ABSTRACT
We consider a framework for non-ideal magnetohydrodynamics in general relativity, paying particular attention to the physics involved. The discussion highlights the connection between the microphysics (associated with a given equation of state) and the global dynamics (from the point of view of numerical simulations), and includes a careful consideration of the assumptions that lead to ideal and resistive magnetohydrodynamics. We pay particular attention to the issue of local charge neutrality, which tends to be assumed but appears to be more involved than is generally appreciated. While we do not resolve all the involved issues, we highlight how some of the assumptions and simplifications may be tested by simulations. The final formulation is consistent, both logically and physically, preparing the ground for a new generation of models of relevant astrophysical scenarios.

Key words: stars: neutron, hydrodynamics, MHD

1 CONTEXT
Electromagnetic phenomena are central to neutron star astrophysics, with issues ranging from the formation and evolution of the star’s internal magnetic field through to the elusive pulsar emission mechanism and the violent dynamics associated with supernova core collapse and binary mergers. The intimate connection between highly dynamical events and powerful observed gamma-ray bursts provides ample motivation to improve the available simulation technology. In this respect, there has been notable progress towards realistic numerical simulations of neutron star mergers in full nonlinear general relativity (with the live spacetime required by Einstein’s theory, see Baiotti & Rezzolla (2017); Bernuzzi (2020) for reviews). In particular, given the problem we focus our attention on here, there has been interesting recent work on the role of the magnetic field. Most current efforts remain within the regime of ideal magnetohydrodynamics (see for example Cipolletta et al. (2021)), but there have also been attempts to account for non-ideal effects, like resistivity and viscous dissipation (Palenzuela et al. 2009; Dionysopoulou et al. 2013; Wright & Hawke 2020). Steps in this direction are important as they take us towards a more detailed implementation of the physics, which is always desirable. In particular, we need to be able to quantify to what extent these (complicating) aspects may leave an observational signature. If they do not, then we can “get away” with a simpler treatment. The argument is straightforward but it raises a number of thorny issues. Not only do we need a better handle on what the input physics should be, we also need to understand to what extent simulations are able to faithfully represent these aspects. Neither of these issues are trivial.

An important part of the discussion links the microphysics (represented by the matter equation of state) to the large-scale dynamics. This inevitably involves considering the composition and state of matter, as well as different possible “flows” (associated with heat, charge currents and possibly superfluidity) that enter the problem. The recent work of Andersson et al. (2017a,b,c) (see also Andersson (2021)) represents a coherent effort in this direction, outlining a flexible multi-component framework (at the level of fluid dynamics) that allows us to represent different aspects of the problem. The results set the scene for more detailed considerations by providing both a fibration perspective—suitable for the local fluid dynamics (Andersson et al. 2017b)—and a foliation description, geared towards spacetime simulations (Andersson et al. 2017c). This paper aims to clarify the connection between the two pictures. Adding context and depth to the previous work—paying particular attention to issues relating to the assumptions associated with magnetohydrodynamics and local charge neutrality on different relevant scales—our discussion takes us another couple of steps towards realism.

Throughout the discussion, we adopt the convention that spacetime indices are represented by $a, b, c, \ldots$ while $i, j, k, \ldots$ are spatial indices in a chosen coordinate frame. The Einstein summation convention is assumed for both sets.

where \( \alpha \) and \( \beta \) represent the lapse and the shift, respectively (see fig. 1). The spatial metric \( \gamma_{ab} \) acts as a projection orthogonal to \( N^a \) and is used to introduce a suitable derivative in each spatial hypersurface

\[
D_i = \gamma^b_{\ i} \nabla_b ,
\]

where all free indices should be projected. We also introduce the Christoffel symbols \( \Gamma^i_{jk} \) associated with \( \gamma_{ij} \), ensuring the compatibility \( D_i \gamma_{jk} = 0 \). Moreover, if \( \gamma \) is the determinant of the induced metric, then

\[
D_i \gamma^{1/2} = \partial_i \gamma^{1/2} - \Gamma^1_{ij} \gamma^{1/2} = 0 .
\]

We also need the extrinsic curvature

\[
2 \alpha K_{ij} = - (\partial_i - \mathcal{L}_\beta) \gamma_{ij} ,
\]

where \( \mathcal{L}_\beta \) is the Lie derivative along \( \beta^i \). We then have

\[
\mathcal{L}_\beta \gamma_{ij} = \gamma_{kj} D_i \beta^k + \gamma_{ik} D_j \beta^k = D_i \beta_j + D_j \beta_i ,
\]

and it follows that the trace of the extrinsic curvature satisfies

\[
\alpha K = - \partial_t \ln \gamma^{1/2} + D_i \beta^i .
\]

Turning to the equations of electromagnetism, let us (for clarity) assume that we opt to work with the electric and magnetic fields. (An alternative description based on working with the vector potential can be found in Baumgarte & Shapiro (2003), with recent implementations discussed by Etienne et al. (2020); Cipolletta et al. (2021).) These are (obviously) observer dependent quantities. In terms of the Faraday tensor \( F_{ab} \) an Eulerian observer (associated with \( N^a \)) will measure the electric field

\[
E_a = - N^b F_{ba} ,
\]

and the magnetic field

\[
B_a = \frac{1}{2} \epsilon_{abc} F^{bc} ,
\]

where we have defined

\[
\epsilon_{abc} = \epsilon_{dabc} N^d ,
\]

(associated with a right-handed coordinate system moving along with \( N^a \)). This then leads to

\[
F_{ab} = N_a E_b - N_b E_a + \epsilon_{abc} B^c .
\]

Clearly, the electric and magnetic fields are orthogonal to \( N^a \) (by construction) and so each will have only three components (as expected).

The equations that govern the electromagnetic field are (obviously) well known, so we simply draw on the results from Andersson et al. (2017c). First of all, we need to introduce the Eulerian frame decomposition of the charge current

\[
j^a \equiv \dot{\phi} N^a + j^a , \quad j^a N_a = 0 .
\]

The charge current actively generates and sustains the electromagnetic field. Yet, much of the astrophysics literature assumes that the charge current plays a more passive role. This step—one of the assumptions that leads to magnetohydrodynamics—is important. It effectively reduces the problem from a multi-component plasma (see Andersson (2012) for discussion and pointers to the relevant literature) to a “single-fluid” model that is easier to work with. The arguments in favour of this strategy are well developed in
non-relativistic physics (Mestel 1999), but the extension to
general relativity tends to be made by analogy rather than
in-depth analysis. Given this, we will pay particular attention
to issues related to the charge current in the following.

Maxwell’s equations follow from, first of all
\[ \nabla_b F^{ab} = \mu_0 j^a , \] (12)
which, from the foliation perspective, leads to a relation be-
tween the divergence of the electric field and the charge den-
sity \( \dot{\sigma} \)
\[ D_i E^i = \mu_0 \dot{\sigma} , \] (13)
where \( \mu_0 \) is the magnetic permeability. Here, and in the fol-
lowing, we use the same matter quantities as in Andersson et al. (2017c) and—in order to make clear the distinction—retain the convention of using hats to denote matter quantities measured by Eulerian observers (while the correspond-
ing electric and magnetic fields are given as capital let-
ters). It is also worth noting that, since we are assuming \( c^2 = 1/\mu_0 \varepsilon_0 = 1 \) we recover the standard form for Gauss’
\[ \varepsilon_0 \dot{E}_i = \frac{\dot{\sigma}}{\varepsilon_0} . \] (14)

We also have an evolution equation for the electric field \(^1\)
\[ \left( \partial_t - \mathcal{L}_\beta \right) E^i = \varepsilon^{ijk} D_j (\alpha B_k) + \alpha \mu_0 \dot{J}^i = \alpha K E^i . \] (15)
The second pair of Maxwell equations follow from
\[ \nabla_\alpha F_{bc} = 0 . \] (16)
Given the absence of magnetic monopoles, we have
\[ D_i B^i = 0 , \] (17)
while the magnetic field evolves according to
\[ \left( \partial_t - \mathcal{L}_\beta \right) B^i + \varepsilon^{ijk} D_j (\alpha E_k) = \alpha K B^i . \] (18)

It is important to keep in mind that, in practice, these equa-
tions refer to a computational cell on a specified numeri-
cal grid. There is no actual observer that moves through spacetime with four-velocity \( N^a \). This is obvious, but de-
serves emphasis as a typical grid resolution involves a fluid
“box” that is much larger than the fluid “elements” of the un-
derlying fluid model. The relevance of this should (hopefully)
become clear as we proceed.

2.2 Towards magnetohydrodynamics

Astrophysical problems tend to be considered in the context of magnetohydrodynamics. As we want to understand the
physics of the problem, it is useful to spell out how this sim-
pifies the equations. The argument is fairly straightforward.
Let us assume that the dynamics is associated with character-
istic length- and timescales, \( L \) and \( T \), leading to an associated
velocity \( V \sim L/T \) (noting that \( K \sim 1/T \) and \( \mathcal{L}_\beta \sim 1/T \)). It then follows from eq. (18) that
\[ \left( \partial_t - \mathcal{L}_\beta - \alpha K \right) B^i + \varepsilon^{ijk} D_j (\alpha E_k) = 0 \]
\[ \sim B/T \]
\[ \sim E/L \]
\[ \implies B \sim E/V . \] (19)

Similarly, it follows from eq. (15) that
\[ \left( \partial_t - \mathcal{L}_\beta - \alpha K \right) E^i - \varepsilon^{ijk} D_j (\alpha B_k) + \alpha \mu_0 \dot{J}^i = 0 . \] (20)

We see that that we can safely neglect the displacement cur-
cent (the first term) as long as \( V^2 \ll 1 \) \((= c^2)\). In effect, we have a low frequency/velocity approximation. Leaving out the corresponding contribution to eq. (15) we arrive at the familiar relation from magnetohydrodynamics:
\[ \varepsilon^{ijk} D_j (\alpha B_k) \approx \alpha \mu_0 \dot{J}^i . \] (21)

As the charge current is slaved to the magnetic field, we have effectively removed a dynamical degree of freedom from the problem.

The argument is (of course) standard in flat space (and the usual Cartesian coordinates), where we have \( \alpha = 1 \), \( \beta^i = 0 \) and \( \gamma = 1 \) in the various equations and the covariant deriv-
atives reduce to partials (Bellan 2006; Mestel 1999). The sug-
gested extension to the curved spacetime setting is intuitive, but we may have to tread a bit more carefully. Clearly, the scal-
ing argument relies on the assumption that the gauge (the choice of lapse and shift) does not impact on the scaling, but there is no guarantee that it could not. For example, if we consider \( \beta^i \) as (effectively) a velocity then we clearly have to restrict it to be small (in a suitable sense). However, there is no reason why one would not be “allowed” to consider gauges with a large enough \( \beta^i \) that the argument is messed up. With a non-trivial choice of the shift vector, one would at least have to consider the possibility that this impacts on the dynamics. In a similar fashion, the lapse \( \alpha \) may affect the assumed scalings. In essence, we have to apply the magne-
tohydrodynamics approximation with some level of caution, as the logic leading to eq. (21) inevitably involves a degree of gauge dependence. One might consider testing the result by actual simulations, which ought to be fairly straightforward. Having said that, perhaps the most natural attitude is to pragmatically assume that any choice of gauge that breaks the logic is likely to be somewhat artificial, ignore the issue
and move on.

Let us see where this takes us. We now have a different problem. By effectively working with the pre-Maxwell form
of eq. (15) (leaving out the displacement current) we cannot solve eq. (18) without providing \( E^i \). We need an additional rel-
bation between the electric and magnetic fields. This is where the issue of the conductivity (effectively Ohm’s law) enters
the discussion. In a perfect conductor, where charges easily
flow, one would expect the electric field to “short out” as the matter becomes locally charge neutral. As this argument
brings in the local physics associated with a given fluid el-
ment, let us change perspective and consider the problem
from that point of view.

---

\(^1\) Here, and in the following, we write the evolution equations
in a way that focusses on the physics involved, rather than the
flux-conservative form required for a numerical implementation.
The translation between the descriptions is, however, standard
and should not present any particular difficulties.
2.3 The local view

The local description introduces a different observer, with four velocity \( \mathbf{u}^a \) (as in fig. 1), associated with the fluid motion. Connecting to the Eulerian observers from the foliation picture, we have

\[
\mathbf{u}^a = W (N^a + \mathbf{v}^a) \,, \quad N_a \mathbf{v}^a = 0 \,,
\]

with \( \mathbf{v}^a \) the relative velocity between the two frames and the Lorentz factor

\[
W = (1 - \mathbf{v}^2)^{-1/2} \,, \quad \mathbf{v}^2 = \gamma_{ij} \mathbf{v}^i \mathbf{v}^j \,.
\]

The electric field measured by the fluid observer follows from

\[
e_a = -u^b F_{ba} \,.
\]

leading to

\[
e_a = W \left( E_a + \epsilon_{abc} \mathbf{v}^b B^c + N_a \left( \mathbf{v}^b E_b \right) \right) \,.\tag{25}
\]

It is evident that, in general, the electric field inferred by the local observer has a component parallel to \( N^a \)

\[
e^\| = -e^a N_a = -W \left( \mathbf{v}^b E_b \right) \,;
\]

as well as an orthogonal piece

\[
e^\perp = W \left( E_a + \epsilon_{abc} \mathbf{v}^b B^c \right) \,.\tag{26}
\]

Let us now bring in the assumption that the local electric field vanishes, as one would expect from the standard (Debye) screening argument in a perfect conductor. Specifically, if we let

\[
e^\perp = 0 \implies E_a + \epsilon_{abc} \mathbf{v}^b B^c = 0 \,,\tag{28}
\]

then is easy to see that we also have \( e^\| = 0 \). If we combine eq. (28) with eq. (18) and eq. (21) we have all the relations we need to solve the problem. This is ideal magnetohydrodynamics. The arguments are, of course, standard but—as we will soon see—we need to pay attention to a number of subtle points. In particular, we need to carefully consider the issue of charge neutrality.

2.4 Charge neutrality

In addition to invoking the low-frequency argument to simplify the Maxwell equations, text-book magnetohydrodynamics involves an assumption of local charge neutrality. This is, effectively, the (previous) argument that the local electric field vanishes. The result follows immediately from the flat-space version of the Gauss law eq. (13). If the electric field vanishes, then so does the local charge density. However, the problem turns out to be more involved—and interesting!—in the relativistic setting.

In order to see why this is the case, we may start from the charge current, which has to satisfy

\[
\nabla_a j^a = 0 \,,
\]

in order to ensure electromagnetic gauge invariance. This is not an independent result—it can be obtained from the Maxwell equations (Thorne & MacDonald 1982)—but it is nevertheless useful to consider it separately. In terms of the Eulerian variables, we have

\[
(\partial_t - \mathcal{L}_\beta) \left( \gamma^{1/2} \hat{\sigma} \right) + D_i \left( \gamma^{1/2} \alpha \hat{J}^i \right) = \gamma^{1/2} \hat{\sigma} D_i \beta^i \,.\tag{30}
\]

Invoking eq. (21), we see that

\[
\mu_0 D_i \left( \gamma^{1/2} \alpha \hat{J}^i \right) \approx \epsilon^{ijk} D_j D_k \left( \gamma^{1/2} \alpha B_k \right) = 0 \,,
\]

which leaves us with

\[
(\partial_t - \mathcal{L}_\beta) \left( \gamma^{1/2} \hat{\sigma} \right) = \gamma^{1/2} \hat{\sigma} D_i \beta^i \,.\tag{32}
\]

In flat space (e.g. special relativity, with \( \beta^i = 0 \) and \( \gamma = 1 \), as before) we immediately arrive at the usual argument for quasi-neutrality:

\[
\partial_t \hat{\sigma} = 0 \,.
\]

If a system starts out with \( \hat{\sigma} = 0 \) (e.g. due to screening on length scales of relevance for the evolution) then this condition is preserved as time marches on.

In the curved spacetime case the problem is more subtle since simulations tend to involve non-trivial choices for the lapse and shift (and the logic obviously breaks if eq. (21) does not hold, as discussed earlier), but it might still seem reasonable to argue that an evolution initiated with a uniformly vanishing charge density should remain charge neutral (in this sense). In principle, we are “allowed” to assume \( \hat{\sigma} = 0 \) (as in the example used as illustration by Andersson et al. (2017c)), but the question is if this is a “sensible” thing to do.

For example, if we combine eq. (28) with eq. (13) we see that

\[
\mu_0 \hat{\sigma} = -D_i \left( \epsilon^{ijk} \mathbf{v}^k B_k \right) \,.
\]

This is also a well-known result—of immediate relevance for neutron star astrophysics as it leads to the Goldreich-Julian charge density for rotating magnetospheres (Goldreich & Julian 1969)—enforcing the point that we should not expect \( \hat{\sigma} = 0 \) to hold everywhere.

Noting this argument, let us shift the emphasis to the local charge density measured by the fluid observer, \( \sigma \). This follows from

\[
\mathbf{J}^a = \sigma \mathbf{u}^a + \mathbf{j}^a \,, \quad \mathbf{u}^a J_a = 0 \,,
\]

leading to

\[
\sigma = -u^a J_a = W \left( \hat{\sigma} - \mathbf{v}^a \hat{J}_a \right) \,.\tag{36}
\]

That is, if the matter is locally charge neutral (in the sense that \( \sigma = 0 \)) then the quantities measured by the Eulerian observer must satisfy

\[
\hat{\sigma} - \mathbf{v}^a \hat{J}_a = 0 \,.\tag{37}
\]

The result is intuitive. A change of observer frame impacts on measured volumes and hence the charge density and the associated current.

So far, we have essentially summarized the standard approach to (ideal) relativistic magnetohydrodynamics. We

\[2\] As a slight aside, it is worth noting that we could always, in principle, construct a gauge such that eq. (30) preserves any initial \( \hat{\sigma} \). All we need to do is set

\[
\hat{\sigma} \beta^i = \alpha \mathbf{J}^i \,.
\]

Of course, this only works for a non-vanishing \( \hat{\sigma} \), as otherwise \( \alpha = 0 \) and time would not progress. Moreover, the suggestion is unlikely to ever be relevant as one has to reserve the gauge choices to deal with more serious issues.
have seen how we may represent the charge current in terms of the curl of the magnetic field as long as we ignore the displacement current. We have also seen how the condition of local charge neutrality ($\sigma = 0$) enters the discussion and how the dynamics (e.g. bulk rotation) may induce an effective $\sigma$ of the curl of the magnetic field as long as we ignore the

2.5 Averaging from the nuclear physics scale

From the neutron star physics point of view it seems inevitable that the condition of local charge neutrality ($\sigma = 0$) should hold on the scale relevant for nuclear physics (in all reasonable settings, with a possible caveat for extended regions with mixed phases). Basically, the fact that the electrons are highly mobile makes the relevant screening length vastly smaller than the size of a typical fluid element (which must, in turn, exceed (say) the electron mean free path). Given this, local charge neutrality is (almost exclusively) assumed in modern equation of state calculations\(^3\). Basically, we need to take the condition eq. (37) seriously.

The question is on what scale we have to enforce the condition—exactly how local is local? In order to explore this issue, let us zoom in on a fluid element from a numerical evolution, as indicated in fig. 2 (where $\Delta L$ could be as large as 100m across even in a state of the art simulation (Baiotti & Rezzolla 2017)), to a much smaller scale (still large enough to be sufficiently close that the approximation makes sense). Given this, the fluid model itself is (obviously) based on the notion of averaging over a large number of particles (represented by suitable distribution functions in the more fine grained kinetic theory picture). Secondly, we average again to reach the computational scale. As we will see, both steps require careful consideration.

Let us first consider the problem at the level of individual fluid elements. Letting the local fluid frame be represented by $u^a$, the four velocity of a fluid component exhibiting relative flow, $u^a_x$, is given by (Andersson et al. 2017b)

$$u^a_x = \gamma_x (u^a + v^a_x) , \quad u_a v^a_x = 0 , \quad (38)$$

where

$$\gamma_x = (1 - v^a_x v^a_x)^{-1/2} . \quad (39)$$

In the problem at hand we need there to be a relative flow because the system has to sustain a charge current. If we assume that the charge carriers are electrons ($x = e$) and protons ($p$) as in a neutron star core, then

$$j^a = \sum_{x=p,e} q_x n^a_x = e \left( n^a_p - n^a_e \right) , \quad (40)$$

where $n^a_x = n_x u^a_x$ and $n_x = -u^a_x n^a_x$ is the (co-moving) number density of each species, where $q_x$ is the charge per particle (so $q_e = -e$). It follows that, in general, we have

$$\sigma = -u_a j^a = e(n_p \gamma_p - n_e \gamma_e) . \quad (41)$$

At this point we note that we need to keep track of the individual Lorentz factors, $\gamma_x$. This may be problematic as it implies that we keep track of the individual velocities, i.e. work at the level of a multi-component plasma (which would at the very least be computationally expensive). Given this, and the fact that we want to make contact with the underlying microphysics (and the charge neutral equation of state), which is determined in dynamical equilibrium, it is natural to simplify the problem by assuming that the relative drift is sufficiently slow that we can linearise the relations to ensure that $\gamma_x = 1$. At the linear drift level, all observers (e.g. co-moving with either of the particle species) will agree on the number densities and the notion of charge neutrality for a given fluid element is not contentious.

It is important to note that the linear drift assumption does not imply the single-fluid approximation. We still retain the distinct flows of the system, although these are now assumed to be sufficiently close that the approximation makes sense.

Let us now ask what happens if we scale the argument up to the (vastly larger) evolution scale. In effect, we consider a set of “boxes within boxes”, illustrated in fig. 3, and ask how the physics averages as we return to the evolution scale. The main point is to illustrate that this involves unknown (perhaps even unknowable) aspects. For obvious reasons—given the context—we concentrate on the charge current. We then need

$$j^a = \sum_x q_x n_x u^a_x \approx \sum_x q_x n_x (u^a + v^a_x) = \sigma u^a + J^a , \quad (42)$$

where

$$u^a J_a = 0 , \quad (43)$$

and we have (again) made use of the linear drift approximation. For fluid elements on the smallest scale, we impose local charge neutrality (as per the previous argument) so take $\sigma = 0$. However, this condition only holds along the world line of a particular fluid element. Suppose we consider a set

---

\(^3\) The situation is notably different for beta equilibrium, for which the governing reactions (the Urca reactions in the case of a neutron star core) are slow enough that the system may not reach equilibrium on the time scale of (say) core collapse or neutron-star merger (see Hammond et al. (2021) for a recent discussion).
of neighbouring fluid elements, as in fig. 3, and ask how the argument changes as we average over a larger volume. Labelling quantities associated with each box by $N$, we then have the total charge current

$$ j^a = \sum_{N} \left[ -(u_b j_N^b) u^a + \perp^a_{ab} j_N^b \right], \quad (44) $$

where the projection is associated with the four velocity of the observer on the averaged scale. In general, this observer would not record a vanishing charge density (even though each $\sigma_N = 0$). However, recalling the linear drift argument we have

$$ \sigma = -\sum_{N} u_b j_N^b \approx \sum_{N} (u_N - v_N) j_N^b = -\sum_{N} v_N j_N^b. \quad (45) $$

Since each term in the sum is quadratic in small quantities it would seem consistent to ignore the contribution and take the charge current (on the larger scale) to be given by

$$ j^a = \perp^a_{ab} \sum_{N} j_N^b. \quad (46) $$

This argument extends to the scale on which we are carrying out the evolution, providing (some) support for the constraint from eq. (37).

However, one can easily come up with a counterargument. Suppose that the linear drift introduces a small scale such that $j_N^b \sim O(\epsilon)$. Then we can easily break the logic by taking the number of boxes in eq. (45) to be of $O(1/\epsilon)$. And clearly, in scaling up from the local fluid scale ($\sim$mm) to the numerical evolution ($\gg$mm) we are dealing with a large number of boxes. This may be problematic, but what we should replace the argument with is less obvious. The key question is if the connection between charge neutrality on the nuclear physics scale (encoded in the equation of state) breaks as we average to the evolution scale, and if so, how we account for the corresponding (subgrid) behaviour in an evolution.

2.6 A filtering argument

Having explained the issue, let us consider how we might be able to get a more quantitative handle on it. To do this we draw on the recent discussion of spacetime filtering/averaging in the context of large-eddy models of turbulence from Celora et al. (2021). The main idea is that, we may squeeze in a lot of physics when we scale up to the resolution of a numerical simulation. We need an effective representation of this physics, e.g. small scale fluctuations, on the resolved scale. Following the discussion of Celora et al. (2021) we may develop the required model by describing the different physical fields according to a “Favre-weighted” observer $\tilde{u}^a$ (constructed to ensure that the equation for baryon number conservation takes the pre-filtered form, without additional closure terms). We then have the filtered charge current (we will not need to prescribe the actual filtering procedure, which is denoted by $\langle ... \rangle$, in order to make the argument we are interested in here)

$$ \langle j^a \rangle = \tilde{\sigma} \tilde{u}^a + \tilde{J}^a, \quad \tilde{u}_a \tilde{J}^a = 0. \quad (47) $$

Introducing the projection

$$ \tilde{I}^a_b = \delta^a_b + \tilde{u}^a \tilde{u}_b $$

we have

$$ \tilde{\sigma} = -\tilde{u}_a \langle j^a \rangle \quad (49) $$

and

$$ \tilde{J}^a = \tilde{I}^a_b \langle j^b \rangle. \quad (50) $$

The fields we would study in an evolution—on the macroscopic scale—are $\tilde{u}^a, \tilde{\sigma}$ and $\tilde{J}^a$. Naturally, we can compare these quantities to the filtered version of the fine-scale quantities. We then have

$$ \langle j^a \rangle = \langle \sigma u^a \rangle + \langle J^a \rangle \quad (51) $$

and it follows that

$$ \tilde{\sigma} = -\tilde{u}_a \langle j^a \rangle + \langle J^a \rangle \quad (52) $$

From this relation it is evident that, even if the small-scale flow is locally charge neutral (in the sense that $\sigma = 0$, as expected from the local nuclear physics argument) there is no reason to expect this to remain the case for the filtered flow. In fact, if $\sigma = 0$ we get

$$ \tilde{\sigma} = -\tilde{u}_a \langle J^a \rangle \quad (53) $$

effectively the filtered version of eq. (45), which is not expected to vanish.

This argument only hints at what a properly developed filtering argument for the electromagnetic problem will entail (we will discuss that problem in more detail elsewhere), but it illustrates the main point we are interested in. The fact that the local charge density vanishes at the equation of state level does not guarantee that this should be true on the evolved scale. In fact, it seems natural to argue that local charge neutrality should not be enforced in a large-scale simulation.

3 THE FLUID EQUATIONS

Having considered the electromagnetic aspects from different perspectives, it is apparent that the problem is intricate.
When it comes to the assumptions associated with magnetohydrodynamics, the low-frequency approximation that leads to the displacement current being ignored (see eq. (15)) should be testable on a case by case basis. The issue of charge neutrality is more involved. One would need to consider how “local” the fluid frame has to be for a given flow. This, in turn, imposes a constraint on the scale on which we are able to average over fluid boxes without violating an assumed charge neutrality. Naturally, this has repercussions for the magnetohydrodynamics and—in absence of a convincing argument—one may have to settle for a pragmatic approach. A sensible way forward may be to focus on consistency—making sure that the chosen formulation is internally “logical”—and then test whether alternative choices make an actual difference. Before we reflect on the options, we need to consider the fluid dynamics.

As a model example we consider the system explored by Andersson et al. (2017c), relevant for the outer core of a neutron star above the superfluid transition temperature. We assume that neutrons and protons are locked to each other as well as any thermal component (i.e. we ignore heat flow relative to the baryons) but allow the electrons to drift. This reduces the set-up to a two-fluid problem. We then need conservation laws for baryon number and total momentum and we also have to account for the charge current. This way we arrive at a system of equations for the baryon number density \( n \) and the (Eulerian) fluid velocity \( \hat{v} \), the electron number density \( n_e \) (noting that we also need to be able to work out the charge density \( \hat{\sigma} \) and the charge current \( \mathcal{J} \)).

At this level, we have two coupled fluid degrees of freedom (e.g. associated with \( \hat{v}^a \) and \( \hat{J}^a \)), which include “plasma” properties that are often ignored in astrophysical modelling. However, the general system allows the two components to flow with a large relative velocity, which becomes problematic when we try to make contact with the microphysics and the equation of state. The reason for this is fairly obvious. Modern equations of state include key many-body interactions but they do so in dynamical equilibrium. The impact of relative flows is rarely considered.

As we have already discussed, the standard approach to making modelling more “manageable” involves reducing the problem to a single-fluid one. In magnetohydrodynamics, this reduction follows from eq. (21). Once the charge current is slaved to the magnetic field, we can ignore the associated dynamics—we only need to track the fluid via the usual Euler equations (adding the Lorentz force). However, suppose we want to proceed more cautiously (in such a way that we keep better control on the assumptions that led to eq. (21)). What can we then sensibly do to simplify the problem?

The first step is natural (and we have, in fact, already outlined it). Returning to the evolution problem and the situation from fig. 1, we can take the fluid frame (represented by \( u^a \)) and let different fluid components flow according to eq. (38). Assuming that the linear drift argument holds on this scale (as we have to in order to arrive at a description that does not require the individual \( \gamma^n \) factors, and in turn the individual velocities) and translating to the point of view of an Eulerian observer, it makes sense to assume that the difference between the two three-velocities \( \hat{v}_x^a \) and \( \hat{v}_x^a \) is small, as well. Linearizing in the Eulerian velocity difference, we then have

\[
W_x = (1 - \hat{v}_x^2)^{-1/2} \approx W \left[ 1 + W^2 \hat{v}_a (\hat{v}_x^a - \hat{v}_a) \right].
\]

Combining this with

\[
u_x^a = W_x (N^a + \delta^a_\gamma) \approx \left[ W (N^a + \delta^a_\gamma) + v^a_x \right],
\]

we find that

\[
v_x^a \approx W [\delta^a_\gamma + W^2 \hat{v}_a (N^a + \delta^a_\gamma)] (\hat{v}_x^a - \hat{v}_a).
\]

and it is easy to confirm that the argument is consistent. A small drift in the fluid frame (the left-hand side) corresponds to a small velocity difference according to the Eulerian observer (the right-hand side).

Let us stress the importance of this intermediate step between the two-fluid model and magnetohydrodynamics, which is (effectively) a one-fluid description. The linear drift allows us to work with a single Lorentz factor, \( W \), associated with the bulk flow (the magnitude of which is not restricted by the assumptions). If we do not assume a linear drift we have to keep track of the individual velocities (which makes large-scale simulations much more complicated and expensive).

3.1 Baryon number conservation

In general, the physical setting we are exploring represents a two-component system with co-moving baryons (and entropy) but allows for a relative charge current. Given this set-up it is natural to associate the “fluid velocity” with the baryons (this is analogous to using the Eckart frame in studies of relativistic heat flow (Andersson & Comer 2021) or working with the Favre-weighted frame in the large-eddy context (Celora et al. 2021)). That is, we have

\[
\hat{v}^i = \hat{v}_b^i = \hat{v}_n^i.
\]

The foliation approach (Andersson et al. 2017c) then makes use of Eulerian observers such that (as before)

\[
u^a = W (N^a + \delta^a_\gamma) = \frac{W}{\alpha} (\epsilon^a - \beta^a + \alpha \hat{v}^a),
\]

with the same Lorentz factor as before.

Baryon number conservation is ensured by

\[
\partial_t \left( \gamma^{1/2} \hat{n} \right) + D_i \left[ \gamma^{1/2} \hat{n} \left( \alpha \hat{v}^i - \beta^i \right) \right] = 0,
\]

where the Eulerian number density is related to the co-moving one by

\[
\hat{n} = n W,
\]

and we have introduced \( n = n_e + n_p \). The relation simply encodes the change in number density that arises because of the length contraction due to the relative motion between the fluid and the (Eulerian) observer.

We have expressed eq. (59) in the usual flux-conservative form within the 3+1 approach (as laid out in Andersson et al. (2017c)). However, as we have suggested, when we consider the microphysics it is natural to pay closer attention to the local physics experienced by a family of observers that ride along with the fluid. Then we have (at least) two alternatives. We can choose to describe the physics in the local fluid frame associated with the four velocity \( u^a \), or we can try to make the equations look “similar” to the more familiar flat space
(Newtonian) ones. In this latter approach (see for example Thorne & MacDonald (1982)) one would introduce a global time (associated with \( t^0 \)) and use a spatial tetrad (relative to this time coordinate) to describe the fluid. The fluid then has four velocity
\[
{u^a} = \frac{W}{\alpha} \left( t^a + V^a \right),
\]
with
\[
V^i = \alpha \dot{v}^i - \beta^i.
\]
Making use of this result, we can rewrite eq. (59) as
\[
(\partial_t + LV) \left( \gamma^{1/2} \tilde{n} \right) + \gamma^{1/2} \tilde{n} D_a V^i = 0,
\]
or
\[
\partial_t (\gamma^{1/2} \tilde{n}) + D_a (\gamma^{1/2} \tilde{n} V^a) = 0,
\]
closely resembling the continuity equation from non-relativistic physics. In this picture, the linear drift argument involves keeping only linear terms in velocity differences in a frame determined by the global time coordinate. This follows immediately from the relations in the previous section, since
\[
V^a_x = V^a + \alpha (\dot{v}^a - \dot{v}^a).
\]
We will use this result later.

### 3.2 The fluid frame

Having discussed the issue of baryon number conservation, we are primed to comment on a question that we have so far avoided. Exactly what do we mean by the “fluid frame” when we discuss the local dynamics? The answer involves an element of choice. In fact, in a somewhat underhand manner, we have already introduced one of the options. In the derivation of eq. (59) we chose to work in the frame that moves along with the baryons (which were assumed to be locked at the outset). This gives precise meaning to the fibreation four velocity \( u^a \). This choice has the advantage of making the conservation law eq. (59) simple and intuitive. To see how this works, consider a general observer \( U^a \) within the family of linear drift models. In general, we then have the baryon flux
\[
\sum_{x=x_{i,p}} n_x (U^a + v^a_x) = (n_u + n_p)(U^a + v^a) \equiv n u^a.
\]
The argument involves two steps. First lock the baryons together \( (v^a = v^a_u = v^a_p) \) and then define the co-moving four velocity \( u^a \) as the desired frame. The logic is simple but important. Any other choice introduces a diffusion velocity in the equation for baryon number conservation.

Now turn to the stress-energy tensor, which takes the form (for the model system we are considering here and leaving out the purely electromagnetic contribution, see Andersson (2021) for more details)
\[
T^{ab} = \varepsilon U^a U^b + \Pi^{ab} p + 2 \sum_x n_x \Pi_x U^{(a} v^{b)}_x
\]
(ignoring quadratic terms in the drift velocities \( v^a_x \)), where \( \varepsilon \) is the energy density and \( p \) is the pressure. We also need the chemical potential \( \mu_x \) for each species. An observer moving along with each individual fluid frame measures the corresponding chemical potential as (introducing tildes to make a distinction at this point)
\[
\tilde{\mu}_x = -u^a \mu_x^a.
\]
If we ignore entrainment (see Andersson & Comer (2021) for the general role of this effect in multifluid systems), then
\[
\mu_x = \mu_x u^a_x,
\]
so we need
\[
\tilde{\mu}_x = -\mu_x (u^a u^a_x).
\]
Within the linear drift model, it is straightforward to show that \( \tilde{\mu}_x \approx \mu_x \). Similarly, if we define the measured number density as
\[
\tilde{n}_x = -u_x n^a_x,
\]
then we also have \( \tilde{n}_x \approx n_x \). This is important; different fluid observers agree on both number densities and chemical potentials, which in turn means that there is no ambiguity associated with issues like chemical equilibrium.

Returning to eq. (67), the first two terms on the right-hand side remind us of the perfect fluid result, while the third term represents the energy/momentum flux that arises due to the relative flow. In the example we are considering we lock the neutrons to the protons, but the electrons exhibits a relative flow. That is, we have
\[
\sum_x n_x \mu_x U^{(a} v^{b)}_x = (n_u \mu_u + n_p \mu_p) U^{(a} v^{b)} + n_e \mu_e U^{(a} v^{b)}_e
\]
If we combine this result with the frame choice from eq. (66) then we arrive at an explicit (non-vanishing) expression for the momentum flux. As an alternative, we may use the freedom of choice associated with \( U^a \) to ensure that the stress-energy tensor is reduced to the perfect fluid form. In order to do this, we must work in a frame such that
\[
(n_u \mu_u + n_p \mu_p) v^a + n_e \mu_e v^a_e = 0
\]
Implicitly, this prescribes the corresponding four-velocity \( u^a \), and corresponds to the standard Landau-Lifshitz frame (Andersson & Comer 2021). Finally, once we have defined the frame we can always replace the electron velocity with the charge current, since
\[
\sum_x q_x n_x (U^{a} + v^{a} _{e}) = e(n_p - n_e) U^{a} + e(n_p v^a_p - n_e v^a_e).
\]
From this last expression, it is worth noting yet another option. We could introduce the observer frame in such a way that the spatial charge current vanishes. This would involve removing the last term in eq. (74). However, as this choice would introduce a drift velocity in the baryon number conservation law as well as a momentum flux in the stress-energy tensor it does not bring any obvious advantages.

The key conclusion here is that we can introduce the fluid frame in whatever way we find most convenient, with the two options eq. (66) and eq. (73) being attractive for different reasons. There is, however, no free lunch. Whichever choice we make, we cannot at the same time arrive at a baryon number conservation law without particle diffusion and a perfect-fluid stress energy tensor. This may be obvious, but it is an important observation as precisely this combination tends to be
assumed from the outset in discussions of relativistic magnetohydrodynamics. Hence, the standard results can only be approximately true. In the following we will make the nature of the required approximation precise by adopting the Eckart frame choice and quantifying the “offending” momentum terms in the stress-energy tensor.

3.3 Energy-momentum conservation

In order to complete the fluid model, we need the evolution equations for energy and momentum. The starting point is the stress-energy tensor from eq. (67), expressed in the 3+1 foliation. After some fairly straightforward algebra, we find that

\[ \partial_t \left( \gamma^{1/2} \rho \right) + D_i \left[ \gamma^{1/2} \left( \alpha S^i - \rho \dot{\beta}^i \right) \right] = \gamma^{1/2} \left( \alpha S^i - \rho \dot{\beta}^i \right), \]

where, noting the linear drift assumption, we have

\[ p + \rho = W^2(p + \varepsilon) + 2W^2 \sum x_n (\dot{v}_n^i - \dot{v}^i) n_x \mu_x, \]

and

\[ S^i = (p + \rho) \dot{v}^i + W^2 \sum n_x \mu_x (\dot{v}_x^i - \dot{v}^i). \]

We also have the momentum equation

\[ \partial_t \left( \gamma^{1/2} S_i \right) + D_j \left[ \gamma^{1/2} \left( \alpha S_i - \beta^i \dot{\beta}^j + \beta^j \dot{\beta}^i - \rho \dot{D}_i \alpha \right) \right] = \gamma^{1/2} \left( \beta_i \dot{D}_j + \beta^j \dot{D}_i - \rho \dot{D}_i \alpha \right). \]

We need to add the purely electromagnetic contributions—the Lorentz force—to the right-hand side of the fluid equations. This involves

\[ j^b = -j_e F^{eb} = N^b (\dot{J}^b E_a) + (\dot{\sigma} E^b + \dot{\beta}^b \dot{J}_a B_d), \]

which means that we need to add, first of all, a term

\[ \alpha \gamma^{1/2} (\dot{J}^b E_a), \]

to the right-hand side of eq. (75), representing the electromagnetic contribution to the energy flow and the Joule heating. Secondly, we need a term

\[ \alpha \gamma^{1/2} (\dot{\sigma} E_i + \dot{\beta} E_i + \dot{J} B^i), \]

on the right-hand side of eq. (79), representing the (spatial) Lorentz force.

In the case of a charged two-component problem it makes sense to represent the relative flow of the electrons with respect to the baryons by the charge current. At the linear drift level, we have

\[ \dot{\sigma} = e (\dot{n}_p - \dot{n}_e) = e (W_p n_p - W_e n_e) \]

\[ = e W \left[ (n_p - n_e) - W^2 n_e \dot{v}_e (\dot{v}_e^i - \dot{v}_e^i) \right], \]

and

\[ \dot{J}^a = e (\dot{n}_p \dot{v}_e^i - \dot{n}_e \dot{v}_e^i) \approx \dot{\sigma} \dot{v}_e^i - e W n_e (\dot{v}_e^i - \dot{v}_e^i) \]

\[ \Rightarrow \dot{v}_e^i - \dot{v}_e^i \approx \frac{1}{e W n_e} \left( \dot{\sigma} \dot{v}_e^i - \dot{J}^a \right). \]

At this point, it is natural to recall the issue of charge neutrality. Inverting eq. (83) we have

\[ \sigma = e (n_p - n_e) = W \left( \dot{\sigma} - \dot{v}_e^i J_a \right), \]

and it is easy to see that if we were to impose the condition that the system should be charge neutral in the fluid frame, \( n_p = n_e \), we must have

\[ \dot{\sigma} - \dot{v}_e^i J_a = \dot{\sigma}, \]

which connects to the earlier discussion of local charge neutrality that led to eq. (37). We now see that the condition arises naturally from the multifluid model (at the linear drift level)—a useful consistency check. It is also worth noting that we need to be careful with what is small and what is not (at least not necessarily). In order to remain consistent, we need pay attention to eq. (84). In general, the linear drift assumption implies that the combination on the right-hand side of eq. (84) must be small, so we should ignore quadratic terms of this form. It does not follow that \( \dot{\sigma} \) and \( J^a \) are individually small. However, if we were to add the assumption of local charge neutrality (\( \sigma = 0 \)) then it follows from eq. (83) that \( \dot{\sigma} \) will be small (of order the linear drift) and hence (via eq. (84)) the spatial current \( J^a \) must be small as well. In essence, whether specific quadratic terms should be ignored in a consistent model depends on the physics assumptions.

At the linear drift level we now have

\[ p + \rho \approx (p + \varepsilon) W^2 + \frac{2\mu_e}{e} W^2 \left( \dot{\sigma} \dot{v}_e^i - \dot{v}_e^i \dot{J}^a \right) \]

\[ S^i \approx (p + \rho) \dot{v}^i + \frac{\mu_e W}{e} \left( \dot{\sigma} \dot{v}_e^i - \dot{J}^a \right), \]

and

\[ S^{ij} \approx \rho \gamma^{1/2} \dot{v}_e^i S^j + \frac{\mu_e W}{e} \left( \dot{\sigma} \dot{v}_e^i - \dot{J}^a \right). \]

Note that there is only one Lorentz factor (associated with the relative velocity between the observer and the fluid frame) in these expressions. Moreover, for low velocities, \( \dot{\sigma} \ll c \), we may be able to ignore the \( \dot{\sigma} \dot{v}_e^i \) term compared to the charge current. Also, for weakly relativistic systems one would expect \( \mu_e \approx m_e \ll m_B \). The upshot of this is that the terms involving the charge current would be another factor of order 2,000 or so smaller than the other “fluid” terms. For this simple reason, these terms tend to be ignored in non-relativistic problems. This then leads to the usual statement that the relativistic problem follows by adding a perfect fluid stress-energy tensor to the electromagnetic contribution. The validity of this assumption is less obvious for a neutron star core, where the electron effective mass may be of order 10% of the baryon (rest) mass (\( \mu_e \approx 100\text{MeV} \)). In essence, one should consider including the charge current contribution from the outset. At the very least, it would be worthwhile quantifying its importance by test simulations.

3.4 Electron dynamics

In order to complete the model, we need to keep track of the electron number density (e.g. in order to work out \( \mu_e \)) and the charge current. In general, when the fluxes are conserved we have (for each species)

\[ \partial_t \left( \gamma^{1/2} \dot{n}_e \right) + D_i \left[ \gamma^{1/2} \dot{n}_e \left( \alpha \dot{v}_e^i - \beta^i \right) \right] = 0. \]
In the present case we focus on the electron number density. The linear drift assumption then leads to
\[ n_e = n_e W_e \approx n_e W \left[ 1 + W^2 \tilde{v}_e (i_e^0 - \dot{v}^0) \right] \]
\[ \approx n_e W \left[ 1 + \frac{W}{c n_e} \left( \sigma \dot{v}^0 - \dot{v}_a J^a \right) \right]. \] (91)
Moreover, making use of eq. (84) we arrive at
\[ \dot{n}_e \tilde{v}_e^0 \approx n_e W \dot{v}^0 + \frac{1}{e} \left( \gamma_1^0 + W^2 \tilde{v}_e^0 \tilde{v}_j \right) \left( \dot{\sigma} \tilde{v}^0 - J^j \right). \] (92)

As a slight aside, using these results in eq. (90), making use of the global time argument and the expression for charge conservation eq. (30), we find that the electron fraction \( Y_e = n_e / n \) satisfies
\[ (\partial_t + \mathbf{L}_v) Y_e = 0. \] (93)
In essence, the electron fraction is advected by the fluid flow. This assumption effectively corresponds to situations where the composition of matter remains frozen during the evolution. That is, the relevant nuclear reactions are slow compared to the dynamics of the system (see for example Hammond et al. (2021)).

The momentum equation for a general component is (correcting a number of typographical errors, basically removing a term involving the extrinsic curvature, tracing back to equations (78)-(80) from Andersson et al. (2017c), and which propagates through to their equation (129))
\[ \left[ \partial_t + (\alpha \tilde{v}_e^0 - \beta^0) D_j \right] S^e_k + S^k_j D_i \left( \alpha \tilde{v}_e^0 - \beta^0 \right) + D_i \left[ \alpha \left( \dot{\mu}_e - \tilde{v}_e S^0_j \right) \right] = \frac{\alpha}{n_e} F^e_i, \] (94)
where
\[ F^e_i = c_e \dot{n}_e \left( E_i + \epsilon_{ijk} \tilde{v}_j B^k \right) + \gamma^e \gamma R^e, \] (95)
with the last term representing resistivity (Andersson et al. 2017a,b,c).

Noting that, in the absence of entrainment (which would not normally link electrons and baryons, anyway (Andersson & Comer 2021)), we have
\[ S^k_e = \mu_e \dot{v}_e^0, \] (96)
and recalling that the fluid velocity is \( V^e_k = \alpha \tilde{v}_e^0 - \beta^0 \), we see that eq. (94) can be concisely written:
\[ (\partial_t + \mathbf{L}_v) S^e_k + D_i \left( \frac{\alpha \dot{\mu}_e}{W^2} \right) = \frac{\alpha}{n_e} F^e_i. \] (97)

In the particular case of the electrons we have
\[ \left[ \partial_t + (\alpha \tilde{v}_e^0 - \beta^0) D_j \right] S^e_k + S^k_j D_i \left( \alpha \tilde{v}_e^0 - \beta^0 \right) + D_i \left[ \alpha \left( \dot{\mu}_e - \tilde{v}_e S^0_j \right) \right] = \frac{\alpha}{n_e} F^e_i \] (98)
where (again, correcting an error in equation (130) from Andersson et al. (2017c))
\[ S^e_k = \mu_e \dot{v}_e^0 = \mu_e W_e \left[ \dot{v}^0 + \frac{1}{c n_e W} \left( \sigma \dot{v}^0 - J^j \right) \right] \approx \mu_e W \left[ \left( 1 + \frac{W}{c n_e \sigma} \right) \dot{v}^0 - \frac{1}{c n_e W} \left( \gamma_j^0 \dot{v}_j + W^2 \tilde{v}^0 \tilde{v}_j \right) J^j \right]. \] (99)

Finally, we need an expression for the resistivity. From Andersson et al. (2017a,b,c) we have the general result (neglecting reactions)
\[ \gamma^e \gamma R^e = \gamma^e \sum_{y \neq x} R^{xy} \left( \delta^a_y + v_y^a u_a \right) \left( v_y^e - v_y^e \right), \] (100)
where the velocities are with respect to the fluid frame. In the linear drift model, these are related to the Eulerian velocities through eq. (56), and in the two-component case we are considering we arrive at
\[ \gamma^e \gamma R^e = R W \left( \delta^a_e + W^2 \tilde{v}_e \tilde{v}_e \right) \left( \tilde{v}_e - \tilde{v}_e \right) = \frac{R}{c n_e} \left[ J^e_e - W^2 (\tilde{\sigma} - \tilde{v}^0 \tilde{J}_e) \tilde{v}_e \right]. \] (101)

3.5 Ohm’s law

Resistivity is usually implemented at the level of some version of Ohm’s law, often viewed as a “closure condition” added to the magnetohydrodynamics relation eq. (28). In the multifluid model, the required relation follows from the electron momentum equation. As a first step, let us assume that we can ignore the electron inertia. Then it follows from eq. (97) that
\[ F^e_i \approx -c_e n_e W_e \left( E_i + \epsilon_{ijk} \tilde{v}_j B^k \right) \]
\[ + \frac{R}{c n_e} \left[ J^e_e - W^2 (\tilde{\sigma} - \tilde{v}^0 \tilde{J}_e) \tilde{v}_e \right] \approx \frac{n_e W_e}{\alpha} D_i \left( \frac{\alpha \mu_e}{W} \right). \] (102)
Introducing
\[ \eta = \frac{R}{c^2 n_e W}, \] (103)
and recalling that
\[ W_e \approx W \left[ 1 + \frac{W}{c n_e} \left( \sigma \dot{v}^2 - \tilde{v}_j \tilde{J}_j \right) \right] \] (104)
we have
\[ E_i + \epsilon_{ijk} \tilde{v}_j B^k + \frac{1}{c n_e W} \epsilon_{ijk} \left( \tilde{\sigma} \tilde{v}^j - \tilde{J}_j \right) B^k \]
\[ + \frac{1}{\alpha c} D_i \left( \frac{\alpha \mu_e}{W} \left[ 1 - \frac{W}{c n_e} \left( \tilde{\sigma} \dot{v}^2 - \tilde{v}_j \tilde{J}_j \right) \right] \right) \]
\[ = \eta \left[ J^e_e - W^2 (\tilde{\sigma} - \tilde{v}^0 \tilde{J}_e) \tilde{v}_e \right]. \] (105)

This is the final result, and we have indicated the main features of the model—the term associated with the Hall drift, that leads to the development of smaller scale features, a “chemical” term of the kind that may be related to battery effects (although, as it turns out, not in this case as a pure gradient will not contribute to (18)) and the resistivity. It is rewarding to note that eq. (105) is consistent with the textbook result for non-relativistic two-fluid systems, e.g. equation (2.75) in Bellan (2006) (see also Mostel (1999)), once we set \( \alpha = W_e = W \rightarrow 1 \) (ignoring terms of order \( \tilde{v}^2 \) and \( \tilde{\sigma} \rightarrow 0 \). Depending on the context, different aspects of eq. (105) may or may not be relevant. Hence, it makes sense to consider possible simplifications. First of all, ignoring the term associated
with the chemical potential gradient, we have

\[ E_i + \epsilon_{ijk} \bar{v}^j B^k + \frac{1}{c n e W} \epsilon_{ijk} \left( \widehat{\sigma} \bar{v}^j - \bar{v} \widehat{\sigma} J^j \right) B^k = \eta \left[ \hat{J}_i - W^2 \left( \widehat{\sigma} - \bar{v} \cdot \hat{J} \right) \bar{v}_i \right]. \]  

(106)

Also leaving out the Hall term, we are left with

\[ E_i + \epsilon_{ijk} \bar{v}^j B^k = \eta \left[ \hat{J}_i - W^2 \left( \widehat{\sigma} - \bar{v} \cdot \hat{J} \right) \bar{v}_i \right], \]  

(107)

and, finally, if the system is locally charge neutral we have

\[ E_i + \epsilon_{ijk} \bar{v}^j B^k = \eta \hat{J}_i. \]  

(108)

It is worth noting that, in the absence of resistivity, this relation leads back to the electric field vanishing in the fluid frame (ideal magnetohydrodynamics). This is as expected, but it is nevertheless a useful consistency check.

Through a hierarchy of approximations and simplifications we have moved from a model that retains the properties of a charged two-component plasma to a simple expression encoding Ohm’s law. This does not necessarily mean that we are done. We still need to consider how the result can be used in practice.

3.6 The traditional approach

Before we proceed, it is instructive to compare the final result eq. (107) to the standard argument (Bekenstein & Oron 1978), which starts from magnetohydrodynamics and arrives at Ohm’s law by taking the current to be proportional to the Lorentz force acting on a particle in the fluid frame. Assuming

\[ \nabla \times j = \kappa F_{ab} u^b, \]  

(109)

(using \( \kappa \) to represent the conductivity to avoid confusion with the charge density \( \sigma \)) and recalling eq. (22), it readily follows that

\[ \hat{\sigma} + W^2 (\bar{v} \cdot \hat{J}) = \kappa W (\bar{v} \cdot E_i), \]  

(110)

and

\[ \hat{J}_i - W^2 \bar{v}_i (\hat{\sigma} - \bar{v} \cdot \hat{J}) = \kappa W (\bar{v} \cdot E_i). \]  

(111)

Moreover, we have

\[ \bar{v} \cdot \hat{J}_i - W^2 \bar{v}_i (\hat{\sigma} - \bar{v} \cdot \hat{J}) = \kappa W (\bar{v} \cdot E_i), \]  

(112)

and

\[ E_i + \epsilon_{ijk} \bar{v}^j B^k = \frac{1}{\kappa W} \left[ \hat{J}_i - W^2 (\hat{\sigma} - \bar{v} \cdot \hat{J}) \bar{v}_i \right]. \]  

(113)

This version of Ohm’s law—notably identical to eq. (107) once we identify \( \eta = 1/\kappa W \)—has been implemented in recent numerical simulations, see for example Palenzuela et al. (2009); Dionysopoulou et al. (2013); Wright & Hawke (2020).

4 A SEQUENCE OF APPROXIMATIONS/ASSUMPTIONS

We have explored the main aspects of the problem of charged flows in general relativity and the connection with numerical simulations. We considered issues relating to both electromagnetism and the fluid dynamics. The analysis provides everything we need to put together a consistent formulation for magnetohydrodynamics. As such a formulation inevitably involves a number of approximations/assumptions—with different strategies having been adopted in the literature—it is useful to consider a hierarchy of models of increasing “simplicity”.

Let us outline the main options, framing the discussion in the context of neutron star physics—as this is an area where the need for different approaches/approximations is obvious. When we consider the neutron-star problem, it is intuitively clear that electromagnetism in the vacuum region far away from the star must be represented by Maxwell’s equations (without local charges or currents). At the same time, the dynamics of the highly conducting degenerate neutron-star interior can be adequately described within (some version of) magnetohydrodynamics. However, this description becomes problematic close to the star’s surface—basically, since the Alfvén wave speed diverges as the density vanishes—yet, an immediate transition to vacuum conditions may not be appropriate. Rather, the star’s magnetosphere may support a significant effective charge density (Goldreich & Julian 1969) and considerable currents. Ignoring the matter inertia in this region one arrives at the force-free assumption (Komissarov 2002; Uchida 1997; Carrasco et al. 2018), which simplifies the dynamics (albeit bringing its own set of issues to consider). In essence, we inevitably need to consider different—more or less physically distinct—regions.

4.1 The top-level model: Dissipative electromagnetism

At the highest level, it would be natural to consider a model that involves the full dynamics associated with Maxwell’s equations combined with a meaningful “single-fluid” approximation. Without such an assumption, we would have to consider multi-fluid (plasma) aspects of the problem and these may be associated with both complexity and computational cost, see Barkov et al. (2014); Barkov & Komissarov (2016) for efforts in this direction. As we have seen, the single-fluid reduction involves two steps. First, we need to make the linear-diffusion approximation. If we do not, then we have to keep track of individual fluid Lorentz factors (which obviously require the individual velocities). Second, we have to neglect the dynamics associated with the charge current (e.g. ignore the electron “inertia”). This step removes the second fluid degree of freedom, and closes the system through some version of Ohm’s law.

As a first step, it is easy to make contact with ideal magnetohydrodynamics. Starting from, for example, eq. (110) and eq. (111) it is easy to see that, if \( \kappa \to \infty \) (i.e. we have a perfect conductor) we must have \( E_i + \epsilon_{ijk} \bar{v}^j B^k = 0 \) so the electric field vanishes in the fluid frame. The problem reduces to the one discussed in section 2.3 and \( \hat{J} \) is slaved to the magnetic field. The opposite limit is not quite as straightforward. Formally, if \( \kappa \to 0 \) we get

\[ W^2 (\bar{v} \cdot \hat{J} - \hat{\sigma} \bar{v}) = 0, \]  

(114)

and

\[ \hat{J}_i - W^2 \bar{v}_i (\hat{\sigma} - \bar{v} \cdot \hat{J}) = 0. \]  

(115)
Solving these two equations we arrive at:
\[
\mathbf{j} = \lambda_{ij} - \frac{\hat{v}_i \hat{v}_j}{\hat{v}^2} \mathbf{j}^f = 0, \quad \text{and} \quad \hat{\sigma} = \frac{\hat{v}_i \hat{j}^i}{\hat{v}^2}.
\]  
(116)

If we then decompose \(\mathbf{j}^f = \mathbf{j}_0 \mathbf{v}^i + \mathbf{j}_1\), the first relation tells us that \(\mathbf{j}_0 = 0\), while the second leads to \(\hat{\mathbf{j}}_1 = \hat{\sigma} \mathbf{v}^i\). At the end of the day, in the limit \(\kappa \to 0\) we have

\[
\hat{\mathbf{j}} = \hat{\sigma} \mathbf{v}^i.
\]  
(117)

In principle, this represents a perfect insulator—any charge imbalance (a non-zero \(\hat{\sigma}\)) will be carried along with the fluid. If we also assume charge neutrality (cf. eq. (86)), then consistency dictates (as we cannot have \(\hat{v}^2 = 1\) for a massive fluid) that \(\hat{\sigma} = 0\) and \(\hat{\mathbf{j}} = 0\). In this sense, Ohm’s law limits to vacuum electromagnetism.

The next level of complexity is to allow for a finite resistivity/conductivity, without assuming charge neutrality, as in eq. (107). This relation is fairly easy to invert—first dotting eq. (107) with \(\hat{v}^i\) to get rid of \(\hat{v}_i \hat{\mathbf{j}}^i\)—leading to an expression for the charge current required to close the system of equations:

\[
\hat{\mathbf{j}} = \hat{\sigma} \mathbf{v}^i + \frac{1}{\eta} \left( \gamma_{ij} \hat{v}_j \mathbf{E}^j + \epsilon_{ijk} \mathbf{B}^k \right).
\]  
(118)

The result would simplify further if we assumed local charge neutrality, but—as we have discussed at length—it is not clear to what extent this assumption will hold in a real system.

The inversion required to include the Hall effect is more involved. It can be done, using standard methods from linear algebra (see Appendix A), but the result is messy (as it implies that \(\hat{\mathbf{j}}\) is a non-zero \(\hat{\sigma}\)).

Recalling that \(\epsilon_{ijk}\) takes the form

\[
\hat{\mathbf{j}} = \frac{1}{\epsilon_{m0}} \epsilon_{ijk} D_j (\alpha B_k)
\]  
(121)

as our starting point. Making use of eq. (106) this leads to

\[
E_i = -\frac{1}{\epsilon_{m0}} \left( 1 + \frac{\hat{\sigma}}{\epsilon_{m0}} \right) \epsilon_{ijk} \hat{v}^j B^k - \eta W^2 \hat{\sigma} \hat{v}_i + \eta \frac{1}{\epsilon_{m0} \alpha \mu_0} B^k \left[ D_i (\alpha B_k) - D_k (\alpha B_i) \right] + \eta \frac{1}{\alpha \mu_0} \left( \gamma_{ij} W^2 \hat{v}_i \hat{v}_j \right) e^{ilm} D_m (\alpha B_n) \epsilon_{m0} = 0.
\]  
(122)

Using this in the Faraday eq. (18) we arrive at the induction equation

\[
(\partial_t - \mathcal{L}_B) B^i = D_m \left( 1 + \frac{\hat{\sigma}}{\epsilon_{m0}} \right) \hat{v}^i B^m + D_m \left( 1 + \frac{\hat{\sigma}}{\epsilon_{m0}} \right) \hat{v}^m B^i - e^{ijk} D_j \left( \alpha \theta B_k \right) + e^{ijk} D_j \left( \frac{1}{\epsilon_{m0} \mu^0} \hat{v}^j \hat{v}_k \right) e^{ilm} D_m (\alpha B_n) = - \frac{\hat{\sigma}}{\epsilon_{m0}} \hat{v}^i B^m.
\]  
(123)

4 Note that this does not have to represent the non-relativistic limit. The assumption refers to the timescale associated with the dynamics, not the bulk motion or, indeed, weak gravity.
This result is complicated, but it is easy to see how it reduces to something more familiar. First of all, leaving out the Hall term the relation simplifies to
\[
(\partial_t - \mathcal{L}_\beta) B^i - \epsilon^{ijk} D_j \left( \alpha W^2 \eta \hat{\sigma} v_k \right) + \epsilon^{ijk} D_j \left[ \frac{n}{\mu_0} (\gamma_{kl} - W^2 \hat{v}_k \hat{v}_l) \epsilon^{imn} D_m (\alpha B_n) \right] - D_m \left( \hat{v}^i B^m \right) + D_m \left( \hat{v}^m B^i \right) = \alpha K B^i.
\] (124)

If we also assume charge neutrality we would have
\[
(\partial_t - \mathcal{L}_\beta) B^i - D_m \left( \hat{v}^i B^m \right) + D_m \left( \hat{v}^m B^i \right) + D_j \left[ \frac{n}{\mu_0} D^i (\alpha B^j) \right] - D_j \left[ \frac{n}{\mu_0} D^j (\alpha B^i) \right] = \alpha K B^i
\] (125)
and it is easy to see that, with \(\beta = 0, \alpha = 1, K = 0\) and assuming \(\eta\) constant, we end up with the standard textbook (special relativistic) version of the (resistive) induction equation. It would obviously be interesting to explore to what extent the additional terms in eq. (123) impact on the large scale magnetic field evolution in a neutron star, but we leave this for future work.

4.3 Force-free electrodynamics

The magnetohydrodynamics approach should be relevant for the dense interior of a magnetized star, while the vacuum Maxwell equations apply at large distances. However, if we want to consider the region immediately outside the star, or indeed the transition through the low-density surface material, then we may need a different prescription. A common assumption is that the magnetosphere is composed of a highly magnetized plasma, which supports a charge current without inducing significant “fluid” motion. In essence, there is no significant matter component to balance the Lorentz force and we arrive at what is called force-free electrodynamics. From eq. (80) we see that we must have
\[
\hat{\sigma} E_i + \epsilon_{ijk} \hat{J}^j B^k \approx 0,
\] (126)
along with
\[
E_i B^i \approx 0,
\] (127)
and it also follows that \(\hat{J}^i E_i \approx 0\). The condition of high magnetization requires that
\[
B^2 > E^2.
\] (128)

These three conditions may be taken as the axiomatic “definition” of the force-free limit (see e.g. Paschalidis & Shapiro (2013) for a discussion of the need for all three conditions.) Since the vanishing of the Lorentz force follows from the low-inertia assumption, the force-free model is often described as the low-inertia limit of ideal magnetohydrodynamics (Komissarov 2002; McKinney 2006). The argument is also motivated by the fact that the last two conditions eqs. (127) and (128) hold in ideal magnetohydrodynamics as well. The limit argument may seem intuitive, but it is not quite that straightforward. In ideal magnetohydrodynamics the electric field vanishes in the fluid frame, while force-free electrodynamics is identified by the electric field vanishing in a frame associated with the charge current. Trivially, the two conditions eq. (28) and eq. (126) are identical if we let \(\hat{v} \rightarrow \hat{J} / \hat{\sigma}\).

That is, the force-free region does not strictly follow from simply taking the low-inertia limit (at least not in the usual mathematical sense). We do not have an adjustable parameter that takes us from magnetohydrodynamics to the force-free case. The argument relies on a boost of the frame in which the electric field is taken to vanish. With this in mind, it is not surprising that the force-free case does not arise naturally from the equations we have discussed. Our starting point was the two-fluid model and the derivation of, for example, Ohm’s law clearly builds on the fluid assumption. As a result, one would not expect to be able to reconcile the derived form of Ohm’s law with the conditions in the force-free region (where the plasma can be assumed to be collisionless). Instead, one would have to consider dissipation associated with collective processes and/or radiation (Komissarov 2004), which obviously changes the argument. Having said that, the conditions required for ideal magnetohydrodynamics and force-free electrodynamics are sufficiently similar that it may nevertheless be useful for numerical implementations to link them through a somewhat ad hoc limiting argument (Paschalidis & Shapiro 2013; Palenzuela 2013).

When it comes to evolving the equations in the force-free region, the typical approach involves solving for both the electric and magnetic fields. At a glance, we need a “closure relation” for the charge current \(\hat{j}^i\) in order to close the system. While this is not exactly true—as we could contract the Maxwell equations with the Faraday tensor, and then use the vanishing of the Lorentz force to get rid of \(\hat{j}^i\) (see Carrasco & Reula (2016) for discussion)—it might still be useful to write the charge current in terms of \(E^i\) and \(B^i\) such that the force free constraints are automatically satisfied. This leads to (see e.g. Gruzinov (2006); Komissarov (2011); Paschalidis & Shapiro (2013))
\[
\hat{j}^i = \frac{B^i}{\mu_0 B^2} \left[ B_j \epsilon^{jkl} D_k B_l - E_j \epsilon^{jkl} D_k E_l \right] - 2B^i E^k K_{jk} + \frac{\hat{\sigma}}{B^2} \epsilon^{ijk} E_j B_k .
\] (129)
As suggested by Palenzuela (2013), we may work with a phenomenological closure for the charge current, such that it limits to ideal magnetohydrodynamics in one case and to force-free electrodynamics in the other.

5 CONCLUDING REMARKS

We have explored the physics of general relativistic magnetohydrodynamics, as required for studies of large-scale magnetic field dynamics associated with, for example, neutron star mergers. With this particular application in mind, we formulated the problem using the standard 3+1 foliation approach to spacetime. However, given the need to faithfully represent the physics, we also considered the spacetime fibration associated with the fluid elements. Our main aim was to

\[000, 000-000 (0000)\]
discuss commonly made assumptions (which tend to be motivated in the non-relativistic setting and then taken, more or less, for granted in the curved spacetime case) and establish to what extent they are appropriate for different problem settings.

The discussion brought issues associated with the charge density and charge current into focus, and we highlighted the connection between the microphysics (associated with a given equation of state) and the global dynamics (from the point of view of numerical simulations). This discussion emphasised different effects, that involve going beyond “standard” ideal magnetohydrodynamics and which may come into play if a more precise description of the problem is desired. For example, our derivation of Ohm’s law takes the two-fluid plasma as its starting point and, hence, includes features beyond the usual scalar resistivity/conductivity (like the Hall effect). This provided a hierarchy of models that should be relevant for future applications.

While we have (admittedly) not resolved all the involved issues, the final formulation is consistent, both logically and physically. This prepares the ground for a new generation of models of various astrophysical scenarios. In particular, our results will allow us to test the validity of different assumptions and simplifications by direct simulations. This seems like an important step in the right direction.

ACKNOWLEDGMENTS

Many colleagues have contributed useful discussion during the development of this material. We are particularly grateful to Kiki Dionysopoulou and Tamanna Jain. We are also grateful for support from STFC via grant numbers ST/R00045X/1 and ST/V000551/1.

APPENDIX A

Assuming that each index is raised (lowered) with $\gamma^{ij}$ ($\gamma_{ij}$) we can rewrite eq. (106) in the form (as the chemical term makes this inversion more complicated, we neglect it in the following)

$$A_{ij} \tilde{J}^i = C_i ,$$

where we have defined

$$A_{ij} = \gamma_{ij} + L \tilde{v}_j \tilde{v}_i + M \epsilon_{ijk} \tilde{B}^k ,$$

$$C_i = NE_i + P \epsilon_{ijk} \tilde{v}^j B^k + Q \tilde{v}_i ,$$

$$L = W^2 ,$$

$$M = \frac{1}{en_{i} \gamma W} ,$$

$$N = \frac{1}{\eta} ,$$

$$P = \frac{1}{\eta} \left( 1 + \frac{\tilde{\sigma}}{en_{i} W} \right) ,$$

$$Q = W^2 \tilde{\sigma} .$$

From Linear Algebra we know that the inverse $A^{ij}$ to a $3 \times 3$ matrix $A_{ij}$ is

$$A^{ij} = \frac{\gamma}{2A} \epsilon^{ikl} \epsilon^{jmn} A_{km} A_{ln} ,$$

where $\gamma = \det \gamma_{ij}$ and $A = \det A_{ij}$. The solution is therefore

$$\tilde{J}^i = A^{ij} C_j .$$

Note that

$$\epsilon^{ikl} \epsilon^{jmn} = 3 \delta^{[i}_{[j} \delta^{k]}_{m]} ,$$

$$\epsilon^{ikl} \epsilon_{ijm} = 2 \delta^k_m \delta_l^i ,$$

$$\epsilon^{ikl} \epsilon_{ikm} = 2 \delta^l_m .$$

Explicitly, we have

$$A^{ij} = \frac{\gamma}{2A} \epsilon^{ikl} \epsilon^{jmn} \left( \gamma_{km} + L \tilde{v}_k \tilde{v}_m + M \epsilon_{kmp} B^p \right)$$

$$= \frac{\gamma}{A} \left[ \gamma_{ij} + L \left( \tilde{v}_k \tilde{v}^k \gamma_{ij} - \tilde{v}^i \tilde{v}^j \right) + M \epsilon_{ijp} B^p + \right.$$

$$\left. LM \tilde{v}_i B^j \left( \epsilon^{ijk} \tilde{v}_k + M^2 B^j B^j \right) \right]$$

and

$$A = \frac{\gamma}{3} \epsilon^{ikl} \epsilon^{jmn} A_{ij} A_{km} A_{ln}$$

$$= \frac{\gamma}{3} \epsilon^{ikl} \epsilon^{jmn} \left( \gamma_{ij} + L \tilde{v}_i \tilde{v}_j + M \epsilon_{ijp} B^p \right)$$

$$= \frac{\gamma}{3} \left[ 1 + L \tilde{v}_n \tilde{v}^n + M^2 B_n B_n + LM^2 \left( \tilde{v}_n B^n \right)^2 \right] .$$

The inverse matrix is therefore

$$A^{ij} = \left[ \gamma^{ij} + L \left( \tilde{v}_k \tilde{v}^k \gamma^{ij} - \tilde{v}^i \tilde{v}^j \right) + M \epsilon^{ijk} B_k + \right.$$

$$\left. LM \tilde{v}_i B^j \left( \epsilon^{ijk} \tilde{v}_k + M^2 B^j B^j \right) \right] \left[ 1 + L \tilde{v}_n \tilde{v}^n + M^2 B_n B_n + LM^2 \left( \tilde{v}_n B^n \right)^2 \right]^{-1} ,$$

and, finally, the current density is

$$\tilde{J}^i = \left[ \gamma^{ij} + L \left( \tilde{v}_k \tilde{v}^k \gamma^{ij} - \tilde{v}^i \tilde{v}^j \right) + M \epsilon^{ijk} B_k + \right.$$

$$\left. LM \tilde{v}_i B^j \left( \epsilon^{ijk} \tilde{v}_k + M^2 B^j B^j \right) \right] \left[ 1 + L \tilde{v}_n \tilde{v}^n + M^2 B_n B_n + LM^2 \left( \tilde{v}_n B^n \right)^2 \right]^{-1} .$$
