Abstract

Wound healing requires the vasculature to re-establish itself from the severed ends; endothelial cells within capillaries must detach from neighboring cells before they can migrate into the nascent wound bed to initiate angiogenesis. The dissociation of these endothelial capillaries is driven partially by platelets' release of growth factors and cytokines, particularly the chemokine CXCL4/platelet factor-4 (PF4) that increases cell-cell de-adherence. As this retraction is partly mediated by increased transcellular contractility, the protein kinase c-σ/myosin light chain-2 (PKCσ/MLC-2) signaling axis becomes a candidate mechanism to drive endothelial dissociation. We hypothesize that PKCσ activation induces contractility through MLC-2 to promote dissociation of endothelial cords after exposure to platelet-released CXCL4 and VEGF. To investigate this mechanism of contractility, endothelial cells were allowed to form cords following CXCL4 addition and exposure to platelet-released CXCL4 and VEGF. To investigate this mechanism of contractility, endothelial cells were allowed to form cords following CXCL4 addition and exposure to platelet-released CXCL4.

Introduction

Wounds prevent skin from acting as a barrier between the body and external harsh environment, a vital function that must be quickly re-established during wound repair. This repair requires a healthy vascular system for both tissue generation and subsequent maintenance. Blood vessels are compromised during wounding which require angiogenesis from the tips of severed vessels for regeneration. This is driven by pro-angiogenic growth factors released first by platelets and then by macrophages in the wound. Endothelial cells that are involved in angiogenesis require initial signals to ‘dedifferentiate’ and separate from the existing severed vessels prior to subsequent inductive signals to migrate into the wound bed. These early wound response signals to initiate angiogenesis are mediated through platelets during clotting including the chemokine CXCL4 and growth factors VEGF, PDGF, HB-EGF, and TGFβ [1].

Many of the intracellular signaling pathways that drive fibroblasts and endothelial cells to migrate are known. Downstream of growth factor receptor activation, PLCγ1 signaling triggers PKCσ to regulate cell motility via increasing transcellular contractility in fibroblasts and endothelial cells [2–8]. Growth factor and matrikine signaling through the epidermal growth factor receptor (EGFR) initiates motility via phosphorylation and activation of PLCγ1 at the membrane [3]. Activated PLCγ1 then catalyzes the hydrolysis of PIP2 (primarily at the leading edge of the membrane) and generates diacylglycerol (DAG) and IP3 [9,10]. Increased levels of DAG at the leading edge [11] synergizes the effect of PKCσ to the membrane [12]. DAG subsequently stabilizes the activation of PKCσ through direct binding of its N-terminal C1 domain [13–15]. Furthermore, PKCσ localization behind the leading edge allows it to propel the cell body towards the extended lamellipodium and also mediate isometric force associated with motility [16]. It has also been previously demonstrated that downstream of PKCσ signaling, an intermediate kinase, specifically myosin light chain kinase (MLCK), relays signaling to MLC through direct phosphorylation [8]. Further supporting EGFR induced regulation of contractility, it was demonstrated that reduced activation of PLCγ1 delayed subsequent activation of PKCσ and downstream MLC-2 [8]. These data have shown that EGFR triggers contractile responses efficiently and quickly through the PLCγ1/PKCσ pathway.

These findings led us to ask whether such a pathway could also account for the initial retraction of severed vessels prior to angiogenic sprouting. Increased PKCσ activation has also been shown to increase vascular permeability [17–19], consistent with cell-cell de-adherence. Inhibition of PKCσ results in downregulation of stress fibers and focal adhesions in endothelial cells [20]. In addition, steady-state activation of stress fiber tension by PKCσ has been found to strengthen the endothelial cell barrier [21,22]. All of these data implicate biphasic PKCσ regulation in maintaining vascular permeability. Furthermore, MLCK that is downstream of PKCσ is involved in endothelial retraction through
MLC-2 phosphorylation. These signals initiating endothelial retraction may be essential for the initial phases of endothelial cell separation from damaged vessels prior to angiogenic sprouting. However, the mechanism in which PKCδ mediates endothelial cell retraction has not been determined.

Therefore, we hypothesized that PKCδ regulates the tension of endothelial cords by promoting cell retraction during neoangiogenesis through VEGFR signaling in addition to CXCL4 mediated retraction.

Results

CXCL4-VEGF-induced dissociation is VEGFR-dependent

To investigate endothelial CXCL4-mediated dissociation, we used human microvascular endothelial cells (HMEC-1) plated on Matrigel. Cell cords were given 24 hours to form and then subsequently induced to dissociate with CXCL4 and VEGF, two factors released by platelets during the initial stages of hemostasis. Inhibition of VEGFR/PDGFR signaling using sunitinib (2.5 µM) inhibited dissociation, as demonstrated by longer cord length (Fig. 1). In addition, CXCL4 had a more pronounced effect than VEGF on mediating tube dissociation (Fig 1).

VEGFR/CXCL4-induced dissociation is partially PKCδ-dependent

Tube dissociation involves the separation of cell-cell contacts, we therefore investigated whether transcellular contractility involves PKCδ, a key signaling nexus in contractility and tension [7,8]. Dissociation was blunted by downregulation of PKCδ. Formed cords were stimulated to dissociate with CXCL4 and VEGF in the presence or absence of antisense towards PKCδ. Endothelial cord length reduction by CXCL4/VEGF was partially rescued by antisense against PKCδ (Fig. 2a). PKCδ downregulation attenuated cord dissociation to a significantly lesser degree. In addition, the antisense decreased PKCδ and MLC-2 levels that are downstream of PKCδ regulation (Fig. 2b, Fig 2c). In addition, adult primary endothelial cells were investigated, as we found that MLC-2 was also down regulated through rotterlin inhibition, a PKCδ inhibitor (Fig. 2d). In response to VEGF/CXCL4, ppMLC-2 levels in adult primary endothelial cells were increased, in contrast to CXCL4 only treatment (Fig 2d). To further investigate endothelial cords themselves for increased contractility, HMEC-1 endothelial cord lysates were analyzed in which showed increased MLC-2 levels in response to VEGF/CXCL4 (Fig. 2e). These data indicate that PKCδ affects MLC-2 expression in a VEGF-dependent manner, which in turn correlates with its regulation of stress fibers.

Dynamics of endothelial cords/capillaries tension require PKCδ-dependent motility of cords and individual cells

Cell motility is critical for vessel formation and vessel regression [23]. To further investigate the role of PKCδ activation during VEGF/CXCL4 mediated dissociation, adult primary endothelial cords were induced to dissociate in the presence of rotterlin (500 nM). Cord motion that is a part of the process of vessel maturation was observed in both groups, however PKCδ inhibition through rotterlin reduced cord mobility (Fig 3, Sup. Movie 1,2). According to these data, dissociation was mediated by the motility of the cells and PKCδ-dependent regulation of cytoskeleton/isometric contractions.

We further investigated cord dissociation/mobility and found increased mobility and contractions in cords that were treated with

Figure 1. VEGFR inhibition decreases CXCL4-induced cord dissociation. a) Representative phase contrast images of HMEC cells treated with indicated treatments are shown. Images were taken of live cords after 24 hours. Disruption in webbed patterning of cells indicates increased dissociation. b) Images described in (Fig 1a) were quantified as described in methods using Metamorph analysis software (N at least 4; mean ± SD, ** P<0.05), Shown are representative of 3 experiments.
doi:10.1371/journal.pone.0093968.g001
CXCL4/VEGF (Movies S3, S4). In addition, increased force was exerted onto the Matrigel by the endothelial cells, as shown by the deformation of the substratum noted in live cell imaging via phase contrast microscopy. Individual endothelial cells at their junctions were compressed and spheroid as this morphology appeared to enable the necessary movements for increased mobility for subsequent cord collapse (Movie S4).

**Activation of PKCδ is increased during CXCL4/VEGF-induced dissociation of endothelial cords**

To further investigate whether PKCδ was activated during dissociation, levels of PKCδ and activated (or phosphorylated) PKCδ were measured in endothelial cords. In CXCL4+VEGF-induced cells, this ratio was increased at junctions with increased phosphorylated PKCδ at junction edges and decreased PKCδ in the inner part of the junction (Fig 4a). In addition, in CXCL4 only- and CXCL4+VEGF-mediated dissociation, endothelial cells with a spheroid morphology and increased levels of activated PKCδ were also observed. Although PKCδ has been shown in previous literature to mediate apoptosis [24,25], it seems that these cells may actually alter their mesenchymal phenotype to incorporate into the cords and to actively mediate tension at junctions (Fig 4b, Movie S4). This would be consistent with our finding that PKCδ directing cell contractility [7]. These data imply that activation of PKCδ is associated with force generation and possibly force mechanics in endothelial cord dissociation.
Mechanotransduction of VEGF/CXCL4 induced cord dissociation is PKCδ-dependent

Cord dissociation involves multiple intercellular forces which coordinate the subsequent collapse of capillaries. To confirm that force impacts the endothelial cords molecularly, focal adhesions/junctions were examined as cellular locations affected by CXCL4/VEGF-induced dissociation. As a focal adhesion protein, the zyxin protein has been previously found regulated in response to vascular stretch. In this study, zyxin was used to investigate mechanosensory input into the cords as they dissociate. The investigation of zyxin showed that its expression is linked to PKCδ activity, as inhibition of PKCδ caused increased zyxin expression in 2D monolayer (Fig 5a). Furthermore, downregulation of PKCδ with antisense oligonucleotides in formed endothelial cords led to increased zyxin expression (Fig 5b). These data suggest focal adhesions are dynamically regulated when force is induced. Furthermore, PKCδ that is inhibited by a dominant negative construct causes focal adhesions to stabilize, thus contributing to inhibition of cord dissociation.

These data suggest that force signaling through VEGFR is applied during cord dissociation through motility signaling via PKCδ. Signaling through VEGFR causes PKCδ to elicit both static and dissociative regulation of force for endothelial capillary stability and dissociation, respectively.

Discussion

The CXCL4 receptor, CXCR3, primarily regulates endothelial capillary dissociation through calcium regulation. When calcium channels are stretch-activated, u-calpain is activated that results in cleavage of focal adhesions leading to cell de-adherence and subsequent anoikis/apoptosis [26]. In this study, we investigated VEGFR signaling to PKCδ as a non-direct molecular mediator of CXCL4-induced cord/capillary dissociation. Based on the results of this study, PKCδ that is activated downstream of VEGFR tyrosine kinase signaling plays a role in endothelial cell dissociation (Fig 1). Attenuation of cord dissociation through inhibition of VEGFR and PKCδ indicates that, for full dissociation of cords on Matrigel, VEGFR signaling through PKCδ is required (Fig 1a, Fig 1b). VEGFR regulation also mediates increased regulation of PKCδ, as seen in our data when PKCδ levels were upregulated (Fig 1d). PKCδ regulation of contractility through MLC-2 was observed in data where PKCδ antisense and PKCδ antisense caused MLC-2 downregulation after CXCL4-VEGF treatment (Fig 1d). However, the effect of PKCδ antisense was lower, and may affect PKCδ activity indirectly through an unknown mechanism. We further inhibited the dissociation response using the pharmacological agent rottlerin and by causing the cell cords to become static and non-motile (Movie S1, S2, Fig 3). Since motility is essential for cord formation, our data also highlight the importance of cord integrity (Movie S3), which translates to cord retraction and dissociation (Movie S4).

PKCδ activation was also investigated during cord dissociation. The ratio of activated PKCδ to PKCδ was increased at junctions in CXCL4-VEGF-treated cells (Fig 4). Moreover, some cells that were activated with PKCδ were circular and were centrally located within junctions (Fig 4). It is interesting to consider whether these cells are functionally important in integrating cord force as the cords dissociate or move. Further experiments are needed to fully test this hypothesis. If further investigation supports this idea, it would offer new insight into how PKCδ regulates motility and force in microvasculature.

We further showed that cord motility and dissociation are directly linked to PKCδ regulation. PKCδ seems to contribute to dissociation more by affecting the plasticity of active movement than by disrupting intracellular junctions mediated by calpains (Fig 1). In this investigation, we show that PKCδ regulates dissociation through VEGFR to PLCγ1 signaling. However, it remains unknown whether force signaling is directing the dissociation, or recursively responding to force regulation. Both situations require PKCδ, but in a different context. These results also demonstrate that motility mechanisms seen in 2D migration play an important role in multi-cellular tissue. Increased calcium signaling perpetuates increased contraction and de-adhesion, while VEGFR signaling is also mediating and directing contractions through PKCδ signaling.

After dissociation has occurred, stabilization of PKCδ may still mediate further contraction of cords in the right context [21,22,27]. As cords shift to a more stabilized and quiescent cellular state, signaling from VEGFR and other receptors with intrinsic tyrosine kinase activity continues in order to further activate downstream mediators of PKCδ. These events fine-tune the development of a normal vascular structure and help stabilize autocrine signaling. Alternately, angiogenic driven VEGF stimulation induces upregulation of PKCδ that would result in destabilization of the vasculature, with the separated endothelial cells now being responsive to motile signaling. This is combined with extracellular signaling of other molecular mediators and regulation by the stroma, allowing for remodeling of the wound bed. Lastly, pericytes also regulate the microvasculature with force regulation [28,29]. Studies investigating how pericytes regulate cord stability/dissociation would further elucidate how force signaling is modulated in vivo. Such studies represent the next step in discerning the function of cord mobility in vascular regeneration.

Methods

HMEC-1 cell culture

HMEC-1 (human dermal microvascular endothelial cells) were obtained from CDC, Atlanta, Georgia, originally described by Ades et al [30]. Endothelial cells were grown in MCDB 131 (Gibco) media with 10 mM L-glutamine supplemented with 10% fetal bovine serum. For stable expression of the zyxin protein,
HMEC-1 cells were transfected with 4 ug of GFP-Zyxin plasmid (obtained from Origene) with 10 uL of lipofectamine in 6 well dish with subconfluent cells. Stable selection of Zyxin focal adhesion markers in HMEC-1 cells was established with neomycin selection (350 ng/mL) as cells were passaged.

Adult-Dermal Human Microvascular Endothelial Cell culture
Primary human endothelial cells were obtained from (Life Technologies) and were grown in EGM-2MV Media, (Lonza). Cells were grown 5 passages prior to incubating cells in quiescent media for 24 hours before experiment.

Matrigel tube formation assay
Cells were grown to 50% confluency prior to seeding onto Matrigel. Growth Factor Reduced (GFR) Matrigel (BD Biosciences) was seeded onto a u-chamber slide at 10 ul per well or 120 ul per well on a 24-well plate and incubated for 30 minutes at 37°C for polymerization. Cells were then re-plated onto Matrigel at 75,000 cells per well (on the 24-well plate) or 15,000 cells per well (on the u-chamber slide, Ibidi) for 24 hours. Cords were grown overnight in quiescent media 0.5% FBS. Afterwards, endothelial cords were allowed to dissociate with VEGF-165 Recombinant growth factor and Recombinant CXCL4 (Pepro-Tech), which were added at 2.5 nM and 100 nM respectively after 24 hours (or as indicated by the time points given in figure/movie). Some experiments were quantified for cord length by adding 2.5 uM Cell Tracker Green for better quantification.

Antisense inhibition
DNA oligonucleotides sequences targeting PKCθ and PKCα were obtained from the literature [31,32] and ordered from IDT; phospho-thioate bonds were added to the end nucleotides. Oligonucleotides sense and anti-sense of human PKCθ are GTGGCATGATGGAGCCTTTT and 5’TTCCTCGAGG-TAGTACCCTG-3’, respectively. Oligonucleotide sense and antisense PKCα are 5’-CGGGCAACGACTCCAGCGG-3’ and ‘5-CGG CGT GGA GTC GTT GCC CG-3’, respectively. DNA oligonucleotides at 20 uM were added after HMEC cords were formed in quiescent media, and additional antisense was added to the cells via lipofectamine (10 uL) for 0.5 ug of DNA in 500 ul of OPTI medium per sample in 6 well plate. DNA/Lipofectamine was added to quiescent media overnight prior to growth factor/cytokine treatment.

Live cell imaging
HMEC-1/Primary endothelial cells were grown and plated in a 6 well glass bottom plate on Matrigel at 75,000 cells per well and incubated in quiescent media overnight. Endothelial cords that formed were treated with indicated treatments and immediately added to live cell chamber with 5% O2, 5% CO2, or 90% N2 at 37°C. Primary endothelial cells (Fig. 3, Movie S1, Movie S2) were imaged for 7 hours and HMEC-1 cells were imaged for 1 hour and 20 minutes at 5 minute intervals (Movie S3 and Movie S4). Images were taken of endothelial cords on top of Matrigel with a Nikon Eclipse Ti live cell imaging microscope at 10× and 20× objective respectively as size bars are indicated in live cell imaging movies.

Figure 4. PKCθ is activated during cord dissociation. a/b) Immunostaining of HMEC endothelial cells formed into cords onto Matrigel treated with indicated treatments for 24 hours after cords are formed. a) Merged representative images of activated PKCθ (red) and PKCα (green) for indicated treatments. b) Representative image of CXCL4 100 nM/VEGF 2.5 nM treated cord that was immunostained with PKCθ and phospho-PKCθ indicated in green and orange separate images. Cells were also stained for nuclei with DAPI staining represented as blue and actin with phalloidin staining (Alexa-633) represented in pseudo-color yellow. Representative image of a larger cord indicates increased effects of force translated in the ratio of activated PKCθ to PKCα. Arrows of increased phosphorylated PKCθ expressing cells indicates positioning of possibly active cells at branch points of cords.
