**Objective:** To investigate the persistent remission rate (PRR) and its predictors within the first year of antipsychotic treatment in first-episode schizophrenia (FES) patients.

**Methods:** In a sample of 301 FES patients who remained in antipsychotic treatment for 1 year, we assessed symptoms with the Positive and Negative Syndrome Scale (PANSS), cognition in six domains and functioning with the Personal and Social Performance Scale (PSP).

**Results:** In total, 75.4% (227/301) of FES patients remaining in antipsychotic treatment reached persistent remission (PR) in one year. The PSP score was higher in remitters than non-remitters at the endpoint of the 1-year follow-up (P <0.0001). The PANSS negative score—but not the PANSS total score, positive score or general psychopathological score; PSP score; or cognitive performance at baseline—was negatively associated with PR. Lower scores for “abstract thinking” and “stereotyped thinking” were independent predictors of PR.

**Conclusions:** In FES, nearly 3/4 patients could achieve PR with 1 year of antipsychotic treatment, and having fewer negative symptoms, especially thinking and volition symptoms, can predict PR.

**INTRODUCTION**

The prognosis of schizophrenia is considered much worse than that of other psychoses (1). Patients with a first episode of schizophrenia tend to respond better to antipsychotics than chronic patients (2). Various guidelines suggest that first-episode schizophrenia (FES) patients should remain on antipsychotics for at least 1 year for maintenance treatment (3). However, only some FES patients
achieve remission in one year of antipsychotic treatment, with remission being the basic aim of such treatment and the basis for an ideal outcome.

It has been reported that the remission rate in FES patients is between 17.0 and 78.0% (4), and this wide range is partly due to the diverse criteria for remission. Remission defined only based upon symptom severity is not stable; approximately 70% of symptom remitters in FES experience symptom exacerbation within 1 year (5). In 2005, Andreasen et al. (with the Remission in Schizophrenia Working Group, RSWG) proposed criteria for persistent remission (PR) in schizophrenia: when eight items on the Positive and Negative Symptoms Scale (PANSS) received a score of less than four points (which was considered to indicate symptomatic remission) for more than 6 months. These criteria were considered to provide researchers and clinicians with a robust, well-defined outcome goal for the long-term treatment of schizophrenia and to facilitate comparison between different studies (6). Jager et al. revealed that the consistency between the criteria by the RSWG (including both symptom severity and minimum time threshold) and other criteria employed previously was between 52.6 and 80.0% (7).

Most studies reporting the persistent remission rate (PRR) of FES patients throughout 1 year of antipsychotic treatment were randomized controlled trials (RCTs) (8, 9). However, due to the strictness of the study design, patients in RCTs are assigned a certain antipsychotic and are excluded from the analysis if they switch to another antipsychotic. Approximately one-third of FES patients require a change in medication within their first year of treatment (10). Thus, the remission rate reported in traditional RCTs may reflect remission from one specific antipsychotic rather than a real-world picture of PRR throughout the 1-year antipsychotic treatment.

Most non-RCT longitudinal studies reported remission rates with criteria other than the criteria by the RSWG (11–15). Lally et al. conducted a meta-analysis of first-episode psychosis (FEP) studies that included longitudinal studies and excluded RCTs (16). According to the results, the symptomatic remission rate in FES reached 56.0%, as judged by diverse criteria and based on a wide follow-up duration ranging from 1 to 17 years. Only two of the included studies reported a PRR based on the criteria by the RSWG. One was conducted in Indonesia and followed 59 FES patients for 17 years. It was reported that 23.7% of the patients achieved both symptom and functional remission, and the remitters ceased antipsychotic use beginning in the 11th year (17). The other study was from Hong Kong and reported a PRR of 59.6% within 1 year in a sample of 104 FES spectrum disorder patients; however, medication information was not reported.

Thus, the PRR of FES during 1 year of antipsychotic treatment remains unclear. We aimed to examine the PRR and its predictors during 1 year of antipsychotic treatment for FES. We hypothesized that 1) more than half of the FES patients could remit during the 1-year antipsychotic treatment and 2) baseline sociodemographic, clinical and cognitive characteristics would predict PR.

**METHODS**

**Participants and Setting**

The data came from a 1-year randomized, open-label clinical trial conducted in 6 major psychiatric hospitals in China from 2008 to 2010 (18). The trial was approved by the ethics committees of the participating centers. Written informed consent was obtained after the participants received a complete description of the study. FES patients with the following characteristics were recruited: illness duration of fewer than 3 years (the onset was determined in the SCID-I/P according to when the first symptom appeared), continuous antipsychotic treatment for fewer than 4 weeks and a cumulative period of intermittent antipsychotic treatment of fewer than 12 weeks. A 3-phase design was employed to mimic the reality of clinical practice (18). Phase I was a randomization phase (comparison of the three antipsychotics (risperidone, olanzapine and aripiprazole) has been published) (19). Patients who showed little or no benefit from the Phase 1 treatment were allowed to enter Phase 2, in which patients underwent a medication switch to one of the other two antipsychotics. Patients who did not respond to the second antipsychotic were allowed to enter Phase 3, which allowed the research psychiatrists to introduce other antipsychotics such as clozapine and augmentation or antipsychotic polypharmacy. Concomitant treatments such as antidepressants or mood stabilizers were permitted if necessary. The design aimed to keep the patients on antipsychotic treatment for as long as possible. The primary outcome in the original RCT was the baseline-to-endpoint change in the PANSS total score (19). This study was a secondary analysis of an RCT database and based on data of subjects who completed the 1-year follow-up. In total, 569 patients were recruited, and 301 subjects completed the 1-year follow-up (20). Data from the 301 patients were included in the analysis. There were no differences in the demographic, psychopathological and functional data between those who completed the 1-year follow-up and those who did not (P >0.05).

**Assessment and Evaluation**

Basic demographic data were collected with a standard data collection form designed especially for this study. Clinical characteristics, including illness duration, acute onset (less than 3 months from symptom onset to full disease manifestation), and early onset (onset before 18 years) was drawn from the SCID-I/P. Psychopathology was measured with the PANSS (21). Function was evaluated with the Personal and Social Performance Scale (PSP) (22). Recruited patients were evaluated by a trained psychiatrist in each hospital at baseline and at week 4, 8, 12, 26, 39 and 52. Six cognitive domains (verbal learning and memory with the Hopkins Verbal Learning Test-Revised [HVLT-R]; visual learning and memory with the Brief Visuospatial Memory Test-Revised [BVMT-R]; speed of processing with the Trail Making Test Part A, Color Trails Test, category fluency test, Stroop Color Test and Wechsler Adult Intelligence Scale digit symbol-coding subtest; working...
memory and attention with the Wechsler Memory Scale-span subtest and paced auditory serial addition task; executive function with the Stroop Color-Word Test and Color Trails Test; and motor skills with the Grooved Pegboard Test) were measured at baseline (23, 24).

There were two to three psychiatrists responsible for the clinical assessments at each site. All interviewers attended a 1-week training workshop on the use of the rating instruments (the PANSS, PSP and cognitive tests) prior to the study and reached a high level of consistency (intraclass correlation coefficients or kappa values >0.75).

Primary Outcome
The primary outcome was PRR within 52 weeks, which was calculated as the number of patients who achieved PR within 52 weeks divided by the number of patients who completed the 52-week follow-up. PR was defined with the PANSS as a score on items P1, P2, P3, N1, N4, N6, G5, and G9 ≤3 for at least 6 consecutive months (6). The secondary outcomes were predictors of PR within 52 weeks.

Statistical Methods
Independent T-tests or nonparametric tests were used to compare the demographic, psychopathological and functional data between remitters and non-remitters. A chi-square test was used to compare categorical data, including gender and originally assigned antipsychotic.

Any variable that was significant in the univariate analysis was confirmed in the multivariate logistic regression analysis with the scores of the six cognitive domains (reported as diathesis factors in schizophrenia).

A final multivariate logistic analysis was conducted on the variables that were confirmed to be significant in the multivariate logistic analysis mentioned above to explore potential interactions.

RESULTS
Rate of Remission Within 1 Year of Antipsychotic Treatment
At the endpoint of the 1-year follow-up, 75.4% (227/301) of patients had achieved PR. In total, with the early discontinuers included in denominator, 39.9% (227/569) of patients achieved PR. At the endpoint, the PSP score was higher in remitters than non-remitters (P < 0.0001) (Table 1).

Demographic and Clinical Characteristics of the Sample
In the 301 patients who completed the first year of antipsychotic treatment, there was no difference between remitters and non-remitters in terms of baseline demographic and clinical characteristics, namely, psychiatric family history, illness duration, acute onset (less than 3 months from symptom onset to full disease manifestation), early onset (onset before 18 years) and concomitant antidepressants or mood stabilizers. Totally, 27 subjects accepted antidepressants, with fluoxetine equivalent dose (25.7 ± 8.9)mg (25, 26). Non-remitters were associated with more medication switch and higher daily antipsychotic dosage (in olanzapine equivalent) (27) during 1-year treatment, which indicated more treatment effort (Table 2).

Comparison Between Remitters and Non-Remitters
Univariate Analysis of the Baseline Characteristics
At baseline, the PANSS negative score was lower in remitters than in non-remitters; however, there were no differences in the PANSS total, positive and general psychopathological scores; PSP score; and cognitive performance (all P > 0.05) (Table 3). Of the seven items on the PANSS negative scale, the N2 “emotional withdrawal”, N4 “passive/apathetic”, N5 “abstract thinking” and N7 “stereotyped thinking” scores were lower in remitters (P < 0.01, P < 0.05, P < 0.01 and P < 0.05, respectively) than in non-remitters, but there were no differences in the N1 “blunted affect”, N3 “poor rapport” and N6 “lack of spontaneity” scores.

Multivariate Analysis of the Baseline Characteristics
In the multivariate analysis including the PANSS negative scale score (P < 0.05, OR = 0.947[0.906, 0.991]), N2 “emotional withdrawal” (P < 0.05, OR = 0.789[0.626, 0.995]), N4 (P < 0.05, OR = 0.799[0.646, 0.990]), N5 (P < 0.05, OR = 0.761[0.602, 0.961]), and N7 “stereotyped thinking” (P < 0.05, OR = 0.745 [0.588, 0.943]) scores, respectively with the 6 cognitive scores, their significance persisted.

In logistic regression analysis including N2 “emotional withdrawal”, N4 “passive/apathetic”, N5 “abstract thinking” and N7 “stereotyped thinking” as independent variables, N5 “abstract thinking” and N7 “stereotyped thinking” remained significant in the analysis.

| TABLE 1 | Comparison of endpoint clinical characteristics between remitters and non-remitters. |
|----------|-----------------------------------------------|-------------------|-------------------|-------------------|-------------------|
| Endpoint characteristics | Remitters (N = 227) | Non-remitters (N = 74) | Remitters and non-remitters (N = 301) | P |
| PANSS-total score | 35.9 (5.8) | 48.2 (13.1) | 38.9 (9.8) | 0.000 |
| PANSS-positive score | 7.4 (1.1) | 10.4 (4.8) | 8.0 (2.8) | 0.000 |
| PANSS-negative score | 9.5 (3.0) | 15.3 (5.8) | 10.9 (4.6) | 0.000 |
| PANSS-general psychopathological score | 19.0 (3.0) | 23.0 (6.0) | 20.0 (4.3) | 0.000 |
| PSP | 80.0 (9.3) | 68.3 (12.4) | 77.2 (11.3) | 0.000 |

PANSS, positive and negative syndrome scale. Theoretical scores range from 30 to 210 (total score), from 7 to 49 (positive scale), from 7 to 49 (negative scale), and from 16 to 112 (general psychopathology scale). Higher scores indicate more severe psychopathology. PSP, personal and social performance scale. Higher scores indicate better function.
significant but N2 “emotional withdrawal” and N4 “passive/apathetic” did not. Considering the potential overlap of N2 “emotional withdrawal” and N4 “passive/apathetic”, we conducted two additional logistic regression analyses including N2 “emotional withdrawal”, N5 “abstract thinking” and N7 “stereotyped thinking” and N4 “passive/apathetic”, N5 “abstract thinking” and N7 “stereotyped thinking” respectively, and the significance of N5 “abstract thinking” and N7 “stereotyped thinking” persisted.

### DISCUSSION

Nearly 3/4 FES patients, who completed the 1-year routine antipsychotic treatment, achieved relatively stable clinical recovery and functional recovery. Patients with fewer negative symptoms had a better chance of PR. One higher score on item N2 “emotional withdrawal”, N4 “passive/apathetic”, N5 “abstract thinking” or N7 “stereotyped thinking” could reduce the possibility of PR by nearly 1/5 to 1/4.

#### FES PRR Within 1 Year of Treatment

Gabeal et al. obtained an average PRR of 42.3% (2–3 years after the acute phase) based on the results from more than 10 FES studies conducted from 2006 to 2011 (5). A recent meta-analysis showed an FES symptomatic remission rate as high as 56.0% (16). All the studies mentioned above included the dropouts in the denominators when calculating the PRR. The PRR in this study was 39.9% (227/569) if the dropouts were included in the analysis, which is consistent with previous studies. This result suggests that more than 1/3 of FES patients achieved PR within the 1-year follow-up. However, including the dropouts in the denominator when calculating the PRR might lead to confusion. On the one hand, the dropouts may achieve PR after dropping out of the study, which might lead to underestimation of the rate. On the other hand, the rate could be greatly influenced by the

### TABLE 3

| Baseline characteristics | Remitters (N = 227) | Non-remitters (N = 74) | Remitters and Non-remitters (N = 301) | P |
|--------------------------|--------------------|-----------------------|--------------------------------------|---|
| PANSS-total score        | 85.7 (13.7)        | 88.3 (15.4)           | 86.3 (14.2)                          | 0.161 |
| PANSS-positive score     | 23.4 (5.2)         | 23.4 (5.3)            | 23.4 (5.2)                           | 0.880 |
| PANSS-negative score     | 20.3 (7.2)         | 22.9 (5.3)            | 23.4 (5.2)                           | 0.007 |
| PANSS-general psychopathological score | 42.0 (7.6) | 42.0 (7.6) | 42.0 (7.6) | 0.741 |
| PSP                      | 42.2 (12.3)        | 41.5 (17.0)           | 42.0 (13.8)                          | 0.252 |
| Verbal learning          | 36.9 (11.7)        | 39.0 (10.8)           | 37.4 (11.5)                          | 0.233 |
| Visual learning          | 38.1 (11.9)        | 37.3 (10.1)           | 37.9 (11.5)                          | 0.657 |
| Working memory and attention | 36.6 (9.9) | 35.4 (10.2) | 36.3 (9.9) | 0.418 |
| Information processing speed | 36.3 (8.3) | 34.6 (9.4) | 35.9 (8.6) | 0.179 |
| Executive function       | 33.1 (10.7)        | 32.2 (9.6)            | 32.9 (10.4)                          | 0.573 |
| Fine motor               | 27.2 (10.6)        | 28.3 (10.9)           | 27.0 (10.7)                          | 0.577 |

All the abbreviations are explained in the first footnote to Table 1.
dropout rate; thus, the PRR with the dropouts included might reflect a social or behavioral dimension rather than the outcome of antipsychotic treatment, although Lally et al. reported that remission in FEP was not associated with dropout rates (16).

When only patients who completed the 1-year follow-up were included in the denominators in RCTs, Boter et al. reported a PRR of 68.7% in the EUFEST study, and Crespo-Facorro et al. reported a PRR of 35.2% (9). Another RCT of 111 patients in Germany showed that the PRR was 58.6% (65/111); however, some patients also received psychological education or CBT for 8 weeks (5). The PRR in our study was much higher, which suggested that a relatively flexible regimen was needed to maximize the possibility of PR in FES.

One naturalistic follow-up study of 104 FEP patients in Hong Kong showed that the PRR was 59.6% (28), but this study did not define the antipsychotic treatment patients had received prior to recruitment. Our study recruited only FES patients with no or minimal antipsychotic exposure. Being previously untreated was a predictor of remission in general schizophrenia (11). The difference in the PRR between our study and the study by Chang et al. suggested that being previously untreated might also be a predictor of PR in the FES population. Thus, most FES patients, who completed the 1-year antipsychotic treatment, achieved relatively stable symptomatic and functional outcomes.

**Predictors of PR in FES**

This study indicates that PR in FES patients who completed the 1-year antipsychotic treatment was not associated with gender, age, onset age (5, 8, 16), medication (9), or education level (14), which was consistent with previous studies.

**Cognitive Impairment and PR**

Cognitive impairment is considered a diathesis factor in schizophrenia. However, Boter et al. failed to demonstrate that cognitive impairment predicted PR in the EUFEST study (8). Ventura et al. also showed that cognitive impairment, including in vocabulary, comprehension and visual information processing speed, was not associated with the PRR in the FEP population (29). Although Simonsen et al. suggested that baseline information processing speed—but not verbal memory, verbal fluency, working memory and interference control—was better in remitters than in non-remitters, the significance disappeared in a multivariate analysis (14). This study confirmed that cognitive impairment was not associated with PR within the first year of antipsychotic treatment.

**Baseline Symptoms and PR**

Notably, negative symptoms were the only independent predictor of PR within the first year of antipsychotic treatment, consistent with several previous studies (28). Baseline symptoms (especially negative symptoms) predicted remission in FES patients in a systemic review (4), although Ceskova et al. followed 93 male FES patients for 1 year and found no difference in the baseline PANSS total score or subscale scores between remitters and non-remitters (30). A more recent meta-analysis of FEP suggested that baseline psychotic symptoms were not associated with remission; however, it did not explore the potential effects of subgroup symptoms (16).

We found that negative symptoms rather than overall symptoms might predict PR and further revealed that “emotional withdrawal”, “passive/apathetic”, “abstractive thinking” and “stereotyped thinking” but not “blunted affect”, “poor rapport” and “lack of spontaneity and flow of conversation” predicted PR. This result suggested that only some negative symptoms are associated with PR.

“Emotional withdrawal” and “passive/apathetic” both refer to others’ observations and are used to assess volition impairment in patients with schizophrenia. There is abundant evidence demonstrating daily activity reduction in schizophrenia; however, the potential predictive power of these symptoms had not been explored previously.

It is interesting that the two items (“abstractive thinking” and “stereotyped thinking”) describing thinking impairment and not the items describing volition impairment were shown to independently predict PR. In other words, volition symptoms were mediated by thinking symptoms in their prediction of PR. P5 “abstractive thinking” refers to the ability to comprehend and abstract. N7 “stereotyped thinking” refers to the flexibility of thinking, that is, the ability to shift between two perspectives (or two beliefs about the world) according to the demands of the social situation. The Word Fluency Test in the cognitive assessment battery was used to assess the richness of thinking; however, performance on this test did not differ between remitters and non-remitters in a post hoc analysis. Thus, impairment in the ability to comprehend and abstract and in thinking flexibility rather than other thinking impairments (e.g., richness) might predict a lower likelihood of PR. Abstract thinking impairment is an established deficit in schizophrenia (31), and impairment in cognitive flexibility has been found in FES patients (32). This subgroup of negative symptoms has a high degree of overlap with cognitive symptoms. In fact, abstract thinking and stereotyped thinking are items of the cognitive rather than the negative component of the PANSS (33). It has been demonstrated that disorganization (with difficulty in abstract thinking as one of the three items) played a key (direct and indirect) role in real-life functioning in patients with schizophrenia (34). Comparelli et al., further demonstrated that difficulty in abstract thinking was correlated with social cognition and did not differ between early schizophrenia and late schizophrenia (35). However, there has been little research exploring the significance of these impairments in the prognosis of schizophrenia, though there has been some research exploring the underlying neural basis (32, 36). Our findings call for further studies with stricter designs to examine the predictive power of negative symptoms for PR, especially thinking symptoms and volition impairment rather than affective symptoms. Additionally, FES patients usually display mild or no negative symptoms, unlike chronic patients; indeed, in this study, the symptom severity as measured by the items on the negative subscale was generally “very mild” or “mild”. This might also explain why there was no difference in the perseveration error in the Wisconsin Card Sorting Test.
and daily activities were more likely to achieve PR, indicating that thinking and volition negative symptoms define the subset of FES patients who are less likely to achieve ideal symptom outcomes in 1 year of antipsychotic treatment. Thus, assessing these symptoms in detail is necessary in clinical practice. Optimization of the current pharmacological and non-pharmacological strategies for treating this group of patients is warranted.

**CONCLUSION**

The present study showed that over 3/4 FES patients achieved PR within 1 year of antipsychotic treatment. Patients with no impairment in their comprehension ability, thinking flexibility (WCST) or the completion time in the Color Trail II test between remitters and non-remitters in the post hoc analysis. However, these two variables reflect thinking flexibility in a rather limited and inflexible way, while the PANSS item N7 “stereotyped thinking” assesses comprehensive judgment of general information and thus better reflects mild impairment. Therefore, we speculate that even mild negative thinking or volition symptoms at baseline might predict a lower likelihood of PR in FES. More studies are needed to confirm this hypothesis.
