Abstract

Background: To evaluate quantitative changes of iris blood circulation in patients with ischemic risk.

Methods: A clinical case series study. Patients with diabetic retinopathy (DR) and retinal vein occlusion (RVO) were included in this study. RVO affected eyes, RVO contralateral, and healthy control eyes were compared. We also compared eyes with proliferative diabetic retinopathy (PDR) and the contralateral eye without PDR (NPDR), patients with diabetes mellitus (DM) without DR (NDR), and healthy control eyes. The microvascular networks of the iris and retina were analyzed using optical coherence tomography angiography (OCTA). The analysis included vessel area density (VAD) and vessel skeleton density (VSD) of iris and retina.

Results: In RVO group, the VAD and VSD of iris in the affected eye were higher than those in contralateral and healthy control, and the VAD and VSD of contralateral eyes were higher than those of healthy control. The retinal blood flow of RVO eye was less than the contralateral and healthy control eyes, but there were no difference between the contralateral eyes and healthy control eyes. The VAD and VSD of iris in PDR were larger than NPDR, and the NPDR were larger than NDR. There were no differences between NDR and healthy control eyes. Also, there were no difference among the four groups in retinal blood flow.

Conclusions: Compared with the retina, iris blood circulation quantitative analysis data are more sensitive to ischemia and may be used as a new predictor of ischemic disease.

Trial registration: The trial is registered with the clinical trial registration number nct03631108.

Background

Diabetic retinopathy (DR) and retinal vein occlusion (RVO) are two of the most common retinal ischemic diseases and cause severe visual impairment in millions of people worldwide [1]. The common mechanism of these two diseases is retinal vascular lesions, resulting in ischemia, hypoxia, and the formation of retinal neovascularization in severe cases. In some patients, neovascularization can appear at the angle of the chamber and surface of the iris [2] and develop into neovascular glaucoma (NVG). NVG is a disease with a high incidence of blindness [1, 3]. At present, intravitreal anti-vascular endothelial growth factor (VEGF) therapy and retinal photocoagulation have a certain curative effect against retinal neovascularization and macular edema secondary to ischemia, but the occurrence of iris neovascularization (NVI) cannot be reduced using these two methods [4]. The regression effect and lowering intraocular pressure of the occurring iris neovascularization are also temporary [5], and NVG can only be delayed but not prevented [6]. Because there are some limitations in the treatment of iris vascular complications caused by ischemic diseases, it is very important to detect iris vascular changes in the early stage for the treatment and prognosis of ischemic diseases.

In the past, some scholars thought that there were changes in the iris blood vessels of patients with ischemic diseases, and some scholars thought that the changes of iris blood vessels occurred earlier than the retina. For example, Demeler et al. [7] performed iris angiography for 75 patients with diabetes mellitus (DM) and concluded that almost all of patients with DR had spot dye leakage in iris vessels, and they speculated that the damage to the iris blood vessels in patients with DM was earlier than retinal vessels. Michel et al. [8] analyzed
the history of four patients with ischemic RVO and concluded that close follow-up should be carried out if iris vasodilation occurs in eyes with ischemic RVO. They believed that such patients are prone to NVI. Davide et al. [9] proposed that if iris blood vessels have changed before retinal neovascularization, the retinal disease are at an early stage of DR and RVO. In the past, these studies were based on qualitative observation of iris vessels using angiography. Angiography lacks objective and quantitative evaluation of iris vascular changes, and it is an invasive examination that is not suitable for the screening and follow-up of patients at risk of ischemic disease. Iris blood vessels can be visualized and quantitatively analyzed using optical coherence tomography angiography (OCTA) of the anterior segment. In our study, to explore the early quantitative changes and clinical value of iris blood circulation in patients with ischemic disease, the iris blood circulation indexes of RVO and DR patients with ischemic factors, their contralateral eyes, and eyes in a healthy control group were quantitatively analyzed using OCTA.

Methods

This study is a series of clinical cases. This study was approved by the Ethics Committee of the First People’s Hospital Affiliated to Shanghai Jiaotong University (ethical approval number: 2018ky181). All experiments on human subjects were conducted in accordance with the ethical standards stipulated in the Declaration of Helsinki. Informed consent was obtained from all subjects before examination. The trial is registered with the clinical trial registration number nct03631108.

This study included patients who visited Shanghai Eye Disease Prevention and Control Center/Shanghai Eye Hospital between January 2020 and April 2020. The inclusion criteria were as follows: (1) age ranging from 18 to 80 years; (2) RVO group: fundus fluorescein angiography (FFA)-based diagnosis of ischemic RVO in one eye, i.e., there were more than 10 optic disc areas without retinal perfusion [10], including central RVO (CRVO) and branch RVO (BRVO), and no ischemic or hemorrhagic fundal lesions were found in FFA of the contralateral eye; (3) monocular PDR group: diagnosed according to the National Academic Conference of Funds Diseases (1985); diagnosis and grading criteria of DR were divided into two groups, FFA-diagnosed monocular PDR and contralateral NPDR; (4) NDR group: DM was diagnosed and matched in terms of age and sex with the monocular PDR group; FFA examination revealed no DR changes in the bilateral fundus; (5) healthy control group: patients in whom bilateral eye examination revealed no obvious abnormalities and with no history of diabetes, hypertension, or other systemic diseases, matched with the age and sex of patients with the monocular RVO and monocular PDR groups; and (6) normal intraocular pressure (10 to 21 mmHg). The exclusion criteria were as follows: (1) previous history of uveitis, iris tumor, iris neovascularization, or cyanosis; (2) history of anti-VEGF or intravitreal steroid therapy; (3) history of retinal laser photocoagulation; (4) history of internal eye surgery; and (5) poor fixation and compliance.

All subjects underwent routine ophthalmic examinations, including uncorrected visual acuity, computer optometry (ARK-1s, Nidek, Japan), best-corrected visual acuity, noncontact intraocular pressure (NT-510, Nidek, Japan), corneal curvature, and axial length (IOLMaster 700). The objective of this study was to investigate the clinical value of laser photocoagulation (SL130, Carl Zeiss, Germany) in the diagnosis of macular and iris diseases. The clinical data of the conjunctiva, cornea, anterior chamber, pupil, iris, lens, vitreous and retina examination, fundus examination, digital photography (Topcon NW300, Topcon, Japan), and OCT blood flow...
scanning (Cirrus HD-OCT 5000, Carl Zeiss Meditec, Dublin, CA) were analyzed. FFA fundus angiography was performed in both the monocular RVO and monocular PDR groups.

Using the CIRRUS HD-OCT 5000 (Carl Zeiss, Meditec, Dublin, CA) plus a + 20D anterior segment lens, we selected the anterior segment vascular mode and scanned a dimension of 3 × 3 mm. All subjects were scanned under the same light source without pupil dilation. The focus was adjusted until the texture of the iris surface was visible, and the horizontal distance of the scan frame was from the center of the pupil to the 9 o'clock position of the corneal limbus. The patients were asked to avoid frequent blinking. We calculated the vessel area density (VAD) and vessel skeleton density (VSD) of the iris using the optical microangiography (OMAG) method and MATLAB software (R2017a; MathWorks Inc, Natick, Massachusetts, USA). VAD is the ratio of the total image area occupied by blood vessels to the total image area, and VSD is the ratio of the length occupied by blood vessels to the total image area [11]. The region of this study was as follows: (1) vertical distance was based on the 9 o'clock position of the pupil margin above and below 150 pixel values; (2) horizontal distance was 150 pixel values from the 9 o'clock position of the pupil margin to the corneal limbus; (3) horizontal distance was divided into 3 equal parts, the 1/3 segment, 2/3 segment, and full segment. We calculated each value three times and obtained the average.

Retinal blood flow was examined as follows: at the end of iris scanning, the anterior segment lens was removed, the macular blood flow mode was selected, the scanning range was 6 × 6 mm, and the macular fovea was placed in the center of the scanning range. The full-thickness image of retinal blood flow was loaded into MATLAB software, and the mean blood flow density (VAD) and mean blood flow density (VSD) of retinal blood vessels were calculated using the OMAG method.

For α = 0.05, power (1-β) = 0.8, expected maximum difference between groups of 0.1, and standard deviation of 0.05, each group required at least six samples [12].

In the DM control group and healthy control group, one eye was randomly taken, and the results were statistically analyzed. Statistical analysis was performed using SPSS16.0 software. Count data are expressed as a percentage (%), and measurement data are shown as mean ± standard deviation (x̄± SD). Measurement data were normally distributed as assessed using the Kolmogorov-Smirnov test, and homogeneity of variance was confirmed using the Levene test. The data were compared between two groups using an independent sample t-test, and data were compared between multiple groups using one-way analysis of variance. Categorical data were compared using the chi-square test. P< 0.05 was considered statistically significant.

**Results**

1. **General information on patients**

This study included 79 patients, including 21 patients in the monocular RVO group, nine men and 12 women, with an average age of 56.67 ± 10.96 years; 19 patients in the monocular PDR group, 10 men and 9 women, with an average age of 57.05 ± 13.02 years; 18 patients in the NDR group, 8 men and 10 women, with an average age of 54.72 ± 13.20 years; 21 healthy controls, 8 men and 13 women, with an average age of 54.05 ± 14.17 years. No significant differences in age or sex were observed among the RVO, PDR, NDR, and healthy control groups (P > 0.05).
2. Comparison of VAD and VSD in different iris segments in RVO eyes

VAD and VSD in the 1/3 iris segment of eyes with RVO were greater than those in the 2/3 iris segment and full range, respectively, and the differences were statistically significant ($P < 0.05$). VAD and VSD in the 2/3 iris segment were greater than those in the full segment, but the differences were not statistically significant ($P > 0.05$) (Table 1).

|                | 1/3 segment | 2/3 segment | Full segment | F    | P    | P1   | P2   | P3   |
|----------------|-------------|-------------|--------------|------|------|------|------|------|
| **RVO VAD**    | 0.34±0.07   | 0.25±0.06   | 0.24±0.06    | 16.058 | 0.000 | 0.000 | 0.000 | 0.505 |
| **RVO VSD**    | 0.24±0.06   | 0.17±0.04   | 0.16±0.04    | 17.434 | 0.000 | 0.000 | 0.000 | 0.632 |
| **PDR VAD**    | 0.34±0.07   | 0.28±0.06   | 0.23±0.05    | 15.369 | 0.000 | 0.005 | 0.000 | 0.011 |
| **PDR VSD**    | 0.25±0.05   | 0.20±0.04   | 0.15±0.04    | 24.055 | 0.000 | 0.001 | 0.000 | 0.001 |

P, comparison of all three segments; P1, comparison between 1/3 segment and 2/3 segment; P2, comparison between 1/3 segment and full segment; P3, comparison between 2/3 segment and full segment; $P < 0.05$ was considered statistically significant.

3. Comparison of VAD and VSD in different iris segments in PDR eyes

VAD and VSD in the 1/3 segment of iris in eyes with PDR were significantly greater than those in the 2/3 segment and full segment, respectively (all $P < 0.05$). VAD and VSD in the 2/3 segment were significantly greater than those in the full segment (all $P < 0.05$) (Table 1).

4. Comparison of the degree of deviation of VAD and VSD values in different iris segments in different eyes

Figure 1 and 2 show the average VAD and VSD values of the iris in different segments for all subjects. The average VAD and VSD values of the 1/3 iris segment were highest, and the degree of deviation is larger than that of the 2/3 and whole iris segment. Considering the anatomic structure, the blood vessels in the 1/3 range of the iris are the densest, which can reflect the quantitative changes in iris blood circulation more intensely than the 2/3 segment and the whole segment. Therefore, we selected VAD and VSD values in the 1/3 segment of iris for analysis.
5. Comparison of retinal blood flow and 1/3 iris VAD and VSD values between RVO, RVO contralateral, and healthy control eyes

Significant differences in the 1/3 iris VAD and VSD values were observed between RVO, RVO contralateral, and healthy control eyes (all \( P = 0.000 \)). Further, pairwise comparison showed that the VAD and VSD values of the RVO eyes were significantly higher than those of the contralateral and healthy control eyes \( (P < 0.05) \). The VAD and VSD values of contralateral eyes were higher than those of healthy eyes, but the difference was not statistically significant \( (P > 0.05) \). The retinal blood flow values in RVO eyes were significantly lower than those in contralateral and healthy control eyes \( (all \ P < 0.05) \), but no statistical difference was observed between the contralateral and healthy control eyes \( (all \ P > 0.05) \) (Table 2).

|                  | RVO eye | RVO contralateral eye | Healthy control eye | F       | P       | P1       | P2       | P3       |
|------------------|---------|-----------------------|---------------------|---------|---------|----------|----------|----------|
| Iris 1/3 VAD     | 0.34±0.07 | 0.29±0.07            | 0.26±0.03           | 11.191  | 0.000   | 0.008    | 0.000    | 0.052    |
| Iris 1/3 VSD     | 0.24±0.06 | 0.20±0.05            | 0.18±0.03           | 8.820   | 0.000   | 0.010    | 0.000    | 0.145    |
| Retina VAD       | 0.51±0.03 | 0.53±0.04            | 0.53±0.01           | 3.487   | 0.037   | 0.031    | 0.022    | 0.891    |
| Retina VSD       | 0.13±0.01 | 0.14±0.01            | 0.14±0.01           | 7.823   | 0.001   | 0.028    | 0.000    | 0.096    |

\( P \), comparison of all three groups; \( P1 \), RVO eye and contralateral eye; \( P2 \), RVO eye and healthy control eye; \( P3 \), contralateral eye and healthy control eye; \( P < 0.05 \) was considered statistically significant.

|                  | RVO eye | RVO contralateral eye | Healthy control eye | F       | P       | P1       | P2       | P3       |
|------------------|---------|-----------------------|---------------------|---------|---------|----------|----------|----------|
| Iris 1/3 VAD     | 0.34±0.07 | 0.29±0.07            | 0.26±0.03           | 11.191  | 0.000   | 0.008    | 0.000    | 0.052    |
| Iris 1/3 VSD     | 0.24±0.06 | 0.20±0.05            | 0.18±0.03           | 8.820   | 0.000   | 0.010    | 0.000    | 0.145    |
| Retina VAD       | 0.51±0.03 | 0.53±0.04            | 0.53±0.01           | 3.487   | 0.037   | 0.031    | 0.022    | 0.891    |
| Retina VSD       | 0.13±0.01 | 0.14±0.01            | 0.14±0.01           | 7.823   | 0.001   | 0.028    | 0.000    | 0.096    |

6. Comparison of retinal blood flow and 1/3 iris VAD and VSD values between PDR, NPDR, NDR, and healthy control eyes

Significant differences in 1/3 iris VAD and VSD values were observed between PDR, contralateral NPDR, NDR, and healthy control eyes \( (all \ P = 0.000) \). No significant difference in VAD or VSD was observed between the NDR and healthy control eyes \( (all \ P > 0.05) \). In addition, no significant difference in VAD or VSD values was observed between the different groups \( (all \ P > 0.05) \) (Table 3).
7. Comparison of iris VAD and VSD between PDR and RVO eyes in the 1/3 segment

There were no statistical difference between PDR and RVO in 1/3 range of iris VAD and VSD ($P = 0.838$ and $P = 0.414$, respectively).

Discussion

We observed that the blood flow of retinal vessels in RVO patients was lower than that contralateral eyes and healthy retina, which was consistent with previous results [13–15]. Although previous studies have suggested that patients with RVO may have an increased risk of retinal vein occlusion in the contralateral eye compared with normal subjects [16], this study did not find any difference in retinal blood flow between the RVO contralateral and healthy control eyes. At the same time, we found for the first time that RVO eyes had significantly higher iris vascular density and blood flow density than contralateral and healthy control eyes. Hypertension is considered the main risk factor for RVO [17], in this study, 85.71% (18) of RVO patients had hypertension. Hypertension affects the blood circulation system of both eyes [18], but the lesions in both eyes are not completely consistent [19]. In our study, the eyes without ischemic retinopathy showed iris blood circulation changes (the iris VAD of the contralateral eye in RVO patients was higher than that in healthy control eyes, $P = 0.052$).

In our study, retinal blood flow density was no difference in patients with different degrees of diabetes, which was inconsistent with previous literature reports. Most of the studies focused on the superficial retinal blood flow in the macular area with a diameter of $3 \times 3$ mm and found the retinal blood flow in this area decreased with the aggravation of DR [20, 21]. This study aimed to analyze the whole retinal blood flow with $6 \times 6$ mm area by OCT, which was more comprehensively reflect the overall changes in retinal blood flow. However, large-
scale research data are affected by bleeding masking and neovascularization. For the first time, we found that in DM patients, from NDR to NPDR and then to PDR, that is, with the increase of the severity of DR, the quantitative analysis data of blood circulation such as iris vessels and blood flow also changed significantly. Theoretically, these changes indicate the existence and severity of intraocular ischemia.

Furthermore, we also found that the degree of change in iris blood circulation of the two ischemic diseases (RVO and PDR) was similar to that of normal people, and such changes were consistent with previously studies by IFA [22]. The possible mechanisms were as follows: (1) Ischemic retinal releases vasoactive molecules, such as VEGF, through the vitreous to diffuse into the anterior chamber, inducing iris vasodilation [8], making the deep iris vessels covered by iris pigment dilate. The number of vessels on the surface and deep layers of the iris is increased by OCTA, that is, the VSD value is increased. The iris ciliary body itself can also produce VEGF, which can induce vascular dilation and increase iris perfusion [4]; therefore, the iris VAD value also increases. (2) Previous studies have reported that a high concentration of vasoconstrictor prostaglandin F(2) (PGF2) alpha can cause constriction of the ciliary artery in monkeys in vitro [23] while the concentration of PGF2 alpha in the vitreous cavity of PDR eyes is significantly reduced [24]. Therefore, we speculate that with the lower levels of PGF2 alpha in PDR eyes, the ciliary artery may expand, leading to an increase in iris VSD.

Our results suggest that in RVO and DR the change in quantitative data of iris blood circulation seems to occur earlier than that in retinal blood circulation. In other diseases, these features of iris vessels have been confirmed. Francesco et al. [25] found that in patients with systemic lupus erythematosus the iris blood flow of patients was higher than that in healthy controls when there were no clinical changes in the fundus. In addition, Kivlin [26] thought that iris vasodilation was a sign of Retinopathy of Prematures (common ischemic retinopathy in childhood). We believe that iris vessels are more sensitive to intraocular ischemia than retinal vessels, which may be related to two different tissue structures. Firstly, the retina is supplied by two sets of vascular systems, namely, the central retinal vessels and ciliary vessels. When our eye is ischemic, the ciliary vessel increases the blood flow to provide blood to retina without changing of retinal vessels. However, the iris is supplied only by the long posterior ciliary artery. When the eye is ischemic, the iris vessels will expand to increase the blood flow. Secondly, the blood of the retina are mainly distributed in the inner layer of the retina. The inner layer of the retina is closely connected to the outer layer, but the iris stroma is a sponge like characteristic [27]. Therefore, we speculate that when central vein occlusion or hyperglycemia leads to insufficient intraocular microcirculation perfusion, iris vessels are more likely to dilate than retinal vessel, and then the iris vessels were the first to change in OCTA.

There are some shortcomings in our study: (1) This was a cross-sectional study; for DR or RVO with obvious iris blood circulation changes, the longitudinal changes during the progression of NVI still need to be further studied. (2) Due to poor vision in patients with ischemic RVO and PDR, some patients have poor fixation. Therefore, in this study, we only included patients from whom iris quantitative analysis data could be obtained. Although this is a study with a small sample size, we found that the application of OCTA, a noninvasive and rapid examination method, can quantitatively analyze iris blood circulation in patients with ischemic diseases, which is more sensitive to fundus ischemia than the retina. Therefore, regular observation and close follow-up of iris vessels in patients with high-risk ischemic factors and possible NVI should be performed. Through the quantitative analysis of iris blood circulation, early detection of changes in iris blood circulation, and early
intervention for fundus lesions caused by ischemia and further NVI are very important for the prognosis of the disease.

**Conclusion**

Compared with the retina, iris blood circulation quantitative analysis data are more sensitive to ischemia and may be used as a new predictor of ischemic disease.

**Abbreviations**

DR: diabetic retinopathy

RVO: retinal vein occlusion (RVO)

PDR: proliferative diabetic retinopathy (PDR)

DM: diabetes mellitus

OCTA: optical coherence tomography angiography

VAD: vessel area density

VSD: vessel skeleton density

NVG: neovascular glaucoma

VEGF: vascular endothelial growth factor

NVI: iris neovascularization

OMAG: optical microangiography
