 1$ where $b_{\nu} \to \nu/\sigma_0$.

\section{Probabilistic treatment}

In linear theory, the redshift space two-point correlation function $\xi^s$ is related to that in real space by a convolution of the two-point correlation function in real space, $\xi(r)$, with the probability distribution for velocities along the line of sight [3, 14]:

\[
1 + \xi^s(s_{||}, s_{\perp}) = \int \frac{dy}{\sqrt{2\pi} f \sigma_{12}} \exp \left[-\frac{(s_{||} - y)^2}{2 f^2 \sigma_{12}^2(r)}\right],
\]

where

\[
K(y) = 1 + \xi(r) + \left(\frac{y}{r}\right) \frac{\nu_{12}(r)}{\sigma_{12}(r)} \left(\frac{s_{||} - y}{f \sigma_{12}(r)}\right) - \frac{1}{4} \left(\frac{y}{r}\right)^2 \frac{\nu_{12}(r)}{\sigma_{12}(r)} \left[1 - \frac{(s_{||} - y)^2}{f^2 \sigma_{12}^2(r)}\right].
\]

Here, $\nu_{12}(r)$ and $\sigma_{12}(r)$ are the mean and dispersion of the pairwise velocity distribution of pairs separated by $r$ in real-space (note that $r^2 = y^2 + s_{\perp}^2$). As emphasized by 15, within the context of linear theory, this expression is exact. This formulation is usually referred to as the “streaming” model. It should be noted that random pairs in real space are mapped to real space differently at different separation $r$ because the pairwise velocity distribution depends on scale [4].

Equation (32) can be generalized to give $1 + \xi^s_{pk}$, the redshift space correlation function of peaks, simply by replacing $\nu_{12}$ and $\sigma_{12}$ with the expressions appropriate for peaks [19]. At first order, these are

\[
v_{12}(r, \mu) = [1 + \xi_{pk}]^{-1} \times \left[2 b_{\nu} \left(\frac{\sigma_0}{\sigma_1} \xi_{12}^{1/2} \xi_{12}^{(1/2)}\right) + 2 b_{\perp} \left(\frac{\sigma_0}{\sigma_1} \xi_{12}^{3/2} - \xi_{12}^{(1/2)}\right)\right] L_1(\mu),
\]

\[
\sigma_{12}^2(r, \mu) = \left[\frac{2}{3} \left(1 - \gamma_0^2\right) \sigma_{-1}^2 + \frac{2 \sigma_0^2}{3 \sigma_1^2} \left(2 \xi_0^{(0)} - \frac{\sigma_0^2}{\sigma_1^2} \xi_0^{(1)}\right) - \frac{2 \xi_0^{(-1)}}{3 \sigma_0^2}\right] - \frac{4}{3} \left[\frac{\sigma_0^2}{\sigma_1^2} \left(2 \xi_2^{(0)} - \frac{\sigma_0^2}{\sigma_1^2} \xi_2^{(1)}\right) - \xi_2^{(-1)}\right] L_2(\mu),
\]

where $\mu = \hat{r} \cdot \hat{z}$ is the cosine of the angle between the line of separation and the line of sight, and the $L_\ell(\mu)$ are Legendre Polynomials [40]. The first term on the right-hand side of Eq. (35) is twice the (one-dimensional)
velocity dispersion of peaks; recall that it is reduced by a factor of \(1 - \gamma_0^2\) relative to that of the dark matter (see Eq. 22). Appendix A demonstrates that Eq. (34) exactly reproduces the result of a lengthy derivation based on the peak constraint.

1. Approximating the integral

When \(\sigma_{12} \ll s_{\parallel}\), then the Gaussian term in the expression above will be sharply peaked around \(y = s_{\parallel}\). Expanding \(\xi, v_{12}\) and \(\sigma_{12}\) about their redshift space values yields

\[
\xi^s \approx \xi - f v'_{12} + \frac{1}{2} f^2 \sigma''_{12} + \frac{1}{2} f^2 \xi'' \sigma_{12}^2 |_{\infty},
\]

where all quantities in the right hand side are evaluated at \(s\) and primes denote derivatives with respect to \(s_{\parallel}\) (re-

\[
\frac{d^2}{ds_{\parallel}^2} \xi^{(n)} = \frac{2}{3} \xi^{(n+1)} L_2(\mu) - \frac{1}{3} \xi^{(n+1)} \drawfrac{d}{ds_{\parallel}} \left[ \xi^{(n)} L_1(\mu) \right] = -\frac{2}{3} \xi^{(n+1/2)} L_2(\mu) + \frac{1}{3} \xi^{(n+1/2)}
\]

As a rule, terms in \(\xi^{(n)}\) appear always multiplied by the Legendre polynomial of order \(\ell\). The calculation of

\[
\xi_{\parallel}(s, \mu) = \frac{8}{39} f^2 \left( \xi^{(0)} - 2 \frac{\sigma_2^2}{\sigma_1^4} \xi^{(1)} + \frac{\sigma_2^4}{\sigma_1^8} \xi^{(2)} \right) L_4(\mu)
\]

the redshift space correlation of peaks \(\xi_{\parallel}(s, \mu)\) is now straightforward. Adding all terms together, we find

\[
\xi_{\parallel}(s, \mu) = \frac{8}{39} f^2 \left( \xi^{(0)} - 2 \frac{\sigma_2^2}{\sigma_1^4} \xi^{(1)} + \frac{\sigma_2^4}{\sigma_1^8} \xi^{(2)} \right) L_4(\mu)
\]

As can be seen, there are harmonics up to \(\xi^{(3)}(s)\) which arise from the second derivative \(\xi''(s)\) in Eq. (35). These terms are significant only at distances less than a few smoothing radii and across the baryon acoustic feature where the density correlation \(\xi^{(0)}\) changes rapidly [28]. Furthermore, terms linear in \(f\) arise only from the derivative of the pairwise velocity, \(-f v'_{12}(s)\).

The redshift space power spectrum \(P_{\parallel}(k, \mu)\) in this approximation is obtained simply by Fourier transforming Eq. (35). For the sake of completeness,
the redshift space power spectrum to take the form
\[ k \times \exp\left[ k^2 r^2 (1 - \gamma_0^2) \sigma_{f,0}^2 \right] \]

where the linear redshift distortion parameter
\[ B(k) \equiv \int \frac{b_{\text{vel}}(k)}{b_{\text{pk}}(k)} \]

is scale dependent. Recall that \( b_{\text{pk}}(k) \) and \( b_{\text{vel}}(k) \) were defined in equations (27) and (21). Thus, except for the second term in the last equality, the above result exactly matches our simple estimate, Eq. (29).

Notice especially that, for linearly biased tracers, redshift space distortions are used to estimate \( \beta = f/b \). The analogous quantity for peaks, \( B(k) \), is \( k \)-dependent. We will consider the implications of this in the next section.

2. A different approximation

A more intuitive approximation to the exact result that is reached upon performing the integral in Eq. (32) can be obtained by Fourier transforming it in the first place. We write
\[ \exp(-i k \cdot s) = \exp(-i k_{\parallel} \cdot s_{\parallel}) \exp[-ik_{\perp}(s-y)] \times \exp[-i k_{\parallel}(s_{\parallel} - y)] \]

and then rearrange the order of the integrals so that the integration over \( s_{\parallel} - y \) is done first. Next, we use the fact that
\[
\begin{align*}
\int dt e^{-t^2/2} e^{-ikt} &= e^{-k^2/2} \\
\int dt t e^{-t^2/2} e^{-ikt} &= -i k e^{-k^2/2} \\
\int dt t^2 e^{-t^2/2} e^{-ikt} &= (1 - k^2) e^{-k^2/2},
\end{align*}
\]

to express the result of the integral over \( s_{\parallel} - y \) as \( \exp[-f^2 k_{\parallel}^2 \sigma_{f,0}^2(r)/2] \) times other factors. Finally, we recast this term as \( \exp[-f^2 k_{\parallel}^2 \sigma_{f,0}^2(\infty)/2] \) times \( \exp[-f^2 k_{\parallel}^2(\sigma_{f,0}^2(r) - \sigma_{f,0}^2(\infty))/2] \) which for small \( k_{\parallel} \) is approximately \( \exp[-f^2 k_{\parallel}^2 \sigma_{f,0}^2(\infty)/2] \times [1 - f^2 k_{\parallel}^2(\sigma_{f,0}^2(r) - \sigma_{f,0}^2(\infty))/2] \). Thus, we generically expect the redshift space power spectrum to take the form \( \exp[-f^2 k_{\parallel}^2 \sigma_{f,0}^2(\infty)/2] \) times other factors. A little algebra shows that, to leading order, these factors are precisely those given by equation (29), giving
\[ p_{\text{pk}}^s(k, \mu) = \exp[-f^2 k_{\parallel}^2 \sigma_{f,0}^2(\infty)] p_{\text{pk}}^s(k, \mu). \]

Here, \( p_{\text{pk}}^s \) is given by Eq. (43). We have also used the fact that, except in pathological cases, the pairwise dispersion at very large separation is simply twice the one-dimensional velocity dispersion of single particles, \( \sigma_{\text{vel}} = \sigma_{\text{pk}}/3 \) for peaks), in units of \( aH_f \). Our notation is purposely kept general to emphasize that these results apply to any tracers of the linear density field.

Our equation (43) corrects a number of important errors in previous analyses [13, 47]. In addition, expanding the Gaussian smoothing term shows the origin of the extra terms identified in the previous subsection (those highlighted by [9]). Finally, the form of our expression reflects the fact that the associated correlation function can be written as a convolution of the original expression \( \xi_{\text{pk}}^s \) (which is the Fourier transform of Eq. 29) with a Gaussian in the line of sight direction:
\[ \xi_{\text{pk}}^s(s_{\parallel}, s_{\perp}) = \int_{-\infty}^{+\infty} ds_{\perp} G(s_{\parallel}', \sigma_{12}(\infty)) \xi_{\text{pk}}^s(s_{\perp}, s_{\parallel} + s_{\perp}'). \]

Now the meaning of our notation should be clear: the superscript 0 refers to the limit in which the dispersion of the Gaussian smoothing term is vanishingly small. We note that this form for \( \xi^s \) was shown to be appropriate for the dark matter, without using any Fourier-space analysis [45]; our analysis demonstrates that it carries through for peaks as well. The interesting subtlety brought by density peaks is that the amplitude of the damping term \( \sigma_{\text{vel}} \) is related to the form of \( b_{\text{vel}} \) (Eq. 22).

The functional form of our equation (43) has been studied previously in the context of modelling nonlinear corrections to the redshift space power of linearly biased tracers [13], although there the assumption was that \( b_{\text{pk}} \) is constant and \( b_{\text{vel}} \) is unity. We will discuss the effects of nonlinearities shortly. For completeness here, we simply borrow all that previous analysis to show the effect that the Gaussian smoothing has on the Fourier space...
FIG. 2: A comparison between the redshift space multipoles of the correlation function of density maxima and linearly biased tracers. (Dotted lines denote negative values.) The peaks were identified in the density field when smoothed with a Gaussian filter of characteristic scale $R_s = 2.5$ (left panel) and $4 \, h^{-1}{\text{Mpc}}$ (right panel). This corresponds to a mass scale $M_S = 1.9 \times 10^{13}$ and $7.8 \times 10^{13} \, M_\odot/h$, respectively. The associated peak height and bias parameters quoted in each panel assume a redshift $z = 0.5$. The linear biased tracers are required to have the same value of $b_r^{\text{Edal}}$. The peak biasing relation enhances the monopole and the quadrupole around the BAO scale relative to that of linearly biased tracers, and induces significant scale dependence in the hexadecapole at $s \lesssim 100 \, h^{-1}\text{Mpc}$.

C. Nonlinear evolution

There are four reasons why nonlinear evolution will act to change the expressions above \([4, 59]\): one is related to the change in the bias parameters, and the three others have to do with the effect of peculiar velocities. Gravitational motions are expected to relate a scale independent, deterministic linear bias parameter in the initial (Lagrangian) field to the evolved (Eulerian) bias according to $b_r^{\text{Edal}} = 1 + b_r$. Ignoring the fact that $b_r$ might also evolve, the large-scale bias thus becomes $b_r^{\text{Edal}} \equiv 1 + b_r + b_r^2 k^2$. Note that we have omitted the smoothing window for brevity, but it effectively makes little difference at scales $k^{-1} \gg R_S$. Regarding the peak motions, we first assume that virial velocities within peaks or halos will increase $\sigma_{\text{vir}}(\infty)$; these are responsible for the fingers-of-god \([53, 54]\) seen in galaxy surveys. Secondly, halo/peak motions may not closely follow linear theory, but this effect is expected to be less dramatic \([57]\). Finally, the real space power spectrum will also be modified as a result of the linear theory motions \([60, 61, 62, 63]\).

For reasons we describe below, nonlinear effects may be approximated by setting

$$P_{pk}^n(k, \mu) = P_{pk}^0(k, \mu) V_{q1}(k, \mu^2) V_{\text{vir}}(k, \mu^2)$$

where $P_{pk}^0$ is given by Eq. 30 with $b_{pk}$ replaced by its nonlinear version. The filters $V_{q1}$ and $V_{\text{vir}}$ are supposed...
FIG. 3: Angular dependence of the redshift space correlation for the density maxima (solid curves) and linearly biased tracers (dashed curves) considered in Fig. 2. Results are shown for a separation vector oriented in the direction parallel ($\mu = 1$) and transverse ($\mu = 0$) to the line of sight. Perpendicular to the line of sight, the contrast of the acoustic peak is more pronounced in the correlation of density peak whereas, in the radial direction, it is comparable to that of linearly biased tracers.

to reflect the quasi-linear and virial corrections to the non-damped linear theory expression, respectively. The exact functional form of $V_{ql}(k, \mu^2)$ depends upon the distribution of pairwise velocities. However, motivated by results from perturbation theory [58, 62, 63], we set

$$V_{ql}(k, \mu^2) = \exp\left[-k^2 \sigma_{vel}^2 (1 - \mu^2) - k^2 \sigma_{vel}^2 (1 + f)^2 \mu^2\right].$$

(50)

This takes into account both the smearing of linear power caused by linear theory displacements and the damping due to the linear pairwise velocity dispersion. In principle, the reduction in linear power should be somewhat mitigated by the addition of nonlinear mode-coupling terms of the sort discussed by [61]. However, we will ignore these terms in what follows. The last multiplicative factor $V_{vir}$ accounts for the damping of redshift space power due to nonlinear virial motions within halos (assumed uncorrelated with the large-scale flows). If the mass range is small (i.e. if the peaks cover a small range in $\nu$), then $V_{vir} = \exp(-k^2 \mu^2 \sigma_{vir}^2)$, where $\sigma_{vir}$ depends on the halo or peak mass, should be a good approximation. If the mass range is broad, then an exponential distribution may be more appropriate [53], leading to $V_{nl} = [1 + k^2 \sigma_{vir}^2 \mu^2]^{-2}$. Removing fingers-of-god from a survey [e.g. 52] is equivalent to setting $\sigma_{vir} \rightarrow 0$ or $V_{vir} \rightarrow 1$.

Here and henceforth, we will assume that $V_{vir}$ is a Gaussian smoothing kernel. This implies that the Fourier space multipoles $P^s_\ell(k)$ are given by Eqs (45), (46) and (47) with

$$\kappa \equiv k \sqrt{\sigma_{vel}^2 f (2 + f) + \sigma_{vir}^2},$$

(51)

upon making the replacement

$$\frac{P^s_\ell(k)}{P_{pk}(k)} \rightarrow \frac{P^s_\ell(k)}{P_{pk}(k)} e^{-k^2 \sigma_{vel}^2}$$

(52)

on the left-hand side. We will now illustrate the effect of the biasing relation Eq. (4) on the 2-point correlation through a comparison between density peaks and linearly biased tracers.

D. Comparison between density peaks and linearly biased tracers

For linearly biased tracers, $b_\nu = 0$, $\gamma_0 = 0$ and all the terms involving $\sigma_0/\sigma_1$ vanish. The pairwise statistics simplify to

$$v_{12}(r, \mu) = \frac{-2b_\nu \xi_1(-1/2)(r)}{1 + \xi_{pk}(r)} L_1(\mu),$$

(53)

$$\sigma_{12}^2(r, \mu) = \frac{2}{3} \sigma_{-1}^2 \left[1 - \frac{\xi_1(-1)}{\sigma_{-1}^2} + 2 \frac{\xi_2(-1)}{\sigma_{-1}^2} L_2(\mu)\right].$$

(54)

Setting $\beta = f/b_\nu$, we recover the linear theory prediction of [2] plus a contribution from the large-scale limit of $\sigma_{12}^2$ (which underestimates the true effect since we neglect
nonlinear corrections to the velocity dispersion),

\[
\xi_L(s, \mu) = \frac{8}{35} r^2 \xi_4(1) L_4(\mu) - \left[ \left( \frac{4}{3} \beta + \frac{4}{7} \beta^2 \right) b_s^2 \xi_2(0) - \frac{2}{9} f^2 \sigma_{\chi}^2 b_s^2 \xi_2(1) \right] L_2(\mu) + \left( 1 + \frac{2}{3} \beta + \frac{4}{7} \beta^2 \right) b_s^2 \xi_0(0) - \frac{1}{9} f^2 \sigma_{\chi}^2 b_s^2 \xi_0(1).
\]

Note that Eq. (55) implicitly assumes that the peculiar velocities of linear tracers match locally that of the matter. To account for the nonlinear evolution, we will also adopt the prescription \( b_v \rightarrow b_v^{\text{Enl}} = 1 + b_v \).

The explicit Legendre decomposition \( \xi^s(s, \mu) = \sum \xi^s(\ell) L_\ell(\mu) \) of the redshift space correlation function can be read off from Eqs. (39) and (55). For illustration, the multipoles \( \xi^s(\mu) \) are plotted in the left and right panel of Fig. 2 for density maxima identified at the smoothing scale \( R_S = 2.5 \) and \( 4 \) h\(^{-1}\)Mpc, respectively. These functions are compared to those of linearly biased tracers with same value of \( b_v^{\text{Enl}} \), namely \( b_v^{\text{Enl}} = 2.0 \) and 3.8 respectively. It is important to note that, in the latter case, the density field is not smoothed (in practice we use \( R_S = 0.1 \) hMpc\(^{-1}\)). Furthermore, we have also neglected the contribution \( \sigma_{\text{vir}} \) from virialized motions to the velocity dispersion and assumed \( \sigma_{\text{vel}}^2 = \sigma_{\text{pk}}^2/3 \) for the peaks and \( \sigma_{\text{vel}}^2 = (8.11 \) h\(^{-1}\)Mpc\(^2\))^2, for the linearly biased tracers.

As recognized in [28], the nonlinear local biasing relation Eq. (4) amplifies the contrast of the (real space) baryon acoustic signature of density maxima relative to that of linearly biased tracers. A similar enhancement is also observed in the baryonic acoustic signature of dark matter halos in very large cosmological simulations [64, 65]. As can be seen in Fig. 2, this amplification is also present in redshift space. In this case however, both the monopole and the quadrupole of \( \xi^s_{\text{pk}} \) are affected by the nonlinear peak biasing across the BAO feature. At distances \( s \approx 100 - 110 \) h\(^{-1}\)Mpc, the quadrupole of the redshift space peak correlation \( \xi^s_{\text{pk}} \) is indeed more negative, damping thereby the correlation in the radial direction \( (\mu \approx 1) \) and increasing it in the perpendicular direction \( (\mu \approx 0) \).

This is more clearly seen in Fig. 3 which compares the redshift space correlation of density peaks and linear tracers in the direction parallel and transverse to the line of sight axis. Relative to the baryon acoustic peak of linearly biased tracers, the BAO of density maxima is enhanced in the direction perpendicular to the line of sight while somewhat distorted in the radial direction. The physical origin of this effect presumably is peak-peak exclusion. Namely, while as discussed in [28] the spatial bias of peaks enhances the contrast of the BAO in the real space correlation, peak-peak exclusion suppresses the infall of peak pairs onto the (slightly overdense) BAO shell at radius \( s \approx 105 \) h\(^{-1}\)Mpc. In redshift space, this amounts to a reduction of the BAO contrast along the line of sight. The dispersion term \( \sigma_{12}(\infty)^2 \) further smoothes the BAO and shifts the position of the local maximum in that direction, but leaves the baryon wiggle unchanged in the transverse direction. The amount of smoothing depends on the exact value of \( \sigma_{\text{vel}}^2 \). Another striking feature of Fig. 3 is the strong suppression of the redshift space correlation and the sharpening the acoustic peak along the line of sight due to linear coherent infall [2, 6].

On scales less than the BAO ring, the contribution of the pairwise velocity dispersion increases with decreasing separation until it reverses the sign of the quadrupole at separation \( \sim 10 - 20 \) h\(^{-1}\)Mpc and stretches structures along the line of sight [6]. Although the velocity dispersion of the density peaks is smaller than that of the linear biased tracers, peak-peak exclusion makes the effect stronger. On those scales, the contribution of the term \( 2b_v^{\text{Enl}} b_s^{\text{Enl}} \xi^s_{\text{pk}}(1) + b_s^2 \xi^s_{\text{pk}}(2) \) becomes comparable to \( (b_v^{\text{Enl}})^2 \xi^s_0(0) \) and steepens the profile of the angle-averaged correlation \( \xi^s_0 \). As a result, the monopole for the density peaks can be larger by a few tens of per cent at separation \( s \lesssim 10 \) h\(^{-1}\)Mpc relative to that of linearly biased tracers. Note that small-scale halo exclusion is not properly accounted for in our treatment since we consider \( \xi^s_{\text{pk}} \) at first order only. Nevertheless, we expect that, while in real space peak-peak exclusion leads to a deficit of pairs at distance \( s \lesssim R_S \), in redshift space the suppression may be weaker because peaks tend to move toward each other.

Fig. 4 displays the Fourier space multipoles \( P_\ell(k) \) in unit of \( P_{\text{pk}}(k) \) for the peaks and linear tracers considered above. To emphasize the importance of the exponential damping, results are shown with and without the smearing caused by quasi-linear and virialized motions. While for the linearly biased tracers the distortion parameter \( B(k) = f / b_v^{\text{Enl}} \) is a constant, for peaks \( B(k) \) is \( k \)-dependent and, therefore, induces a scale dependence in the multipoles even when the pairwise velocity dispersion is negligible. In this limit \( (\sigma_{\text{vel}} = 0) \), for the linearly biased tracers the ratios \( P_\ell(k)/P_{\text{pk}}(k) \) are constant (as in the original Kaiser formula), whereas for peaks they decay rapidly to reach \( 1 + 2B(\infty)/3 + B^2(\infty)/5, 4B(\infty)/3 + 4B^2(\infty)/7 \) and \( 8B^2(\infty)/35 \) when \( \ell = 2, 3 \) and 4, respectively. Here, \( B(\infty) = - (\nu / \sigma_0 - b_v^{\text{Enl}})^{-1} \) is the value of \( B(k) \) in the limit \( k \rightarrow \infty \) (see Eq. 11). The difference between peaks and linear tracers is largest in the hexadecapole and increases with mass scale. For instance, the fractional deviation is 5 per cent at wavenumber \( k \approx 0.037 \) hMpc\(^{-1}\) and \( 0.027 \) hMpc\(^{-1}\) for the peaks identified at filtering scale \( R_S = 2.5 \) and \( 4 \) h\(^{-1}\)Mpc, respectively.

When the Gaussian damping term, Eq. (50), is included, the behaviour of the Fourier space multipoles of density peaks (solid curves) and linear tracers (dashed curves) becomes similar at small-scale: they damp to zero like the coefficients \( A_\ell(k) \) defined in Eq. (40). Still, significant deviations persist on scale \( k \gtrsim 0.01 \) hMpc\(^{-1}\) due to the \( k \)-dependence of \( B(k) \) and unequal velocity dispersions.
IV. COSMOLOGICAL IMPLICATIONS

A. Estimating the growth rate \( f \)

Following [2, 9, 66], the redshift space power spectrum of density peaks can also be written as

\[
P_{pk}^s(k) = \left[ P_{pk}(k) + 2\mu^2 P_{pk,\theta_p}(k) + \mu^4 P_{\theta_p}(k) \right] F(k, \mu^2) \tag{56}
\]

where \( P_{pk,\theta_p}(k) \) and \( P_{\theta_p}(k) \) are the peak-velocity and velocity-velocity power spectra. Here, \( P_{pk} \), \( P_{pk,\theta_p} \) and \( P_{\theta_p} \) are linear spectra and \( F(k, \mu^2) = \delta(k) / (V_{\text{vir}}(k, \mu^2)) \) describes both the quasi-linear damping and the smearing from the small-scale velocity dispersion. As noted in [30, 53, 67], \( P_{\theta_p}(k) \) is independent of the spatial bias and directly measures the matter velocity power spectrum provided there is no velocity bias. Owing to the angular dependence, a measurement of the velocity power spectrum furnishes an estimate of the linear growth rate \( \sigma_8 \ln dD/d\text{ln}a \) that is not affected by the spatial bias.

Although the hexadecapole does not depend upon the spatial bias, it may be noisier than the monopole and dipole, so this has motivated the search for other combinations of \( P_0 \) and \( P_2 \) which may be more robust [3]. Reference [30] showed that \( P_0^s \) and \( P_2^s \) can be used to derive an estimate of the velocity power spectrum \( P_{\theta_p}(k) \) when the density and velocity fields are perfectly correlated, namely, when the cross-correlation coefficient

\[
r_{\theta_p}^2(k) = \frac{P_{pk,\theta_p}^2(k)}{P_{pk}^2(k) P_{\theta_p}(k)} \tag{57}
\]

is unity. For example, when smoothing is ignored, then

\[
\hat{P} = \frac{245}{48} P_0^s \left[ 1 + \frac{P_{20}^s}{7} - \sqrt{1 + 2P_{20}^s - (P_{20}^s)^2/5} \right] \tag{58}
\]

[30] is proportional to \( f^2 P_s(k) \) when velocities are unbiased. Here, \( P_{20}^s \equiv P_2^s / P_0^s \). For peaks \( r_{\theta_p}^2(k) \equiv 1 \) indeed holds at the lowest order, even though the linear spatial and velocity bias \( b_{\text{sp}}(k) \) and \( b_{\text{vel}}(k) \) are scale dependent. However, the velocity power spectrum now is \( P_{\theta_p}(k) = f^2 b_{\text{vel}}^2(k) P_s(k) \), so there is an extra \( k \)-dependence associated with the estimator \( \hat{P} \). Since this could be interpreted erroneously as a signature of modified dark energy or gravity, any scale dependent velocity bias (a scale independent bias may also be present if the tracers do not move with the matter) will limit the information that can be recovered about the growth factor [30, 53, 67]. For peaks, the velocity bias is \( b_{\text{vel}}(k) \leq 1 \), and it converges towards unity (i.e. unbiased velocities) in the limit \( k \to 0 \). At the first order, the deviation from unity is controlled by \( \sigma_0/\sigma_1 \) (Eq. 21) so that, at fixed wavenumber, \( b_{\text{vel}}(k) \) decreases with increasing mass scale (see Fig. 1). For \( M_S = 1.9 \) and \( 7.8 \times 10^{13} \text{ M}_\odot/\text{h} \) considered here, \( P_{\theta_p}(k) \) is suppressed by \( \approx 5 \) and 9 per cent at wavenumber \( k = 0.05 \text{ hMpc}^{-1} \), respectively. The predicted \( k \)-dependence is smaller than current constraints.
on the growth rate\textsuperscript{55} \textsuperscript{68}. Furthermore, numerical simulations to date show that the power spectrum of dark matter halo velocities is consistent with $f^2P_{\delta\delta}(k)$ within 10 per cent at wavenumber $k \lesssim 0.1\ h\text{Mpc}^{-1}$ \textsuperscript{68}. Nevertheless, since forthcoming large-scale galaxy surveys will dramatically improve constraints on the growth factor (down to the percent level), it is interesting to assess the extent to which a $k$-dependent bias would degrade the constraint on the growth rate.

**B. Error forecast with a $k$-dependent velocity bias**

To this purpose, we use the Fisher based formalism developed in \textsuperscript{67}. For Gaussian random fields, the Fisher matrix for a set of parameters $\{p_i\}$ is \textsuperscript{70} \textsuperscript{71}

$$F_{ij} = \frac{1}{2} \int \frac{d^3k}{(2\pi)^3} \left( \frac{\partial \ln P}{\partial p_i} \right) \left( \frac{\partial \ln P}{\partial p_j} \right) V_{\text{eff}}(k),$$  

(59)

where $P$ is the power spectrum and individual wave mode contributions are weighted by the effective volume \textsuperscript{69}

$$V_{\text{eff}}(k) = V \left( \frac{n_P}{1+n_P} \right)^2,$$

(60)

which depends upon the surveyed volume $V$ and the number density $n$ of the tracers (assumed homogeneously distributed). To illustrate, we assume the linear, plane-parallel approximation and consider the model

$$P^*(k, \mu) = [b_{pk}(k) + f b_{vel}(k) \mu^2]^2 P_b(k),$$

(61)

where $b_{pk}(k) \equiv b_v + b_\zeta k^2$ (we drop the superscript Eul for brevity), and $b_{vel}(k) \equiv 1 - R_{vel}^2 k^2$ (for some $R_{vel}$) are motivated by the functional form of the spatial and velocity bias of density peaks (c.f., Section \textsuperscript{11}C and \textsuperscript{11}F).

In what follows, we fix the shape and amplitude of the matter power spectrum (i.e. the fractional error on $f \sigma_8$ is equal to that on $f$) and consider the four-parameter set $\{b_v, b_\zeta, R_{vel}, f\}$. Our fiducial model has $(b_v, b_\zeta, R_{vel}, f) = (1, 16, 3, 0.46)$. The values of $b_\zeta$ and $R_{vel}$ closely correspond to those of density peaks identified at the mass scale $1.9 \times 10^{13} \ M_\odot/h$. Derivatives of the logarithm of the power with respect to the parameters are computed easily:

$$\frac{\partial \ln P}{\partial b_v} = \frac{2}{(b_{pk} + f b_{vel} \mu^2)^2}, \quad \frac{\partial \ln P}{\partial b_\zeta} = \frac{2k^2}{(b_{pk} + f b_{vel} \mu^2)^2},$$

$$\frac{\partial \ln P}{\partial R_{vel}} = -4f R_{vel}^2 k^2$$

and

$$\frac{\partial \ln P}{\partial f} = \frac{2b_{vel} \mu^2}{(b_{pk} + f b_{vel} \mu^2)^2}.$$  

(62)

We integrate over wavenumbers from $k_{\text{min}} \sim \pi/V^{1/3}$, where $V$ is the volume of the survey, up to a maximum wavenumber $k = 0.1\ h\text{Mpc}^{-1}$, above which nonlinear effects are expected to become important \textsuperscript{67}.

In order to illustrate the effect of including a $k$-dependent velocity bias into the analysis, we initially set $b_{vel} \equiv 1$ (i.e. ignore $R_{vel}$) and compute the Fisher matrix for $b_v, b_\zeta$ and $f$ solely. For a survey of volume $V = 10 \ h^{-3}\text{Gpc}^3$ at redshift $z = 0$, we find a fractional marginalized error of $\delta f/f = 1.6\%$ in the limit $n_P \gg 1$ of negligible shot noise (In practice, a suitable weighting of galaxies may help approaching this limit \textsuperscript{72}). For a number density $n = 5 \times 10^{-4}$ and $10^{-4} \ h^3\text{Mpc}^{-3}$, the constraint weakens to 1.9% and 2.9%, \textsuperscript{73} respectively. (These values are consistent with those of \textsuperscript{67}). Unsurprisingly, $b_v$ and $b_\zeta$ are strongly anti-correlated (the correlation coefficient is $r \approx -0.8$) because an increase in $b_v$ can be mostly compensated by a decrease in $b_\zeta$. However, while the correlation between $b_v$ and $f$ is moderate ($r \approx -0.5$), $b_\zeta$ and $f$ are weakly degenerate ($r \approx -0.05$). In other words, including a $k$-dependent bias component $b_{vel} k^2$ has little effect on the uncertainty on $f$. Extending $k_{\text{max}}$ beyond 0.1 $h\text{Mpc}^{-1}$ (where the shot noise becomes again important) can reduce the uncertainty on $f$ (because the fractional error scales as $k^{-3}$), but this is at the price of having to model the smearing due to quasi-linear motions and small-scale velocities.

Introducing the parameter $R_{vel}$ substantially increases the uncertainty on $f$. For the volume $V$ and the average number densities $n$ considered above, the fractional marginalized uncertainty on the growth rate becomes $\delta f/f = 4\%$, 4.4% and 6%, respectively. This can be traced to the strong correlation ($r \approx 0.9$) between $R_{vel}$ and $f$. The error degradation reflects the fact that we are adding more freedom to the model. It does not depend upon the exact value of $R_{vel}$.

Are the constraints on $f$ obtained using the multi-tracer method proposed in \textsuperscript{74} affected in a similar way? Reference \textsuperscript{72} pointed out that several populations of differently biased tracers can achieve a much better determination of the growth rate than a single sample of objects. When power spectra are measured, calculating the Fisher matrix for multiple tracers requires summing over the distinct components of the inverse covariance matrix $C^{-1}_{AB}$, where $A, B$ label a different pair of tracer populations,

$$F_{ij} = V \sum_{A,B} \int \frac{d^3k}{(2\pi)^3} \left( \frac{\partial P_A}{\partial p_i} \right) C^{-1}_{AB} \left( \frac{\partial P_B}{\partial p_j} \right).$$

(63)

The calculation of the covariance matrix is straightforward if one assumes that the noise term can be treated as an uncorrelated normal variate \textsuperscript{67} \textsuperscript{72}. For completeness, the diagonal and off-diagonal components of the covariance matrix are \textsuperscript{67}

$$\langle C_{aaaa} \rangle = 2P^2_{aa} N_a^2, \quad \langle C_{abab} \rangle = P^2_{ab} + P_{aa} P_{bb} N_a N_b$$

(64)

and

$$\langle C_{abcd} \rangle = 2P_{ab} P_{cd}, \quad \langle C_{aabc} \rangle = 2P_{ab} P_{ac}$$

$$\langle C_{abac} \rangle = P_{ab} P_{ac} + P_{aa} P_{bc} N_a$$

(65)

$$\langle C_{aaab} \rangle = P_{ab} P_{aa} N_a, \quad \langle C_{aabb} \rangle = 2P^2_{ab}.$$
where $P_{ij}$ is an auto- or cross-power spectrum and $N_a = [1 + 1/(nF_{ba})]$. We will consider the simplest case of two types of tracers, since the gains saturate rapidly as the number of samples increases [67]. In this case there are 3 distinct measured power spectra

$$P_{ab} = \left( b_{pk}^{(a)} + f b_{vel}^{(a)} \mu^2 \right) \left( b_{pk}^{(b)} + f b_{vel}^{(b)} \mu^2 \right) P_{\delta}(k)$$

where $a, b = 1, 2$ and the bias factors are $b_{pk}^{(a)} = b_{vel}^{(a)} + b_{vel}^{(a)} \kappa^2$, $b_{vel}^{(a)} = 1 - (R_{vel}^{(2)})^2 \kappa^2$. The power spectra are thus described by 7 parameters, and their derivatives are

$$\frac{\partial P_{ab}}{\partial b_{vel}^{(c)}} = \left[ \left( b_{pk}^{(b)} + f b_{vel}^{(b)} \mu^2 \right) \delta_{ac}^{(K)} + \left( b_{pk}^{(a)} + f b_{vel}^{(a)} \mu^2 \right) \delta_{bc}^{(K)} \right] P_{\delta}(k)$$

$$\frac{\partial P_{ab}}{\partial \kappa^{(c)}} = k^2 \left[ \left( b_{pk}^{(b)} + f b_{vel}^{(b)} \mu^2 \right) \delta_{ac}^{(K)} + \left( b_{pk}^{(a)} + f b_{vel}^{(a)} \mu^2 \right) \delta_{bc}^{(K)} \right] P_{\delta}(k)$$

$$\frac{\partial P_{ab}}{\partial R_{vel}^{(1)}} = -2f k^2 \mu^2 \left[ \left( b_{pk}^{(b)} + f b_{vel}^{(b)} \mu^2 \right) R_{vel}^{(a)} \delta_{ac}^{(K)} + \left( b_{pk}^{(a)} + f b_{vel}^{(a)} \mu^2 \right) R_{vel}^{(b)} \delta_{bc}^{(K)} \right] P_{\delta}(k)$$

$$\frac{\partial P_{ab}}{\partial f} = \mu^2 \left[ \left( b_{pk}^{(b)} + f b_{vel}^{(b)} \mu^2 \right) b_{vel}^{(a)} \right] P_{\delta}(k) + \left( b_{pk}^{(a)} + f b_{vel}^{(a)} \mu^2 \right) b_{vel}^{(b)} \right] P_{\delta}(k)$$

Here, $\delta_{ac}^{(K)}$ is the Kronecker delta.

Fig. 5 shows the fractional marginalized error $\delta f/f$ obtained by combining two different biased sample of the same survey volume. The constraints are shown as a function of the abundance of the second tracers with and without including a k-dependent velocity bias (solid and dotted curves, respectively). We set $b_{vel}^{(2)} = 1.4$, 2 and 4 to facilitate the comparison with Fig.3 of [67]. Although we have assumed the fiducial values $R_{vel}^{(1)} = R_{vel}^{(2)} = 3 h^{-1}$Mpc for simplicity, we may expect from the analysis done in the previous Section that $R_{vel}$ has some mass or bias dependence. E.g., $R_{vel}^{(2)} > R_{vel}^{(1)}$ when $b_{vel}^{(2)} > b_{vel}^{(1)}$. The marginalized error on $f$ is, however, weakly dependent on the fiducial value of $R_{vel}^{(a)}$. Note the considerable improvement in the constraint on $f$ in agreement with the findings of [67], [72]. The smallest error is achieved with a large number density $n_2$ and large relative bias $b_{vel}^{(2)} / b_{vel}^{(1)}$. (We have used values of $b_{vel}$ to simplify comparison with [67].) However, including a k-dependent velocity bias degrades the uncertainty on the growth rate roughly by a factor of two when $n_2 \geq 10^{-2} h^3$Mpc$^{-3}$, like in the single tracer case. The error degradation becomes increasingly severe as one goes to lower number densities.

Although these constraints are only indicative, our analysis demonstrates that allowing for a k-dependent velocity bias (with the specific functional form predicted by the peak model) has a large impact on the determination of the growth factor and, therefore, may possibly hamper our ability to distinguish between different dark energy or gravity scenarios [76, 77]. Therefore, despite the lack of current evidence for a k-dependent velocity bias [30], it seems prudent to study this possibility further with large cosmological simulations. We hope the peak model can serve as a useful baseline with which to compare the simulations.

**V. STOCHASTICITY**

**A. Cross-correlation coefficient**

The biasing eq. [4] derived from the large-scale properties of peak correlation functions is a mean bias relation that does not contain any information about stochasticity. Therefore, it is unsurprisingly deterministic like the local bias model considered by [38], the main difference residing in the fact that peak biasing involves derivatives of the density field. Still, because of the discrete nature of density peaks, one can expect that the peak overdensity $\delta_{pk}$ at location $x$ generally be a random function of the underlying matter density (and its derivatives) in some neighbourhood of that point. We note that stochastic
The cross-correlation coefficient $r_v(r)$ for density peaks identified at the smoothing scale $R_s = 2.5$ and $4\ h^{-1}\text{Mpc}$ (upper and lower panel, respectively). There is significant stochasticity only at the zero-crossings of the auto and cross-correlation functions and across the BAO, where the derivatives of the density correlation $\xi^{(1)}$ and $\xi^{(2)}$ are not negligible [28].

Models of the form $\delta n_{pk}(x) = X[\delta(x)]$ have been studied in [28, 78, 80] for instance.

Computing the probability of $X$ given $\delta$ etc. is beyond the scope of this paper (because it requires the full hierarchy of correlation functions). Still, it is instructive to compute the cross-correlation coefficient to gain further understanding of the peak biasing model. The cross-correlation coefficient is defined as

$$r_v^2(k) = \frac{P^2_{pk}(k)}{P_{pk}(k)P_{\delta}(k)}, \quad r_v^2(r) = \frac{\xi^{2}_{pk,\delta}(r)}{\xi_{pk}(r)\xi_{\delta}(r)}$$ (71)

in Fourier and configuration space, respectively. Ignoring the damping term, we find $r_v(k) = 1$ for peaks even though the ratio $P_{\delta}/P_{\delta}$ depends on $k$. Thus, a $k$-dependent bias at the linear order does not yield stochasticity in Fourier space. On the other hand,

$$r_v^2(r) = \frac{[b_v + b_s \xi^{(1)}_{\delta}/\xi^{(0)}_{\delta}]^2}{b_v^2 + 2b_v b_{\xi^{(1)}_\delta}/\xi^{(0)}_{\delta} + b_{\xi^{(2)}_\delta}/\xi^{(0)}_{\delta}}.$$ (72)

Therefore, although the bias is deterministic in Fourier space, it is generally stochastic and scale dependent in configuration space. However, when $\nu > 1$ then $b_v \to 0$, so $r_v \to 1$. Namely, in the high peak limit, the bias becomes linear and deterministic in both Fourier and configuration space.

The real space cross-correlation coefficient is shown in Fig. 6 as a function of comoving separation for the peaks identified at the smoothing radius $R_s = 2.5$ and $4\ h^{-1}\text{Mpc}$. $r_x$ is very close to unity at all separations larger than a few smoothing radii, except around the baryonic bump and the zero crossing of the correlation function. As a result, $r_x$ can be negative. Around the BAO scale $\approx 105\ h^{-1}\text{Mpc}$, $r_x$ is slightly less than unity, reflecting the fact that the BAO contrast is enhanced in the auto- and cross-correlation of peaks. Finally, the amount of stochasticity depends upon the shape of the matter power spectrum; it increases as the power on small scales increases.

**B. Evolution of stochastic bias**

As discussed in Sec III C, gravitational evolution maps a scale independent, deterministic linear bias factor in the initial conditions onto a similar quantity in the evolved distribution [41]. The scaling $b_{Eul}^\text{Eul} = 1 + b_v$ also works for a $k$-dependent deterministic bias. More precisely,

$$b_{Eul}^k(k, z) - 1 = b_{pk}(k, z) = \frac{b_{pk}(k, z_0) - 1}{D(z)/D(z_0)} = \frac{b_{pk}(k, z_0)}{D(z)/D(z_0)}$$ (73)

where $D(z)$ is the linear theory growth factor [81, 82]. This is easily understood if one recognizes that a peak of height $b_0 \delta_0$, where $\delta_0$ is the linearly evolved field at $z$, could also have been written as having height $b_0 \delta_0$ where $\delta_0$ is the field evolved to $z_0$. The relation $b_0 \delta_0 = b_0 \delta_0$ implies $b_0 = b_2 (\delta_0/\delta_0) = b_2 D(z)/D(z_0)$, from which the above expression is derived. Alternatively, notice that $b_0 \propto 1/\sigma_0(z_0) \propto D(z)/D(z_0)/D(z_0) \propto b_2 D(z)/D(z_0)$, so the factor $D(z)/D(z_0)$ is simply converting from one choice of fiducial time to another.

In configuration space, it has been argued that for linear stochastic bias,

$$b_{Eul}^\xi(z) r_\xi^2(z) - 1 = \frac{b_{Eul}^\xi(z_0) r_\xi^2(z_0) - 1}{D(z)/D(z_0)}$$ (74) [e.g. [83]. The corresponding expression for the evolution of $b_{Eul}^\xi(r, z)$ itself is

$$b_{Eul}^\xi(z)^2 D^2(z) = b_{Eul}^\xi(z_0)^2 D^2(z_0) + [D(z_0) - D(z)]^2 - 2 [D(z_0) - D(z)] D(z_0) \times b_{Eul}^\xi(z) r_\xi(z).$$ (75)

This is a good model of $b_{Eul}^\xi r_\xi$ for density peaks, provided we interpret the denominator of Eq. (74) as $b_{Eul}^\xi$. Moreover, the numerator of this equation is similar to (the square of) an Eulerian bias factor minus one: $
abla \left[ (1 + b_v + b_{\xi^{(1)}_\delta}/\xi^{(0)}_{\delta}) - 1 \right]$. This quantity clearly scales with the growth factor like its Fourier space analog. Hence, the real space evolution of the stochastic bias of density peaks is simple in spite of the additional scale dependence. Notice that both $b_{Eul}^\xi pk$ and $b_{Eul}^\xi r_\xi$ tend to unity at late times (even though they might effectively
not reach this limit because the growth factors freeze out in $\Lambda$CDM-like models). In fact $b_\ell$ does as well, but this is not as easy to see from our expressions.

C. Connection to previous work

We mentioned earlier that peak bias and its evolution have been studied in simulations by $^{25,41}$. These authors found that the peak background split argument (Eq. 15) provides a good description of the large scale bias of the peaks extracted from their simulations. They also found that Eq. (73) is in reasonable agreement with the evolution of this large scale bias. However, on smaller scales, the real space bias was found to be scale dependent and stochastic $^{40}$, two features which a peak-background split based analysis does not model. Nevertheless, Eqs (73) and (74) were found to provide a good description of the evolution. The above analysis shows why. It would be interesting to see if our approach correctly predicts the scale dependence of the bias. We defer this issue to a future work.

VI. DISCUSSION AND CONCLUSIONS

We have presented an extensive analysis of the Gaussian peak model. Density peaks are biased tracers of the underlying matter density field – on large scales this bias is scale independent – and we studied the limit in which this bias just starts to exhibit a scale dependence, both in the spatial and velocity fields (Eq. 5). In almost all cases we presented a relatively straightforward analysis in the main text, which was sometimes backed up with detailed calculations in the Appendix.

We showed that, in the large scale, scale independent limit, our expressions reduce to those of the peak background split (Section II D), but in general the scale dependence in our model implies a much richer structure. For example, even though the peaks flow with the underlying field, their velocities appear to be biased (Section II F). In addition, we showed how this $\ell$-dependent bias propagates into the analysis of redshift space distortions (Section III H). We derived an exact formula for the linear theory redshift space correlation function (Eq. 52), and then argued that it should be well-approximated by a simpler expression which has considerable intuitive appeal (Eq. 53). Our formula shows that redshift space distortions of peaks can be modelled i) using the same formula (and physics) derived by reference $^2$, except that various terms now become $\ell$-dependent, and ii) including a Gaussian smoothing term, which reflects the dispersion of particle velocities in linear theory. Thus, our formula has the same form as the phenomenological relation that is commonly used to model nonlinear effects, and which has been shown to provide increased accuracy when comparing theory with simulations. Here, we demonstrated that this functional form is also part and parcel of linear theory. The Kaiser’s relation $^2$ assumes that the exponential is unity, whereas Scoccimarro’s formula $^9$ corresponds to expanding the exponential and retaining only the monopole and quadrupole. Our result implies that linear theory can account for some of the effects that such a phenomenological model would otherwise ascribe to nonlinear evolution.

We then explored how this smoothing term, and the $\ell$-dependence of the bias factors, modify a number of the estimators currently used to derive cosmological constraints from galaxy redshift survey (Section IV). Our analysis showed that allowing for a $\ell$-dependent velocity bias degrades the constraint on the growth rate $f$ by at least a factor of two. Large cosmological simulations will be needed so as to ascertain whether dark matter halos hosting the surveyed galaxies exhibit a $\ell$-dependent velocity bias. If any, then improving the determination of $f$ will lie in our ability to model such a velocity bias. Clearly, the nonlinear prescription considered in this work needs to be refined since, among others, it does not properly accounts for the nonlinear evolution of the matter density and velocity fields $^{85}$ nor for the mode-coupling contribution induced by nonlinear gravitational clustering $^{80}$. We also used the peaks bias model to investigate the stochasticity of the bias and its redshift evolution (Section V). We provided explicit expressions for the evolution of the scale dependent peaks bias and stochasticity, and argued that they helped to understand recent measurements of these quantities in numerical simulations.

As regards the evolution of peak bias, it is interesting to consider the peak model in light of recent work on possible modification of gravity. In standard gravity, the linear theory growth factor is scale independent. Therefore, a peak retains its height when the initial density field is linearly evolved. However, in modified gravity models, the linear growth factor is $\ell$-dependent. As a result, peaks in the initial field may not correspond to peaks in the linearly evolved field because the shape of the power spectra for the two Gaussian fields is different. This can also be seen directly by studying the (linear theory) motions of peaks. In such models, the bias of objects which coherently flow with the matter evolves just as it does in standard gravity $^{82}$. Thus, whereas objects initially placed at maxima of the density field will still move in accordance with the (modified) matter flows, gravitational motions will bring them to positions which are no longer local maxima.

The question then arises as to whether it is the initial peaks, or those in the evolved field, which bear a closer resemblance to the galaxies and clusters we see today. Presumably it is the peaks which have managed to survive from the initial time to the present which are the ones of most interest – the ones which are transients are probably less interesting. In theories with $\ell$-dependent linear growth, only the peaks with exactly the right large scale surroundings (determined by the $\ell$-dependence of linear theory) will survive at later times; this raises the
possible that the correlation between galaxy clusters and their environments can constrain theories of large-scale modifications to gravity. We have not pursued this further, but note that this is consistent with recent analyses of dark matter halos [44].

To conclude, it is worth mentioning that halo-based approaches, which provide a reasonably good description of the weakly nonlinear clustering of simulated dark matter haloes and galaxies [e.g. 88], are now commonly used to extract cosmological information from redshift surveys (see [87] for a review). Although the dark matter halos and stochasticity of the spatial and velocity bias – which are
data the study of density peaks [e.g. 23, 28], particularly with re-

tional density maxima. This is the reason why the peak

APPENDIX A: CHECKING THE CONSISTENCY
OF THE PEAK BIASING RELATION

In this Appendix, we sketch the derivation of the cross-correlation between peaks and the underlying density field, \( \xi_{pk,\delta}(r) \), and the averaged peak pairwise velocity, \( v_{12}(r, \mu) \), which have not been derived previously. We compute both quantities using the peak constraint and demonstrate that the results are consistent with those inferred (after a trivial calculation) from the peak biasing relation [4]. See [28] for complementary details about the calculation.

1. Cross-correlation between peaks and density field

Let \( \eta_i = \partial_i \delta(x)/\sigma_1 \) and \( \zeta_{ij} = \partial_i \partial_j \delta(x)/\sigma_2 \) be the normalised first and second derivatives of the density field. Furthermore, let \( \Lambda \) be the diagonal matrix of entries \( \text{diag}(\lambda_1, \lambda_2, \lambda_3) \) where \( \lambda_1 \geq \lambda_2 \geq \lambda_3 \) is the non-increasing sequence of eigenvalues of the symmetric matrix \( -\nabla^2 \). The cross-correlation \( \xi_{pk,\delta}(r) = (\partial_{pk}(x_1)\nu(x_2)) \) (\( r = |x_2 - x_1| \)) follows from the Kac-Rice formula [89],

\[
\xi_{pk,\delta}(r) = \frac{3^{3/2} \sigma_0}{n_{pk}(\nu) R_1^3} |\det(\zeta(x_1))|^3 |\nu(x_1)| \theta(\lambda_3) \nu(x_2),
\]

where \( n_{pk} \) is the differential number density of peaks of height \( \nu \) as given in Eq. (9), \( R_1 \) is the typical radius of peaks and \( \lambda_3 \) is the smallest eigenvalue of \( -\nabla^2 \) at \( x_1 \). We have omitted the \( \nu \)-dependence for brevity. The Heaviside step-function arises because we are interested in counting maxima solely, for which \( \zeta_{ij} \) is negative definite at the extrema position. Unlike [19] who expresses the covariance matrix in a coordinate system where the two density maxima lies on the z-axis, we write the expectation value in the right-hand side of Eq. (A1) as an integral over the angular average, joint probability distribution function \( P(y, \nu_2; \nu) \). Here, \( y = (\eta_y, \nu, \zeta_A) \) is a ten-dimensional vector whose components \( \zeta_A, A = 1, \ldots, 6 \) symbolise the entries \( ij = 11, 22, 33, 12, 13, 23 \) of \( \zeta_{ij} \).

To evaluate the 11-dimensional covariance matrix \( C(r) \), it is convenient to split the degrees of freedom associated with the tensor \( \zeta \) into the scalar \( u = -tr(\zeta) = \sum \lambda_i \) (so that \( u \) is positive when \( \lambda_3 > 0 \)) and the traceless matrix \( \tilde{\zeta} = \zeta - 1/3(tr(\zeta))I \), where \( I \) is the 3 \( \times \) 3 identity matrix. Let \( \tilde{\zeta}_A \) designate the 5 degrees of freedom of \( \tilde{\zeta} \). We see that \( C(r) = (1/4\pi) \int d\Omega r C(r) \) has the block diagonal decomposition \( C = \text{diag}(C_1, C_2, C_3) \). Consequently, \( P(y_1, \nu_2; \nu) \) can be expressed as a product of three joint probability distributions

\[
P(y, \nu_2; \nu) = P(\nu_1, u_1, \nu_2; \nu) P(\tilde{\zeta}_1) P(\tilde{\zeta}) \quad (A2)
\]

where, for shorthand convenience, subscripts denote the variables evaluated at different Lagrangian positions. The 1-point probability distributions \( P(\eta_1) \) and \( P(\tilde{\zeta}_1) \) are

\[
P(\eta_1) = \left( \frac{3}{2\pi} \right)^{3/2} \exp \left( -\frac{3\eta_1^2}{2} \right) \quad (A3)
\]

\[
P(\tilde{\zeta}_1) = \frac{15^3}{(2\pi)^{5/2}2\sqrt{5}} \exp \left( -\frac{15}{4} \text{tr}(\tilde{\zeta}_1^2) \right),
\]

while the joint density \( P(\nu_1, u_1, \nu_2; \nu) \) has a covariance matrix

\[
C_1 = \begin{pmatrix}
1 & \xi_0^{(0)}/\sigma_0^2 & \gamma_1 \epsilon_0^{(1)}/\sigma_1^2 \\
\xi_0^{(0)}/\sigma_0^2 & 1 & \gamma_1 \\
\gamma_1 \epsilon_0^{(1)}/\sigma_1^2 & \gamma_1 & 1
\end{pmatrix} \quad (A4)
\]
Upon inversion of $C_1$, the quadratic form $Q_1$ that appears in the probability density $P(\nu_1, u_1, \nu_2; r)$ reads as

$$Q_1 (\nu_1, u_1, \nu_2) = \frac{\nu_1^2 + u_1^2 - 2\gamma_1 \nu_1 u_1}{2 (1 - \gamma_1^2)} + \frac{(\nu_2 - A_1)^2}{2 \Delta_1}$$ (A5)

where

$$\Delta_1 = 1 - \frac{1}{\sigma^2_0} \left( \frac{\xi_0^{(0)} - \frac{2\alpha_{\xi_0}}{\sigma^2_0} \xi_0^{(1)}}{1 - \gamma_1^2} \right)^2$$ (A6)

$$A_1 = \frac{1}{\sigma_0} \left[ \frac{1}{\sigma_0} \left( \frac{\nu_1 - \gamma_1 u_1}{1 - \gamma_1^2} \right) \xi_0^{(0)} + \frac{1}{\sigma_2} \left( \frac{u_1 - \nu_1/\nu_1}{1 - \gamma_1^2} \right) \xi_0^{(1)} \right].$$ (A7)

The calculation now proceeds along lines similar to [25]. We choose a coordinate system whose axes are aligned with the principal frame of $\zeta_1$ and introduce the asymmetry parameters

$$v = (\lambda_1 - \lambda_3)/2$$
$$w = (\lambda_1 - 2\lambda_2 + \lambda_3)/2.$$ (A8)

Our choice of ordering impose the constraints $v \geq 0$ and $-z \leq w \leq v$, while the peak constraint enforces $(u + w) \geq 3v$. Upon integration over the angular variables that define the orientation of the orthonormal triad of $\zeta_1$ and the variables $v$ and $w$, the cross-correlation $\xi_{pk,\delta}(r)$ of peaks of height $\nu$ is given by

$$\xi_{pk,\delta}(r) = \sigma_0 G_0 (\gamma_1, \gamma_1 \nu_1)^{-1} \int_{-\infty}^{+\infty} du_1 \nu_2 \frac{e^{-(\nu_2 - A_1)^2/2 \Delta_1}}{\sqrt{2\pi \nu_2}}$$
$$\times \int_0^{+\infty} du_1 f(u_1) \frac{e^{-(u_1 - \gamma_1 \nu_1)^2/(2(1 - \gamma_1^2))}}{\sqrt{2\pi (1 - \gamma_1^2)}}.$$ (A9)

where the auxiliary function $f(u)$ is defined as in Eq. (A15) of [16], and

$$G_n (\gamma_1, \omega) = \int_0^{+\infty} dx x^n f(x) \frac{e^{-(x - \omega)^2/(2(1 - \gamma_1^2))}}{\sqrt{2\pi (1 - \gamma_1^2)}}.$$ (A10)

are moments of the peak curvature. In particular, $\bar{u}(\nu) = G_1 (\gamma_1, \gamma_1 \nu)/G_0 (\gamma_1, \gamma_1 \nu)$ is the average curvature of peaks of height $\nu$. Finally, the integral over $\nu_2$ is performed and we arrive at the desired result,

$$\xi_{pk,\delta}(r) = \frac{1}{\sigma_0} \left( \frac{\nu_1 - \gamma_1 \bar{u}}{1 - \gamma_1^2} \right) \xi_0^{(0)}(r) + \frac{1}{\sigma_2} \left( \frac{\bar{u} - \gamma_1 \nu_1}{1 - \gamma_1^2} \right) \xi_0^{(1)}(r),$$ (A11)

which agrees with Eq. (18) obtained with much less effort from the peak biasing relation [16]. It is worth noticing that, while the derivation based on the peak biasing relation is formally exact at the first order only, this appendix shows that Eq. (A11) is exact to all orders.

The cross-correlation $\xi_{pk,\delta}(r)$ has a straightforward interpretation: it is the average density profile around a density maxima, i.e. $\langle \delta(\mathbf{x}_2) \rangle$ peak at $\mathbf{x}_2$. As shown by [16], this constrained density profile can be calculated easily and, after some algebra, one indeed finds $\xi_{pk,\delta}(r) = \langle \delta(\mathbf{x}_2) \rangle$ peak at $\mathbf{x}_2$. Note, however, that reference [16] quotes a slightly different result: an additional factor of $1/3$ multiplies $\nabla^2 \xi_0^{(0)} = -\xi_0^{(1)}$, in their Eq. (7.10) (their $\psi(r)$ corresponds to our $\xi_0^{(0)}(r)$).

### 2. Mean streaming of peak pairs

The calculation of the mean streaming is more intricate since we have three more degrees of freedom and an extra angular dependence. Our derivation is based on reference [25], who calculated the pairwise velocity dispersion along the line of sight.

We introduce the normalised velocity field $\mathbf{x}_1 = v_i/(a H \sigma_1) = v_i/\sigma_1$. Also, we assume that the line of sight axis coincides with the third-axis, such that $\Delta \varpi_z$ denotes the difference $\varpi_3(\mathbf{x}_2) - \varpi_3(\mathbf{x}_1)$. The line of sight pairwise velocity weighted over all peak pairs with co-moving separation $r$ can be expressed as

$$[1 + \xi_{pk}(r)] v_{12}(r, \mu) = \bar{n}_{pk}^{-1} \sigma_1$$
$$\times \int_0^{+\infty} \frac{1}{2\pi} \int_0^{+\infty} d\varpi_1 d\varpi_2 \Delta \varpi_z \bar{n}_{pk}(\mathbf{x}_1) \bar{n}_{pk}(\mathbf{x}_2) P(y_1, y_2; r)$$

where $\mu$ is the cosine of the angle between $\mathbf{r} = r/r$ and the third axis, and $\phi$ is the azimuthal angle in the plane perpendicular to the line of sight. The local peak density $n_{pk}(\mathbf{x})$ is given by $3/2 \Delta \varpi_z |\det \zeta(\mathbf{x})|^{1/2} \eta(\mathbf{x})$, supplemented by the appropriate conditions to select those maxima with a certain threshold height.

In the above expression, the joint probability density $P(y_1, y_2; r)$ is now a function of $y_i = (\varpi_i, \eta_i, \varpi_i, \varpi_i)$, where $\eta_i \equiv 0$ owing to the peak constraint. The corresponding covariance matrix $C$ can be decomposed into four $13 \times 13$ block matrices, the zero-point contribution $M$ in the top left and bottom right corners, and the cross-correlation matrix $B(r)$ and its transpose in the bottom left and top right corners, respectively. In the large distance limit $r \gg 1$ where $|B| \ll M$, an expansion in the small perturbation $M$ yields at first order

$$P(y_1, y_2, r) \approx \frac{1}{(2\pi)^{31} |\det C|^{1/2}} \frac{1}{1 + y_1 M^{-1} B M^{-1} y_2}$$
$$\times e^{-\tilde{Q}(y_1, y_2)},$$ (A13)

where the quadratic form $\tilde{Q}(y_1, y_2)$ reads

$$2\tilde{Q} = \frac{3 \varpi_1^2}{1 - \alpha_0} + \nu_1^2 + \left( \frac{\gamma_1 \nu_1 + \nu_1^2}{1 - \gamma_1^2} \right)^2$$
$$+ \frac{5}{2} \left[ 3 \nu_1^2 - (\nu_1^2) \right] + 1 \leftrightarrow 2,$$ (A14)

$\varpi_1$ being the velocity vector at comoving position $\mathbf{x}_1$. The inverse $M^{-1}$ and $B(r)$ can be further decomposed.
into the block matrices

\[
M^{-1} = \begin{pmatrix} P & R^T \\ R & Q \end{pmatrix}, \quad B = \begin{pmatrix} B_1 & B_4^T \\ B_3 & B_2 \end{pmatrix}. \tag{A15}
\]

where

\[
P = \begin{pmatrix} \frac{3}{(1-\gamma_1^2)} & -\frac{3\beta}{1-\gamma_1^2} & 0 & 0 & 0 & 0 \\ -\frac{3\beta}{1-\gamma_1^2} & \frac{3}{1-\gamma_1^2} & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{\gamma_1}{1-\gamma_1^2} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{\gamma_1}{1-\gamma_1^2} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{\gamma_1}{1-\gamma_1^2} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{\gamma_1}{1-\gamma_1^2} \end{pmatrix}, \quad Q = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ \frac{6-5\gamma_2^2}{1-\gamma_1^2} & \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & 0 & 0 \\ \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & \frac{6-5\gamma_2^2}{1-\gamma_1^2} & \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & 0 & 0 \\ \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & \frac{6-5\gamma_2^2}{1-\gamma_1^2} & \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & 0 & 0 \\ \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & \frac{2(1-\gamma_2^2)}{1-\gamma_1^2} & \frac{6-5\gamma_2^2}{1-\gamma_1^2} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 15 & 0 & 15 & 0 & 15 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}.
\]

and

\[
R = \begin{pmatrix} 0 & 0 & \frac{\gamma_1}{1-\gamma_1^2} & 1 \end{pmatrix}
\]

The explicit expressions for \( B_i \) are too long to be given here as they depend upon the correlation functions of \( \tau_i, \eta_i, \nu_i \) and \( \zeta_i \) in a rather complicated way. Fortunately, the mean streaming involves only the azimuthal average \( \tilde{B}(r, \mu) = 1/(2\pi) \int d\phi B(r, \mu) \), which can generally be expanded as

\[
\tilde{B}(r, \mu) = \frac{4}{\ell} \tilde{B}_\ell(r) L_\ell(\mu), \quad \tilde{B}_\ell(r) = \begin{pmatrix} \tilde{B}_1^\ell & \tilde{B}_4^\ell \\ \tilde{B}_3^\ell & \tilde{B}_2^\ell \end{pmatrix}.
\tag{A17}
\]

Note that the multipole matrices \( \tilde{B}_1^\ell \) and \( \tilde{B}_4^\ell \) are not independent of each other since we have \( \tilde{B}_4^\ell = (-1)^\ell \tilde{B}_3^\ell \). As we will see shortly, all the contributions but that from \( \ell = 1 \) multipole (unsurprisingly) cancel out. We will thus detail the results for the dipole contribution solely. After some algebra, we find

\[
\tilde{B}_1^\ell(r) = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \quad \tilde{B}_4^\ell(r) = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}.
\tag{A18}
\]

whereas the matrix \( \tilde{B}_2^\ell \) is identically zero. Right and left multiplication by \( M^{-1} \) then gives

\[
M^{-1}\tilde{B}_1^\ell M^{-1} = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \quad M^{-1}\tilde{B}_4^\ell M^{-1} = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 9\alpha_3 & 0 & 9\alpha_4 & 0 & 9\alpha_4 & 0 \\ 9\alpha_3 & 0 & 9\alpha_4 & 0 & 9\alpha_4 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}.
\tag{A19}
\]

where the functions \( \alpha_i(r) \) are identical to those defined in Eq. (A12) of [28]. Namely,

\[
\begin{align*}
\alpha_1(r) &= \frac{\sigma_2^2 e^{(1/2)}(3)}{\alpha_1^2 \xi_1} + \frac{\sigma_2^2 e^{(1/2)}(1)}{\alpha_1^2 \xi_1} - \frac{\sigma_2^2 e^{(-1/2)}(1)}{\alpha_1^2 \xi_1} - \frac{\sigma_2^2 e^{(-1/2)}(1)}{\alpha_1^2 \xi_1}, \\
\alpha_2(r) &= \frac{\sigma_2^2 e^{(1/2)}(3)}{\alpha_1^2 \xi_1} + \frac{\sigma_2^2 e^{(1/2)}(2)}{\alpha_1^2 \xi_1} - \frac{\sigma_2^2 e^{(-1/2)}(2)}{\alpha_1^2 \xi_1} + \frac{\sigma_2^2 e^{(-1/2)}(2)}{\alpha_1^2 \xi_1}, \\
\alpha_3(r) &= \frac{e^{(1/2)}(1)}{\alpha_1^2 \xi_1} - \frac{\sigma_2^2 e^{(1/2)}(3)}{\alpha_1^2 \xi_1}, \\
\alpha_4(r) &= \frac{e^{(1/2)}(1)}{\alpha_1^2 \xi_1} - \frac{\sigma_2^2 e^{(1/2)}(3)}{\alpha_1^2 \xi_1}.
\end{align*}
\tag{A20}
\]

The rest of the calculation is easily accomplished owing to the separability of the one-point probability distribu-
The scalar $y_1 M^{-1} \tilde{B} M^{-1} y_2$ contains terms linear and quadratic in $\varpi$, as well as terms independent of the velocity. Upon multiplication by $\Delta \varpi$, and integration over the velocities, only quadratic terms survive. We eventually find

\[
\int d^3 \varpi_1 d^3 \varpi_2 \Delta \varpi \left( y_1 M^{-1} \tilde{B} M^{-1} y_2 \right) P_{\varpi} (\varpi_1) P_{\varpi} (\varpi_2) = \left[ \alpha_1 (\nu_1 + \nu_2) + \gamma_1 \gamma_0 \left( \text{tr} \zeta_1 + \text{tr} \zeta_2 - 3 \alpha_3 (\zeta_{1,3} + \zeta_{2,3}) \right) \right] \\
\times \left( \frac{1 - \gamma_0^2}{-3\gamma_0^2} \right) L_1 (\mu) \\
- \frac{3}{2} \left[ \zeta_{1,1} + \zeta_{1,2} + \zeta_{2,2} - 2 (\zeta_{1,3} + \zeta_{2,3}) \right] \\
\times \left( \frac{\sigma_{1,0}^2}{\pi} \right) \left( \frac{\sigma_{0,0}^2}{\pi} \right) L_1 (\mu) .
\]

Here, $\zeta_{1,0}$ and $\zeta_{2,0}$ designate the component $\zeta_A$ of the hessian $\zeta$ at location $x_1$ and $x_2$, respectively. As we can see, although the even multipoles cancel out, a term proportional to $L_3 (\mu)$ remains. Also, the dipole receives a contribution from $-3 \alpha_3 (\zeta_{1,3} + \zeta_{2,3})$ which is not invariant under rotations. However, we have to remember that the principal axes of the tensors $\zeta_1 = \zeta (x_1)$ and $\zeta_2 = \zeta (x_2)$ are not necessarily aligned with those of the coordinate frame. Let us first consider $\zeta_1$. Without loss of generality, we can write $\zeta_1 = -O \Lambda O^\top$, where $O$ is an orthogonal matrix and $\Lambda$ is the diagonal matrix consisting of the three ordered eigenvalues $\lambda_i$ of $-\zeta_1$. The properties of the trace implies that $\text{tr} \zeta_1 = -\text{tr} \Lambda$, while $\zeta_{1,j} = -\sum_i \lambda_i O_{ji}^2$. Since the one-point probability density $P (y)$ does not depend on $O$, the integral over the SO(3) manifold that describes the orientation of the orthonormal triad of $\zeta_1$ is immediate,

\[
\int d\Omega \zeta_{1,j} = -3 \sum_i \lambda_i \int d\Omega O_{ji}^2 = -\frac{3}{3} \sum_i \lambda_i = \frac{1}{3} \text{tr} \zeta_1 .
\]

Similarly, averaging over the orientation of the eigenvectors of $\zeta_2$ yields $dO \zeta_{2,j} = (1/3) \text{tr} \zeta_2$. Consequently, the $\ell = 3$ term vanishes and we only need to integrate

\[
\left[ \alpha_1 (\nu_1 + \nu_2) + (\gamma_1 - \gamma_0) \left( \text{tr} \zeta_1 + \text{tr} \zeta_2 \right) \right] \left( 1 - \gamma_0^2 \right) L_1 (\mu) .
\]

over the eigenvalues of $\zeta_1$ and $\zeta_2$ subject to the peak constraint. Substituting the expressions \[5\] of the bias parameters $b_\nu$ and $b_\zeta$, the result can be recast into the form of Eq. \[5\] when $\nu_1 = \nu_2 = \nu$.

[29] In terms of the normalised (and smoothed) variables $\nu_S = \delta_S/\sigma_0$ and $u_S = -\nabla^2 \delta_S/\sigma_2$, the peak number density is $\delta n_p = \sigma_0 b_v u_S + \sigma_2 b_c u_S$ at the first order. This shows that the relative importance of the $b_v$ and $b_c$ terms is controlled by $\sigma_0 b_v$ and $\sigma_2 b_c$.

[46] Our expression for $v_{12}$ corrects a sign error in Eq. (50) of [28], which propagated to Fig. 8 of that paper.
[47] We believe their expression for the real space peak power spectrum, their Eq. (70), should read $P(k) = P(k) (x+y)^2/\sigma_0^2$. Once corrected, this relation is equivalent to our Eq. (19) provided that $\sigma_0 b_v = (W/C)/\sqrt{1-\gamma_1^2}$ and $\sigma_2 b_c = (\gamma_2 - \gamma_1 (W/C))/\sqrt{1-\gamma_1^2}$ (see their paper for details about their notation). For the redshift space power, they have the same Gaussian damping term as we do, but their expression for $P^0_{\parallel}$, their Eq. (84), does not reduce to the square of peak density and velocity bias terms. In their Eq. (84), their $w$ should be a $y$, and their $x-y$ should be $x+y$ (this is the same error that affected their expression for the real space power spectrum; it also affects their expression for $v_{12}$). These errors appear to have propagated to their Figure 6.
[48] See, e.g., T. Matsubara, Astrophys. J. Suppl. 101, 1 (1995) for a discussion of nonlocally biased fields.
