Department of Anaesthesiology, Amrita Institute of Medical Sciences, Amrita Vishwa Vidyapeetham, Kochi, India

**Background:** Inappropriate use of intravenous and inhaled anesthetics may be dangerous in infants undergoing facial cleft surgeries. This study primarily aimed to compare the effect of infraorbital nerve block on sevoflurane requirement in infants undergoing cheiloplasty. Intraoperative opioid consumption, hemodynamics, blood glucose levels, extubation time, and delirium were also compared.

**Methods:** This prospective, randomized, double-blinded study was conducted in 34 infants undergoing cheiloplasty under general anesthesia. After induction, group A received bilateral infraorbital nerve block with 0.5 mL of 0.5% bupivacaine and group B 0.5 mL saline. An increase in heart rate or blood pressure > 20% was managed by increasing sevoflurane by 2–2.5%, followed by fentanyl 0.5 µg/kg bolus. The chi-square test and independent-sample t-test were used where applicable.

**Results:** Demographics, duration of surgery, and intravenous fluids used were comparable between the groups. Compared to group A, patients in group B had significantly higher consumption of fentanyl (14.2 ± 4.4 µg vs. 22.1 ± 6.2 µg) and sevoflurane (14.2 ± 4.8 mL vs. 26.8 ± 15.6 mL). Intraoperative hemodynamic parameters were significantly lower in group A, the number of times increases in hemodynamic parameters occurred, and fentanyl supplemental bolus was required remained significantly lower in group A than in group B. Intraoperative glycemic levels remained higher in group B, and the extubation time was significantly shorter in group A than in group B (4.40 ± 1.60 min vs. 9.2 ± 2.18 min). Group A had a lesser occurrence of postoperative delirium.

**Conclusion:** Supplemental infraorbital block in infants undergoing cheiloplasty under general anesthesia resulted in significantly decreased anesthetic requirements and optimal hemodynamic and glycemic levels with faster extubation and lesser delirium.

**Keywords:** Cleft Lip; Fentanyl; Infant; Nerve Block; Sevoflurane.

INTRODUCTION

The repair of the primary cleft lip promptly is gaining popularity. Due to concerns about the age group and the possibility of associated conditions predisposing to difficult airways, perioperative pain management in infants undergoing facial cleft surgeries is often considered complicated. Respiratory depression caused by the inappropriate use of opioids or volatile agents could be dangerous [1,2]. Therefore, extubation following cleft repair in infants is usually delayed until the child...
is fully awake.

Infraorbital nerve block, if given pre-emptively to augment general anesthesia, reduces the requirements of anesthetic agents during cleft lip surgery [3-6]. The resultant lesser sedation in the immediate postoperative period reduces the risk of respiratory complications. As the surgical stress response becomes blunted with the addition of a regional block to supplement general anesthesia, the intraoperative glycemic levels could remain optimal. We hypothesized that secondary to administration of infraorbital nerve block and proper analgesia, the use of opioids and inhalational agents could be reduced, which would be reflected by a shorter extubation time with less emergence delirium.

This study aimed to primarily compare the effect of supplemental bilateral infraorbital block on intraoperative sevoflurane requirement in infants undergoing cleft lip correction under general anesthesia. The secondary objectives were to assess intraoperative fentanyl consumption, changes in the heart rate (HR) and blood pressure (BP), the number of times intervention was required to correct intraoperative hemodynamic changes, the number of times additional fentanyl bolus was required, and blood glucose levels. The extubation time and degree of post-extubation delirium were also compared between the groups.

METHODS

This prospective randomized, double-blinded study was conducted after obtaining approval from the hospital ethical committee (IRB-AIMS-2018-286) and parental consent. It was registered in the Clinical Trial Registry India (CTRI/2019/02/017592). Thirty-four patients who underwent cleft lip surgery under general anesthesia, aged 1 month to 1 year, of American Society of Anesthesiologists physical status 1, were included in the study. Those with diabetes, anticipated difficult airway, infants of diabetic mothers, and surgery duration lasting > 3 hours were excluded. Patients were randomly divided into two equal groups of 17 each based on a computer-generated random sequence of numbers. Sequentially numbered opaque sealed envelopes were used for the conceal allocation.

To the best of our knowledge, no similar studies have been published. A pilot study was initially conducted with 10 infants in each group who underwent cheiloplasty with and without infraorbital block. Sevoflurane consumption during surgery was compared between patients who received preoperative bilateral infraorbital nerve block (13.26 ± 4.49 mL) to those who did not (33.14 ± 17.79 mL). Based on this result, with 90% power and 95% confidence interval, the sample size was calculated to be 17 per group to obtain statistically significant results.

All infants fasted for 6 h for formula feeds or solids, 4 h for breast milk, and 2 h for clear fluids. The total duration of nil per oral (NPO) attained in all infants was noted. On the day of surgery, all infants received general anesthesia according to a standardized protocol. Once infants were taken into the operation theater, standard preinduction monitors such as electrocardiograms, pulse oximetry, and non-invasive BP monitoring were attached. All patients were induced with sevoflurane 8% in oxygen at a flow rate of 6 L/min, and intravenous access was obtained with a 22G or 24G cannula. Subsequently, the first random blood sugar (RBS) reading was performed using a standard glucometer from the finger/toe prick before intravenous fluid administration was initiated.

All patients received glycopyrrolate (0.01 mg/kg body weight), fentanyl (2 µg/kg), and propofol (1 mg/kg), following which sevoflurane concentration was reduced to 2% vaporizer dial setting. The volume of sevoflurane required for induction was noted at this point. Muscle relaxation was provided with suxamethonium (1.5 mg/kg body weight), and the patients were intubated with an oral Ring Adair Elwyn endotracheal tube with an internal diameter of 3.5-4.5 mm as appropriate. Anesthesia was maintained with sevoflurane (1.5-2%) in oxygen and nitrous oxide mixture (1:1) at a flow rate of 1 L/min to maintain an end-tidal minimum alveolar concentration (MAC) of 1. A 0.5 mg/kg body weight bolus of tracurium
Infraorbital block reduces anesthetic requirements

was administered after securing the airway, followed by 0.01 mg/kg body weight intermittent boluses.

Patients in group A received bilateral infraorbital nerve block with 0.5% bupivacaine (0.5 mL) by the extraoral landmark technique, while the same volume of normal saline was used in group B. The block was administered under sterile conditions using a 26G needle by first palpating the infraorbital rim at a point on a vertical line drawn caudally through the center of the pupil to the angle of the mouth, and the infraorbital foramen was localized by palpation just below the orbital rim. The finger was kept at the infraorbital rim throughout to prevent penetration into the orbit. A cephalo-medial direction was used to infiltrate the infraorbital foramen with 0.5 mL of 0.5% bupivacaine bilaterally (Fig. 1).

Anesthetic management after administration of the block was carried out by another anesthetist, who was blinded to the type of solution used for giving the infraorbital block and collected the subsequent data. Intraoperative hemodynamic variables such as HR, systolic blood pressure (SBP), and mean arterial pressure (MAP) were documented every 15 min until the end of surgery. Any increase in HR or SBP > 20% of the baseline was initially managed by increasing the sevoflurane to 2-2.5% to attain an end-tidal MAC of 1.5, and thereafter persistent increase in HR and SBP were considered as inadequate analgesia, and fentanyl 0.5 µg/kg body weight bolus was administered, not exceeding 1 µg/kg in 30 min. The number of times increases in HR, or SBP > 20% from baseline occurred, requiring intervention such as increasing sevoflurane concentration and the number of times fentanyl supplemental bolus was required were noted in both the groups.

Maintenance fluid, Ringers lactate (RL) with 1% dextrose, was administered according to the bodyweight using the Holliday and Segar formula, and the total volume of intravenous fluid used was noted. RBS levels were checked at hourly intervals of 1, 2, and 3 h or at the end of surgery if the duration of surgery lasted < 3 h, using a standard glucose meter (FreeStyleOptium H System, Copyright © 2015 Abbott Laboratories, Abbott Park, Illinois, USA) with a test strip on capillary blood. Hypoglycemia (RBS < 65 mg/dL) was managed with 10% dextrose at 2.5 mL/kg body weight, and in the presence of hyperglycemia (RBS > 150 mg/dL), the glucose-containing solution was replaced with plain RL. The incidence of hyperglycemia and hypoglycemia were documented, and infants presenting with these incidences were excluded from the study.

Thirty minutes before the end of the surgery, paracetamol (15 mg/kg body weight) was administered intravenously to all infants for postoperative analgesia. At the end of the surgery, infants belonging to group B received bilateral infraorbital nerve block before the inhalational agent was stopped. Reversal of neuromuscular blockade was performed with neostigmine (0.05 mg/kg) and glycopyrrolate (0.01 mg/kg). Extubation was performed when the infants were fully awake with the return of protective airway reflexes, eye-opening/crying on suctioning with full motor power, and presenting regular and adequate tidal volume generation with a normal respiratory rate. Extubation time was calculated from the time the inhalational agents were discontinued after extubation. The degree of emergence delirium after extubation was assessed using the Pediatric Anesthesia

http://www.jdapm.org  131
CONSORT Flow Diagram

Emergence Delirium (PAED) scale score [7] at 5 min and 10 min after extubation (minimum score = zero, maximum score = 20).

An Avance CS2 workstation and Tec 7 vaporizer were used to administer anesthesia. At the end of the surgery, the volume of sevoflurane used after induction until the end of surgery was noted from the anesthesia workstation, and fentanyl consumption and surgery duration were also documented. All cases were performed in the same theater using the same anesthesia workstation and vaporizer.

The chi-square test was used to compare the distribution of gender in each group. An independent sample t-test was used to compare variables such as fentanyl and sevoflurane consumption, hemodynamic variables, RBS, age, and weight. The number of times fentanyl was administered and sevoflurane was increased and PAED scores were compared using the Mann-Whitney test. Statistical analyses were conducted using SPSS version 20.0 for Windows (IBM Corporation, Armonk, NY, USA).
Table 1. Comparison of demographic data

| Variables       | Group A   | Group B   | P-value |
|-----------------|-----------|-----------|---------|
| Age in months   | 4.6 ± 2.3 | 5.3 ± 2.2 | 0.383   |
| Weight in kg    | 6.3 ± 1.0 | 6.8 ± 1.4 | 0.197   |
| Gender          | n (%)     | n (%)     |         |
| Male            | 6 (35.3)  | 7 (44.4)  |         |
| Female          | 11 (64.7) | 10 (55.6) | 0.836   |

RESULTS

Four children were excluded initially after assessing eligibility as parents of two infants were not willing to participate in the study, and two had a fasting RBS of < 65 mg/dL and had received 10% dextrose. Data of 34 infants were analyzed (Fig. 2), and the demographic variables were comparable in both the groups (Table 1). Fentanyl consumption in group A was significantly lower than that in group B (14.2 ± 4.4 µg vs. 22.1 ± 6.2 µg, P < 0.001). Sevoflurane consumed in group A was 14.2 ± 4.8 mL and that in group B was 26.8 ± 15.6 mL; the difference was statistically significant. Extubation time was significantly shorter in group A than in group B (4.40 ± 1.60 min vs. 9.2 ± 2.18 min, P < 0.001). The total volume of intravenous fluids used intraoperatively, duration of NPO, and surgery were comparable in both the groups (Table 2).

The number of times an intervention was required, in response to HR and/or BP change of > 20% from baseline, was significantly higher in group B than in group A. The same observation was made by comparing the number of times fentanyl bolus was required.
Table 4. Comparison of mean random blood sugar values in mg/dL

| Time                     | Group A Mean ± SD | Group B Mean ± SD | P-value |
|--------------------------|-------------------|-------------------|---------|
| Baseline                 | 90.4 ± 8.5        | 92.8 ± 13.2       | 0.516   |
| 1st hour                 | 98.1 ± 14.6       | 116.4 ± 16.1      | 0.001   |
| 2nd hour                 | 105.5 ± 13.3      | 131.7 ± 12.6      | < 0.001 |
| 3rd hour/End of surgery  | 114.5 ± 11.0      | 132.7 ± 19.6      | 0.057   |

SD, standard deviation.

intraoperatively (P < 0.001). The PAED scale score at 5 and 10 min after extubation was significantly lower in group A than in group B (P < 0.001, Table 3).

The baseline hemodynamic variables were comparable between the two groups. The mean HR, SBP, and MAP were significantly higher in group B at most time points intraoperatively (Figs. 3 and 4).

Baseline RBS and that at 3 h/end of surgery did not show any significant difference between the groups. However, RBS at 1 h and 2 h intraoperatively was significantly higher in group B (Table 4). No patient in either group required the use of an additional 10% dextrose or change of maintenance fluid to RL as RBS of patients remained within the range of 65–150 mg/dL, indicating no incidence of hypoglycemia or hyperglycemia during the study period.

**DISCUSSION**

An infraorbital nerve block is commonly performed during cheiloplasties [3,4,8,9]. Two approaches have been described for performing infraorbital nerve block: the intraoral or extraoral technique. However, the extraoral technique is considered safer than the intraoral technique because the risk of orbital globe injury is lower [3,4,8,10]. It is safe and easy to administer the block using the extraoral landmark technique, which provides profound intraoperative and postoperative analgesia. We also observed a significant decrease in intraoperative consumption of anesthetics when the block was administered preoperatively.

As the intraoperative requirement of opioids is reduced, it decreases the risk of postoperative airway complications such as opioid-induced respiratory depression, desaturation, airway obstruction, and postoperative nausea and vomiting. Due to faster awakening and less delay in extubation, the use of pre-emptive infraorbital block has been shown to ensure early recovery and feeding in infants receiving this block[3,4,8,10]. In our study, we also observed shorter extubation times in such infants.

The degree of emergence delirium after extubation was assessed using the PAED scale score [7]. The degree of emergence delirium increased directly with the total score. Our study showed significantly lower scores at 5 and 10 min after extubation in the block group, which can be interpreted as lesser residual anesthetic effects and better postoperative analgesia.

We used 0.5% bupivacaine (0.5 mL) because we did not use any additives and it has been shown that infraorbital nerve block with 0.5% bupivacaine, when combined with general anesthesia, resulted in significantly reduced consumption of opioids during pediatric cleft lip correction [11]. Various other studies have also shown that infraorbital nerve block supplemented with adjuncts prolonged analgesia and reduced the requirement for opioids. The adjuncts used were clonidine [3] fentanyl, [12], pethidine [13], tramadol [14], ketamine [15], dexamethasone, and dexmedetomidine [16]. Adjuncts prolong the duration of analgesia and lower the concentration of local anesthetic used.

Higashizawa et al. [17] demonstrated a decreased requirement of inhalational agent, isoflurane, when infraorbital nerve block was pre-emptively administered in adults undergoing functional endoscopic nasal sinus surgery. Eipe et al. [5] and Salloum et al. [6] showed the usefulness of bilateral infraorbital nerve block as the sole anesthetic technique with no requirement of opioids intraoperatively. However, the age of subjects was above 12 years in the study by Eipe et al. [5] and of varying age groups in a trial by Salloum et al. [6]. M N Mayer et al. [18] also showed that general anesthesia for infants with cleft lip using bilateral infraorbital block was a safe,
