Abstract
We introduce a new approach to assess the error of control problems we aim to optimize. The method offers a strategy to define new control pulses that are not necessarily optimal but still able to yield an error not larger than some fixed \textit{a priori} threshold, and therefore provide control pulses that might be more amenable for an experimental implementation. The formalism is applied to an exactly solvable model and to the Landau–Zener model, whose optimal control problem is solvable only numerically. The presented method is of importance for applications where a high degree of controllability of the dynamics of quantum systems is required.

(Some figures in this article are in colour only in the electronic version)

1. Introduction

The theory of optimal control (OC) that was mathematically formulated in the last century by the seminal works of Pontryagin, Bellman, Kalman and Stratonovich [1–3] has been instrumental for the achievement of highly reliable electronic devices used not only to control, for instance, mechanical systems such as airplanes, cars, etc, but also to control chemical reactions or to design ultra-fast laser pulses for manipulating molecules (e.g. to break a certain bond while leaving other bonds intact [4]), and today even to optimize (stochastic) financial analyses [5].

A possible (empirical) approach relies on applying an arbitrary distortion to the OC solution and then looking at the error that it produces on the objective functional, or by selecting a region in the Hilbert space that is robust against noise (decoherence-free subspace) [11], whose existence follows from the symmetry properties of the noise. Recently, a more systematic methodology based on the Hessian analysis of the cost functional has been proposed [12] or using an improved genetic algorithm in the presence of control noise [13].

The aim of this work is to provide an alternative method to evaluate to what extent a given OC scheme can tolerate errors. The method is based on the Hessian approximation of the cost functional, as in [12], but it is applicable to any system Hamiltonian $\hat{H}(u_t)$ and Hilbert space dimension. Such arbitrariness is important in several circumstances where either
the control pulse \( u_t \equiv u(t) \) does not appear linearly in \( \hat{H}(u_t) \) or where the state to be controlled is an auxiliary state (e.g., the motional state of an atom [14]) and not the quantum bit itself (e.g., an atomic internal state). The control of such states is relevant not only for several QIP implementations, but also for quantum metrological purposes, where the control of large quantum superpositions may increase the sensitivity of precise measurements.

Even though it is not usually possible to know the OC pulse analytically, we underscore that our assumption is that the parameter obtained with some numerical algorithm is very close to the global optimum. More precisely, the error on the cost functional obtained with the numerically found OC pulse has to be much smaller than the error allowed by the process we are interested in optimizing. Besides the interest on its own, we believe that our approach might be of importance for experiments, where, typically, optimal pulses are extremely difficult to achieve. To this aim, our method could help to find easily implementable control signals (EICS) while still being able to satisfactorily fulfill the performance criterion we are interested in. Here with ‘EICS’ reference is made to pulses that can be utilized to control an experiment at the quantum level. More precisely, since nowadays the experiments are typically controlled by a computer, an obvious requirement for the control signal is that its Fourier spectrum has to match the bandwidth of the transducer or it cannot vary faster than the clock frequency of the processor. Besides this, since the computer during the course of the experiment controls some device (e.g., the applied voltage on electrodes or electric current [14, 15]), the control pulse has, for instance, to take into account the bandwidth of those devices. These conditions might not be satisfied by the OC pulse obtained with the aforementioned optimization algorithms. Even though, recently, some extensions of those optimization methods in order to include spectral constraints on the control pulses have been made [16, 17], these are not always easy to handle, especially when the dynamics of a many-body quantum system is concerned.

2. The method

Let us briefly review what is the purpose and what are the methodologies adopted commonly in the quantum control research area concerning closed quantum systems and the link between OC theory and analytical mechanics. The usual problem is the engineering of a system Hamiltonian \( \hat{H}(u_t) \) such that the initial state \( |\psi_{in}\rangle \) at time \( t = t_0 \) of the quantum system under consideration is brought at time \( t = T \) to some desired goal state \( |\psi_g\rangle \) (see also figure 1). To this aim, there are two (equivalent) techniques for searching optimal pulses at our disposal: the variational method and dynamical programming. In both cases, the goal is the minimization of the cost functional

\[
J_{\{t_0, u_t, |\psi_g\rangle\}} = G(|\psi_f\rangle) + \int_{t_0}^{T} dtC(t, u_t, |\psi_g\rangle) \tag{1}
\]

over all admissible control pulses \( u_t \) and state trajectories \( |\psi_g\rangle \equiv |\psi(t)\rangle \) given a certain initial state \( |\psi_{in}\rangle \). Here by admissible we mean any \( u_t \) for which the Schrödinger equation is well defined and has a unique solution \( |\psi_g\rangle \) given the initial condition \( |\psi_{in}\rangle \). The first term on the rhs of equation (1) is the terminal functional, e.g., the overlap infidelity \( 1 - |\langle \psi_g | \psi_{T}\rangle|^{2} \). The second term provides additional constraints on the control pulse\(^4\). In the variational method, the additional constraint \( \text{Re} \left\{ \int_{t_0}^{T} dt \left[ \langle \chi_t | \hat{H}(u_t) | \psi_t \rangle \right] \right\} \) is introduced [18], where we set \( \hbar \equiv 1 \) and \( |\chi_t\rangle \) is a Lagrange multiplier often referred to as costate, which ensures that the state \( |\psi_g\rangle \) satisfies the Schrödinger equation. The search for an extremum of the cost functional produces a set of equations for the state, costate and the control pulse.

On the other hand, dynamical programming, based on Bellman’s optimality principle [19], produces an equation, the so-called Hamilton–Jacobi–Bellman equation, for the optimal cost \( S(t, |\psi\rangle) := \inf_{u_t} J(t, u_t, |\psi\rangle) \). This equation is expressed in formally the same way as the Hamilton–Jacobi equation of classical mechanics, but with the difference that it is propagated backwards in time. The role of the Hamilton function in classical mechanics is played in control theory by the (quantum) Pontryagin Hamiltonian \( H(x, |\psi\rangle) := \sup_{u_t} \left\{ \text{Re} \left[ i \langle \chi_{t} | \hat{H}(u_{t}) | \psi_{t} \rangle \right] - C(t, u_{t}, |\psi_{t}\rangle) \right\} \) [20, 21], which is not to be confused with the system Hamiltonian \( \hat{H}(u_{t}) \) that we control through \( u_{t} \). From the Hamilton–Jacobi–Bellman equation, it is possible to retrieve the equations of motion for the state and the costate, the same as in the variational approach, which look, given the aforementioned Pontryagin Hamiltonian, formally as the Hamilton equations for the phase-space variables \((q, p)\) in analytical mechanics. Besides this, the solution of the Hamilton–Jacobi–Bellman equation, defined through the solution of the latter (the Hamilton boundary-value problem), is given by [21]

\[
S(t_0, |\psi_{0}\rangle) = G(|\psi_{f}\rangle) + \int_{t_0}^{T} dt \left[ \langle \psi_{f} | \chi_{t} \rangle - H(x_{t}, |\psi_{t}\rangle) \right], \tag{2}
\]

which is very similar to the action in classical mechanics. We note, however, that the variational approach, based on the so-called Pontryagin maximum principle [19], yields necessary

\(^{4}\) For instance, the ‘laser electric field fluence’ with \( C(u_{t}) = u_{t}^{2} \), where \( u_{t} \) is an electric field amplitude.
and sufficient conditions for local minima, whereas dynamical programming produces results that are globally optimal.

Motivated by this analogy between OC theory and analytical mechanics we can view the cost functional as an ‘action functional’. Indeed, in analogy to Hamilton’s principle where the actual evolution of a classical system is an extremum of the action functional, which produces the well-known Euler–Lagrange equations of motion, an extremum of $J$ produces the OC equations for the state and the costate.

Now, let us describe how our method works. To begin with, we fix the desired cost, $\mathcal{J}$, that the system (at least) has to attain. Since the advantage of optimizing quantum dynamics is connected with the possibility of reaching $|\psi_f\rangle$ by exploiting the interference of several paths in the space of control parameters $\mathcal{U}$, we define a path integral in such a space. To this aim, we introduce the weight $K = \int D[u_i] e^{i\mathcal{K}[u]}$, with $D[u]$ being some suitable measure on the space $\mathcal{U}$. The form of this weight resembles the Feynman propagator, which is motivated by the previous discussed analogy between analytical mechanics and OC theory, and by expression (2) for the optimal cost. The choice of the exponential, however, does not emerge from fundamental physical requirements. We think that any well-behaved function peaked around the OC pulse will allow us to estimate the robustness of an OC problem. This conjecture is based on the observation, see the discussion in the following, that according to our analysis the curvature of the cost functional around the optimal solution is the relevant quantity to analyse.

The numerical factor $\alpha$, given in the weight $K$, which we shall refer to as ‘infidelity tolerance’, has the following property: when $\mathcal{J}$ approaches (from above) the minimum of $J$, then $\alpha \to 0$. Hence, $\alpha$ is the analogue of $h$ in the Feynman path integral. Indeed, when $\alpha \to 0$ we retrieve the OC equations for the state and the costate we mentioned before. Besides this, we assume that $\alpha$ exists and is unique for a given OC problem, regardless of the form of the distortion $\delta u_t = u_t - u_t^\phi$. The uniqueness is first of all a necessary condition or else our method would be ineffective. There is, however, a deeper reason why we make such an assumption. This is more easily understood in the case where $\mathcal{C} \equiv 0$ in equation (1). In such a scenario, the cost functional relies solely upon the state at the final time $T$, that is, the cost functional will depend on some time integral of $u_t$ over $[t_0, T]$ (and eventually on other time integrals for its time derivatives over $[t_0, T]$ depending on the particular control problem one is interested in). Thus, minimizing the cost functional means finding the right conditions for those integral functionals which depend only on time $T$. Hence, the form of $u_t$ in the interval $[t_0, T]$ does not matter, if those functionals of the control pulse and its time derivatives fulfill the right conditions at the final time $T$. In this respect, the infidelity tolerance has to be independent of the distortion we utilize, that is, it is unique. This is also what is shown by the analysis carried out on the examples we will discuss later in the paper.

Even though it relies on the particular control problem we have at hand, from the above outlined discussion, at least in the most relevant cases for QIP where $\mathcal{C} \equiv 0$ in equation (1), the set of EICS, $\mathcal{A}$, is dense, since what matters is the fulfillment of the right conditions at the final time $T$. For instance, in the first example we are going to consider in the next section, that is, the optimal transport of a particle confined in a moving harmonic trap, $[22]$ has shown that if $u_t^\phi$ is the optimal solution then $\delta u_t^\phi = u_t^\phi + \alpha u_t^\phi \forall \alpha \in \mathbb{R}$ is optimal as well (here $\mathcal{J} = 0$, see also section 3). Thus, there is a group of optimal solutions, parametrized by the continuous variable $\alpha$, which is topologically dense. Similarly, this will occur for $\mathcal{J} \neq 0$, whose set of control pulses forms another (dense) subset $\mathcal{U}$ in $\mathcal{U}$. Each of these possible control signals will have a precise spectrum that has to be within the bandwidth of $\mathcal{U}$, namely the largest bandwidth of the elements of $\mathcal{U}$. Now, if the EICS needs to have a specific bandwidth, then one has to select from $\mathcal{U}$ the $u_t$ that have the right bandwidth, namely restrict (continuously) the bandwidth of $\mathcal{U}$ such that the right subset of $\mathcal{U}$ becomes $\mathcal{A}$, even though such a procedure might produce an empty set.

To be specific let us set, for the sake of simplicity, $t_0 = 0$ and consider only one control pulse $u_t : [0, T] \to \mathbb{R}$, that is, only one control pulse is applied to the system we aim to steer during the time interval $[0, T]$. We also assume that the state $|\psi_f\rangle$ obeys the Schrödinger equation with the time-dependent Hamiltonian operator $\hat{H}(u_t)$ and the initial condition $|\psi_0\rangle \equiv |\psi(0)\rangle$. Contrarily to (1), where the state $\psi$ is an independent variable, hereafter we render explicitly the dependence of $\psi$ on the control parameter $u_t$. Thus, we introduce the reduced cost functional $J[u] : = J[u, \psi(u)]$, Then by performing the Taylor expansion of $J[u]$ around $u_t^\phi$ to the second order in $\delta u_t$ we obtain

$$J[u] \approx J[u^\phi] + \frac{1}{2} \delta u_t H \delta u_t^\top + \mathcal{O}(\|\delta u_t\|^3), \quad (3)$$

where $\| \cdot \|$ is some norm in $\mathcal{U}$, $J[u^\phi]$ is the minimum, which, without loss of generality, we will set to zero, $\delta u_t^\top$ is the transpose of the vector $\delta u = (\delta u_2, \ldots, \delta u_{N-1})$, and the time interval $[0, T]$ is divided into $N - 1$ equal parts $\Delta t = T/(N - 1)$. The Hessian $H$ is a real, symmetric, and positive defined matrix, and therefore it can be diagonalized. Additionally, we assume the boundary conditions $\delta u_0 = \delta u_T = 0$, that is, the values $u_0$ and $u_T$ are fixed. We underscore that henceforth we shall work with the discretized system time evolution since in most cases the optimization of a given control problem is performed numerically, and therefore it is discretized, but most importantly, because any experiment is performed with a finite number of control time steps.

Given that, let us define a suitable norm in $\mathcal{U}$ for $\delta u_t$ by means of $K$, in order to obtain a quantitative appraisal of the tolerated error by a given OC scheme. A suitable choice for such a norm is given by $\|J\| = \|f[D[u_i] D[u]]\exp(\frac{1}{2} \mathcal{J}[u])\|$ with $\int D[u_i] = \lim_{N \to \infty} \int d\nu_{N-1} \ldots \int d\nu_2$. Because of the second-order approximation in equation (3), the integrals appearing in $\langle J \rangle$ over the control pulse at different times can be replaced (by making a change of integration variables) with $\delta u_k \forall k = 2, \ldots, N-1$. This norm is indeed an ‘average’ in $\mathcal{U}$ of the reduced cost functional itself with the exponential function being a ‘probability distribution’. A similar approach has been introduced by Rabitz $[23]$, where the terminal functional $G$ in equation (1) is averaged over a distribution function $P(\delta u_k)$. Within our method $P(\delta u_k)$ can
be identified with the exponential function in \( \langle J' \rangle \). We remark that we are not interested in some specific noise model, but rather to identify the portion \( \Omega \subset U \) which enables us to satisfy \( J' \leq J \). Basically, \( \Omega \) is determined by \( \langle J' \rangle \), which only relies on \( u_0^2 \) and \( J' \), and any kind of noise has to yield pulses such that \( u_0 \in \Omega \). Hence, our approach is applicable to any OC problem and cost functional (1). Furthermore, we consider only real-valued \( u_0 \) (e.g. an electric current [14]), but we underscore that the path integral can be easily generalized to complex-valued \( u_0 \) like the amplitude and the phase of a laser field.

Close to the optimal solution, we can approximate \( J' \) with its second-order expansion, and therefore the norm becomes

\[
\langle J' \rangle \approx \sqrt{\frac{\pi}{2}} \alpha_r \sum_{k=1}^{M} N_k \lambda_k, \tag{4}
\]

where \( N_k^{-1} = \prod_{j \neq k} \int d\xi_j e^{\xi_j^2/(2\alpha_r)} \) are the normalization factors and \( \lambda_k \) are the non-zero eigenvalues of \( H \) with \( M \leq N - 2 \). The above formula makes good sense because when \( \alpha_r \to 0 \) also \( \langle J' \rangle \to 0 \).

In order to apply the above-outlined formalism to some concrete example we shall consider hereafter \( J[u_0] = 1 - F(\psi_T) \), with \( F(\psi_T) = |\langle \psi_g | \psi_T \rangle|^2 \). We note that the state \( |\psi_T\rangle \) is implicitly depending on the whole history of \( u_0 \) \( \forall t \in [0, T] \). Assuming that \( F(u_0, \psi(u_0)) \) is a differentiable functional of its arguments, we have

\[
J'[u_0] = 1 - F(\psi_0) + 2 \int_0^T dt \text{Im}[\langle \psi_g | \psi_t | \hat{H}(u_t) | \psi_g \rangle]. \tag{5}
\]

Here, we used the fact that \( F(\psi_T) = F(\psi_0) + \int_0^T dt dF(\psi_t) \). The most difficult part of our method is the computation of the Hessian matrix \( H \). To this aim, we have two possibilities at our disposal: either we estimate \( H \) by means of the Broyden–Fletcher–Goldfarb–Shanno (BFGS) formula [24] or we compute the first and second derivatives of the state \( |\psi_t\rangle \) with respect to the control \( u_0 \). Here, we choose the latter approach, where we have to solve the following equations:

\[
\partial_\alpha |\delta^2 \psi_t \rangle + i \hat{H}(u_0^2) |\delta^2 \psi_t \rangle = -2i\delta \hat{H}(u_0^2) |\delta \psi_t \rangle - i\delta^2 \hat{H}(u_0^2) |\psi_0^2 \rangle, \tag{6}
\]

which apply to any quantum closed system. Here, \( |\psi_0^2 \rangle \) is the solution of the Schrödinger equation for \( \hat{H}(u_0^2) \), and \( \delta \hat{H}(u_0^2) \) and \( \delta^2 \hat{H}(u_0^2) \) are the Gateaux derivatives of the system Hamiltonian (defined as \( \delta \hat{H} = \lim_{\alpha \to 0} \frac{\delta \hat{H}[u, \text{re} \hat{u}^a] |_{u=0} }{\alpha} \)). These derivatives are always analytically computable, since the dependence of the system Hamiltonian \( \hat{H}(u_0) \) on the control pulse \( u_0 \) is always known, whereas the analytical dependence of both \( \delta^2 \psi_t \) and \( \delta \psi_t \) on \( u_0 \) is known only in few cases (e.g. the driven and parametric harmonic oscillator [25]).

Because of the latter, we need to solve equations (6) which allow us to determine the matrix \( H \). However, depending on the particular control problem, the BFGS method might be more efficient. Besides this, we note that the case of a linear quadratic regulator (or even Gaussian) control, that is, a system for which the state equation is linear and the performance criterion to be minimized is a quadratic form of the state and eventually also of the control pulse [19], is not contemplated in our scheme. Indeed, the system state \( |\psi_t\rangle \) is always dependent on the control pulse \( u_t \) through the Schrödinger equation of motion, even in the simple scenario where the system Hamiltonian \( \hat{H}(u_t) \) depends linearly on \( u_t \). Indeed, we are interested in the Hessian of the reduced cost functional \( J'[u] = J[u, \psi(u)] \), whose dependence on \( u_t \) might not be trivial through \( |\psi(u_t)\rangle \). Hence, the cases in which the Hessian relies only upon the state do not concern \( J'[u] \).

We also remark that the above-outlined formalism concerns state vectors in Hilbert spaces. If we were interested in the optimization of unitary transformations \( \hat{U}(t) = \hat{U}(u_t) \), then we should perform the Taylor expansion of \( F(\hat{U}(T)) = \frac{1}{2!} \text{tr} \{ \hat{U}_g^2 \hat{U}(T) \} \), where \( \hat{U}_g \) is the ideal unitary we wish to accomplish and \( d \) is the dimension of the Hilbert space. Thus, the previous analysis can be easily generalized to unitary operations.

3. Applications of the method

Let us first apply our method to an exactly solvable model. We consider the transport of a particle in a movable one-dimensional harmonic trap potential, for which the OC pulse and the functional dependence of the state on the controller are analytically known [22]. Such a control problem is of relevance for the realization of a quantum ion processor. Indeed, optimistic estimates show that transport processes may account for 95% of the operation time of a quantum computation [26]. Besides this, the harmonicity of the ion confinement in segmented Paul traps has been proven both numerically [27] and experimentally [28].

The system Hamiltonian is given by \( \hat{H}(u_t) = \frac{1}{2} \{ \hat{p}^2 + (\hat{x} - u_t)^2 \} \) with \( [\hat{x}, \hat{p}] = i \) (we use harmonic oscillator units). We focus our attention on the ground state, that is, when the particle is initially prepared in the lowest vibrational state of the trap. The aim is to transport such a state over the distance \( \Delta x \) in a time \( T \) such that \( |\psi_T(x) = e^{i\phi_1(x - \Delta x)}|\psi_g(x) \), where \( \psi \) is an unimportant phase factor and \( \phi_1(x) \) is the Gaussian harmonic oscillator ground-state wavefunction. Thus, our goal is to find a prescription such that when the OC pulse is perturbed the system has to reach at least the—a priori fixed—value of fidelity \( F \in [0, 1] \).

In [22] the analytic solution for the time-evolved state is provided. This enables us to compute analytically the Gateaux derivatives of the state of the system without the need of solving (6). In figure 2(a), we show results for a distortion given by: \( \delta u_t = a \sin(\kappa \pi t / T) u_0^2 \), with \( a_0^2 \) being the OC pulse of [22] (see equation (5) therein). Such simple distortion modulates the OC pulse at the rate \( \kappa \) and gives a direct quantitative measure of the distortion degree applied to \( u_0^2 \); the larger \( a \) is, the larger the infidelity. Thus, figure 2(a) shows the largest admissible value of \( a \) for a fixed value of the (reduced) cost functional, whereas in the inset we show the deviation from the linear behaviour of \( 2\Delta J' = 6uH \delta u^T \) for \( \kappa = 1 \).

Now, we write the cost functional as \( 2J[u_0] = 6uH \delta u^T \). In this specific example, it turns out, numerically, that the
Secondly, we perform a fit of the obtained curve for $\alpha$, as a function of the overlap infidelity. For the present example, as shown in figure 2(b), we found that the following function well represents the data: $\alpha = a(1-F) + b\sqrt{1-F}$, with $a = 0.130$ and $b = 0.029$. Given that, all distortions of the OC pulse that satisfy the inequality $\delta u_\text{H} \delta u_\text{T} \leq \sqrt{\pi \lambda_0^2 N_k^2/(2\lambda_0)} =: \epsilon(F)$ for a fixed (a priori) value of a desired fidelity $F$ will yield an overlap fidelity $F(\psi_T) \geq F$. From an operational point of view, this means that if we randomly choose a distortion $\delta u_\text{T}$ such that $I = [\delta u_\text{H} \delta u_\text{T} \sqrt{2\lambda_0^2/(N_k^2\pi)}]^{2/3} / \alpha_\text{T} \leq 1 - F$, then we will certainly attain a state $|\psi_T\rangle$ whose overlap fidelity is greater than $F$ (see also figure 1). This permits us to find control pulses that might be more appropriate for an experimental implementation. This conclusion follows from the procedure we established for the determination of the infidelity tolerance $\alpha$. We underscore, however, that the threshold $\epsilon(F)$ depends only on $u^2_T$, because $\text{H}$ relies only on $u^2_T$, and that it is the result of an average in $U$ through the path integral we defined. This provides a ‘universal’ character to $\epsilon(F)$ for the given control problem.

As a second example, we consider the Landau–Zener model which has been proven useful to describe the tunnelling of Bose–Einstein condensates in accelerated optical lattices [29] and the dynamics of a quench-induced phase transition in the quantum Ising model [30]. The model is described by the following system Hamiltonian: $\hat{H}(u) = u_\text{H} + \Omega u_\text{T} \sigma_x$, where $\sigma_\text{X}, \sigma_\text{Z}$ are Pauli matrices. The goal is to bring the system from the ground state $|\psi^\text{g}\rangle$ to the ground state $|\psi^\text{f}\rangle$ of the Hamiltonian $\hat{H}(u)$ through the avoided level crossing. As objective functional we consider $J(u) = 1 - \text{Re}[|\psi^\text{f}\rangle \langle \psi^\text{f}||\psi^\text{g}\rangle]$, that is, we also control the phase of the state. Even though the analytical dependence of the system Hamiltonian $\hat{H}(u)$ is known, and therefore the Gateaux derivative $\delta \hat{H} = (\delta \sigma_\text{X}, \delta \sigma_\text{Z})$, for such a control problem, both $u^2_T$ and the dependence of $|\psi_T\rangle$ on $u_T$ are not analytically known. Concerning the latter, this implies that it is not possible to compute analytically the Gateaux derivatives $\delta |\psi\rangle$ and $\delta^2 |\psi\rangle$, and therefore the Hessian $\text{H}$. Hence, we need to solve (6). Given that, we seek an $u^2_T$ by using the Krotov iterative method [1, 31]. We then proceed, as in the former example, by determining the infidelity tolerance $\alpha$, for which we obtain a similar fit $\alpha = a(1-F) + b(1-F)^c$ with $a = 0.016$, $b = 0.047$ and $c = 0.650$. The criterion to be satisfied is then again given by $\delta u_\text{H} \delta u_\text{T} \leq \epsilon(F)$, but with a different numerical value for $\epsilon(F)$.

In figure 3, the exact results of the infidelity (red dashed-dotted) and the second-order approximation $I$ (black) for 50 random realizations of $\delta u_\text{T}$ for a distortion similar to that of figure 2(a) are shown. Instead, the desired upper limit of infidelity $1 - F = 0.01$, that the system has at least to attain, is represented by the horizontal thick blue line. Analogous to the former example, only the realizations of $\delta u_\text{T}$ that fulfill $\delta u_\text{H} \delta u_\text{T} \leq \epsilon(0.99)$ have an infidelity below 1%. As for the previous example, the single-frequency model has been adopted for convenience in order to illustrate the effectiveness of our approach as depicted in figure 3. Such a choice, however, does not invalidate our methodology, which we

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure2}
\caption{(a) Distortion amplitude $a$ (see the text) versus infidelity. Inset: the second-order Taylor expansion of $J(2\Delta^2 J[a^2, \delta u_T, \delta H_k] \equiv \delta u_\text{H} \delta u_\text{T}$) versus the reduced cost functional itself (red dashed, $\kappa = 1$) for different values of the distortion amplitude $a$, whereas the black line is a guide to the eye that helps to see when the second-order approximation holds. (b) Infidelity tolerance parameter $\alpha_\text{T}$: the solid (black) line represents $[2\lambda_0^2(2\Delta^2 J[a^2, \delta u_T, \delta H_k]/\pi^2]^2$, whereas the red (dashed–dotted) line is a fit.}
\end{figure}
have tested for a Fourier-like distortion model (i.e. a sum over a finite number of harmonics with different amplitudes), similar to the above-outlined determination of the infidelity tolerance.

In general, in order to identify robust control pulses amenable to an experimental implementation one should proceed as follows: (1) determine the OC $u_0^\alpha$ with some numerical optimization algorithm; (2) compute the eigenvalues of the Hessian matrix $H$; (3) determine the infidelity tolerance $\alpha_1$ as described in the first example; (4) randomly generate distortions $\delta u$ such that the condition $I = \left[ 2 \left( \frac{\pi a_0^2}{2} \right) \sum_{k=1}^{\infty} \frac{\sin(\pi k)}{\pi k} \right]^{-1} \delta u H \delta u^T)^{1/3} < J$ is fulfilled for a fixed (a priori) value of $J$; (5) define the new control pulse as $u = u_0^\alpha + \delta u$; (6) choose the most suitable control pulse to be employed in the laboratory from the ensemble $E = \{u\}_{u < J}$. We note, however, that such a ‘recipe’ does not guarantee that we are able to obtain with certainty a control pulse more amenable for use in an experiment, but at least it helps to design new ones that are still able to yield a value of the cost functional below the fixed threshold $J$. In other words, the set $E \cap A$ might be empty, and the elements of $E$ are not necessarily close to the optimal $u_0^\alpha$ (e.g. see [22]). In this respect, such a procedure might help the quest of both robust and experimentally feasible pulses for controlling different quantum phenomena.

4. Conclusions

In conclusion we have presented a method to assess the error of solutions to OC problems. The method might be a helpful tool for experimentalists in order to design experiments robust against a source of noise. For instance, to estimate how robust the schemes for realizing quantum gates are against imperfections of the optimal pulse shape. Compared to other methods, such as the one of [13], our technique does not need the simulation of a large ensemble of samples in order to minimize on average both the mean and the variance of the objective functional. Instead, once the Hessian matrix $H$ and the infidelity tolerance $\alpha_1$ are known, which only rely on the optimal (known) control pulses, one has simply to randomly generate the distortion $\delta u$ and perform the matrix multiplication $\delta u H \delta u^T$, which is a less demanding computational task than the application of a genetic algorithm, such as the one proposed in [13]. Besides this, our method can be applied to both known error models and to evaluate unknown errors such as random telegraphic noise. For the future, we plan to extend our formalism to dissipative quantum systems (e.g. systems governed by the Born–Markov master equation).

Acknowledgments

We acknowledge financial support by the IP-SOLID and the National Research Foundation and Ministry of Education Singapore (R F), IP-AQUTE and PICC (T C), SFB/TRR21 (A N,T C), the Marie Curie program of the European Commission (Proposal No. 236073, OPTIQUOS) within the 7th European Community Framework Programme and the Forschungsfond of the University of Ulm and of the UUG (AN). AN acknowledges conversations with K Urban, J T Stockburger, and I Kuprov.
