ABSTRACT

Context. During the course of a large spectroscopic survey of X-ray active late-type stars in the solar neighbourhood, we discovered four lithium-rich stars packed within just a few degrees to the sky. Although located in a sky area rich in CO molecular regions and dark clouds, the Cepheus-Cassiopeia complex, these very young stars are projected several degrees away from clouds in front of an area void of interstellar matter. As such, they are very good “isolated” T Tauri star candidates.

Aims. We present optical observations of these stars conducted with 1–2 meter class telescopes. We acquired high-resolution optical spectra as well as photometric data allowing us to investigate in detail their nature and physical parameters with the aim of testing the “runaway” and “in-situ” formation scenarios. Their kinematical properties are also analyzed to investigate their possible connection to already known stellar kinematic groups.

Methods. We use the cross-correlation technique and other tools developed by us to derive accurate radial and rotational velocities and perform an automatic spectral classification. The spectral subtraction technique is used to infer chromospheric activity level in the Hα line core and clean the spectra of photospheric lines before measuring the equivalent width of the lithium absorption line.

Results. Both physical (lithium content, chromospheric, and coronal activities) and kinematical indicators show that all stars are very young, with ages probably in the range 10–30 Myr. In particular, the spectral energy distribution of TYC 4496-780-1 displays a strong near- and far-infrared excess, typical of T Tauri stars still surrounded by an accretion disc. They also share the same Galactic motion, proving that they form a homogeneous moving group of stars with the same origin.

Conclusions. The most plausible explanation of how these “isolated” T Tauri stars formed is the “in-situ” model, although accurate distances are needed to clarify their connection with the Cepheus-Cassiopeia complex. The discovery of this loose association of “isolated” T Tauri stars can help to shed light on atypical formation processes of stars and planets in low-mass clouds.

Key words. stars: fundamental parameters – stars: pre-main sequence – stars: formation – stars: kinematics – X-rays: stars

1. Introduction

Although most studies of very young low-mass stars have concentrated on star-forming regions (SFRs) or young clusters, it has become increasingly evident that a considerable number of very young stars unrelated to prominent SFRs is present in the solar neighbourhood. Their existence far from interstellar material is difficult to reconcile with the standard picture of star formation. Different scenarios, such as “runaway” T Tauri stars (Sterzik & Durisen 1993, 1998) or formation in small turbulent clouds (Feigelson 1996), have been proposed as possible explanations. Most of the comoving associations of nearly coeval stars (i.e., moving groups (MG) discovered so far) are located in the southern hemisphere and may be tied to the Scorpius-Centaurus association (see, e.g., Zuckerman & Song 2004 and Torres et al. 2008).

Single active stars in the field, selected on the basis of their high coronal emission, are mostly young stars with an age of a few 100 Myr, i.e., in the zero-age main sequence (ZAMS), or even younger: post-T Tauri stars (PTTS) or T Tauri stars (TTS). Guillout et al. (2009) conducted a large ground-based observing program designed to perform the physical characterization of ≈ 1000 RasTyc stellar X-ray sources (Guillout et al. 1999) by analysing their high-resolution optical spectra. Although the sky density of the youngest stars (identified thanks to their very high-lithium content) is more or less uniform (Klutsch 2008), we discovered an unusual group of four lithium-rich stars towards the Cepheus-Cassiopeia (Cep-Cas) complex (see, e.g., Kun et al. 2008 and references therein). However, their space distribution in a wide region devoid of dense CO clouds and their stellar properties make the relation between these stars and the Cep-Cas complex uncertain. Young stars in the sky region around the Cep-Cas complex are indeed not necessarily associated with these SFRs. A good example is represented by the nearby young visual binary HIP 115147 (V368 Cep) and its reported comoving companion (Makarov et al. 2007), which are also projected towards the same region of the sky. HIP 115147 is currently classified as a very young “naked” PTTS (Nations et al. 1990, Chusanov et al. 1991, 1993), 20 to 50 Myr old, located at 20 pc whose origin remains disputed although it is certainly unrelated to the Cep-Cas complex (Montes et al. 2001a, López-Santiago et al. 2010).
In the present paper, we concentrate on the four stars that we previously discovered and study their properties, evolutionary status, and kinematics. The observations and data reduction are outlined in Sect. 2. The determination of their stellar parameters as well as the level of chromospheric activity, lithium content, and age are briefly discussed in Sect. 3. We discuss the properties of each star under scrutiny in Sect. 4. We conclude and summarize the results from the ongoing study of these sources in Sect. 5.

2. Observations and data reduction

Spectroscopic observations were conducted in 2001, 2002, and 2003 (see Table 1) at the OHP 1.52-m telescope using the Aurelie spectrograph to acquire spectra in both the H\(\alpha\) (\(\lambda\lambda \approx 6500–6620 \text{ Å}\)) and lithium (\(\lambda \lambda \approx 6650–6775 \text{ Å}\)) spectral regions at a resolution of \(R \approx 38000\). An echelle spectrum at \(R \approx 21000\) of TYC 4500-1478-1 was also taken with the FRESCO spectrograph of the 0.91-m telescope of the OAC in 2009. For details about the reduction of Aurelie and FRESCO spectra, the reader is referred to [Guillout et al. (2009)].

In 2008, complementary photometric observations were performed in the standard UBV system and Strömgren uvby filters with the 91-cm telescope of the OAC and a photon-counting refrigerated photometer equipped with an EMI 9893QA/350 photomultiplier, cooled to \(-15^\circ\text{C}\). For details about the reduction of photometric data, the reader is referred to [Frasca et al. (2006)].

CCD images in Johnson-Cousins V, Rc, and Ic filters were also acquired for two stars using the OAC focal-reducer imaging camera. The reduction of these data was performed following standard methods and the \(VRcIc\) magnitudes were extracted from the corrected images by means of aperture photometry. Photometric data are summarized in Table 2.

3. Astrophysical parameters, chromospheric activity, and lithium abundance

High-resolution spectroscopic observations allow us to derive radial (RV) and projected rotational velocities (\(v \sin i\)), spectral type, luminosity class, and metallicity. They also enable us to identify spectroscopic binaries. Cross-correlation functions (CCFs) were computed to derive radial velocities (Table 2) and we used the ROTFIT code [Frasca et al. (2003, 2006)] to evaluate effective the temperature (\(T_{\text{eff}}\)), gravity (log g), metallicity ([Fe/H]), and \(v \sin i\) of our targets (Table 3). We were also able to infer both the level of chromospheric activity (from the emission in the H\(\alpha\) line core) and the age (from the lithium abundance). The equivalent width of the lithium line (\(W_{\text{Li}}\)) and the net equivalent width of the H\(\alpha\) line (\(W_{\text{H\alpha}}\)) were measured in the spectrum obtained after subtracting the non-active template by integrating the residual H\(\alpha\) and lithium profile. We refer to [Frasca et al. (2006)] and [Guillout et al. (2009)] for a more detailed presentation of the methods we used to derive lithium abundances, along with chromospheric and coronal luminosities (Table 3).

As an independent estimate of the main astrophysical parameters, we evaluated the effective temperature, radius, and metallicity of these stars from our Strömgren photometry using the \(uvby\) algorithm [Moor (1985)], which also provides an estimate of the color excess \(E(b - y)\). As seen in Table 3, the values of effective temperature derived from spectroscopy and Strömgren photometry agree with each other to within 200 K. The metallicity index \(d_{\text{m0}}\) is in substantial agreement with the spectroscopic value [Fe/H] for all stars. Estimated radii and log g values excluded the possibility of lithium-rich giant stars.

4. Discussion

4.1. Star properties

The high resolution spectra and CCFs of our stars are shown in Figs. 1 and 2 for both H\(\alpha\) and Li i spectral regions. The characteristics of the stars, derived from the analysis of the spectra acquired in the H\(\alpha\) and lithium spectral regions, are now summarized below:

**BD+78 853**: Although both the H\(\alpha\) and lithium spectra display broad absorption lines, which are sometimes asymmetric, the automatic procedure failed to detect double peaks in any of the CCF. The H\(\alpha\) profile is seen in absorption, but the analysis found that the line is partly filled. The equivalent width of the lithium line is \(W_{\text{Li}} = 0.18 \text{ Å}\), corresponding to a lithium abundance log N(Li) = 3.05, which implies that BD+78 853 is young. The rotational velocity derived from the line broadening decreases by a factor two or so from the H\(\alpha\) (\(v \sin i = 50 \text{ km s}^{-1}\)) to lithium spectra (\(v \sin i ≈ 28 \text{ km s}^{-1}\)). This could be indicative of a spectroscopic binary, but may also be the result of a different system.

$^1$ Derived from spectra  $^2$ Derived from Strömgren photometry

CFC shape in the two spectral domains. The radial velocities derived from Hα and Li i spectral regions are compatible within 0.2 km s$^{-1}$ at RV = −6.4 km s$^{-1}$. Our present data suggest that BD+78 853 is a single star that is rotating relatively quickly, but they do not exclude a spectroscopic binary system. More data are needed to settle this point.

**TYC 4496-780-1**: The Hα line exhibits an absorption feature roughly centered on a strong asymmetric Hα emission profile. The Li i $\lambda 6707.8$ line with $W_{Li}=0.18\,\AA$ (log $N$(Li) = 3.14) is stronger than the nearby calcium line, as in the case of BD+78 853. In both spectra, the lines are very broad and the code detected two Doppler-shifted dips (at −5.5 and 45.2 km s$^{-1}$) in the Hα CCF with very different depths, suggesting a binary in which the two stars of the system have significantly different luminosities. In the lithium CCF, the footprint of a secondary component is clearly visible (although not detected by the automatic analysis) as an asymmetry on the red side of the main CCF dip, which is centered on about −4 km s$^{-1}$. We derived an RV ≈25 km s$^{-1}$ for the secondary dip, which would imply an RV variation of +2 and −20 km s$^{-1}$ for the primary and secondary component, respectively, of this SB2 candidate. The projected rotational velocity of TYC 4496-780-1 is estimated to be $v\sin i = 37 +/−10\,\text{km s}^{-1}$.

**TYC 4500-1478-1**: The FRESCO spectrum displays an Hα profile markedly filled-in by emission (see Fig. 1). The lithium region shows very sharp absorption lines and exhibits a very strong Li i $\lambda 6707.8$ line with $W_{Li}=0.30\,\AA$ corresponding to log $N$(Li) = 3.09. The perfect fit of the CCF allows us to derive accurate values of radial velocity (RV = −8.8 km s$^{-1}$) and projected rotational velocity ($v\sin i ≈ 9\,\text{km s}^{-1}$). Unless we observed a binary system in a conjunction, we consider TYC 4500-1478-1 as a single star.

**BD+78 19**: The Hα spectrum is typical of a mid-G type star without any remarkable characteristics. Both RV = −9.7 km s$^{-1}$ and $v\sin i ≈ 12\,\text{km s}^{-1}$ were derived from the Gaussian fit of the CCF. Apart from the observed Li i $\lambda 6707.8$ deep absorption line ($W_{Li}=0.22\,\AA$; log $N$(Li) = 3.00), the lithium spectrum CCF is clearly not Gaussian and a fit of a rotational profile provides a closer match. The radial velocity determination from the lithium region is compatible with the former value but the rotational velocity is larger by a factor 2 or so. This suggests that, although the individual spectra appear as single-lined, BD+78 19 may be a binary system of mass ratio ≈ 1 observed with Aurelie close to conjunction at both epochs.

The chromospheric and coronal luminosities (see Table 3) were computed assuming that all stars are 15 Myr old (see Table 4) for the adopted distances $d_{15\text{Myr}}$ and Sect. 4.3 for its justification. We found X-ray luminosities $L_X \approx 10^{30.4}$ erg s$^{-1}$ for all sources (within 0.2 dex), which is typical of weak-line T Tauri stars (WTTS) in Taurus-Auriga-Perseus SFRs. For both BD+78 853 and BD+78 19, we found $L_{X}\approx 10^{29.5}$ erg s$^{-1}$, a value slightly higher than that found by Guillout et al. (2009) for their PTTS candidates and about an order of magnitude lower than that in old binary systems, in which the coupling of spin and orbital motions by tidal actions can maintain high chromospheric activity for a very long time (Frasca et al. 2009). The Hα luminosity of TYC 4496-780-1 is an order of magnitude higher than that of BD+78 853 and BD+78 19, but both the shape of the Hα profile and the IR excess (see Sect. 4.2) infer that accretion is the primary cause of the observed emission.

**4.2. Spectral energy distributions**

The standard $UBVR_{CIC}$ photometry (Table 2), complemented with $HK_c$ magnitudes from the 2MASS catalogue (Cutri et al. 2003), allowed us to reconstruct the spectral energy distribution (SED) from the optical to the near infrared (IR) domain for all sources.

We used the grid of NextGen low-resolution synthetic spectra, with log $g = 4.0$ and solar metallicity by Hauschildt et al. (1999), to perform a fit to the SEDs. The effective temperature ($T_{\text{eff}}$) was kept fixed to the value derived with ROTFIT (Table 3) and we allowed the interstellar extinction ($A_V$), which affects the SED shape particularly at the shortest wavelengths, and the angular diameter, which scales the model surface flux to the stellar flux at Earth, free to vary. The Cardelli et al. (1989) extinction law with $R_V = 3.1$ was used. The optimal solution was found by minimizing the chi-square of the fit. The latter was performed only on $UBVRJ$ data, which are dominated by the photospheric flux of the star and are normally not appreciably affected by infrared excesses. The $A_V$ values are in the range 0.06−0.2 mag, in agreement with the color excesses $E(b-y)$, which were inferred from the Strömgren photometry. The rather low $A_V$ values are typical of sources at $\approx 80$−200 pc that are not embedded in dusty nebulae, and consistent with their position far from dark clouds. The angular diameters ($\phi$), all on the order of 0.1 mas, are reported in Table 4.

Figure 2 displays the results of our fitting procedure. As is clearly evident, the SEDs are reproduced well by the synthetic spectrum blueward of the $K_c$ band, with the exception of TYC 4496-780-1, which displays a strong near- and far-IR excess (IRAS fluxes). The lack of significant IR excess in three of our targets implies that these stars are likely to be either WTTS or PTTS. The slope of the SED between $K_c$ and 24 μm, $\alpha \approx -1.1$, allows us to tentatively classify TYC 4496-780-1 as a Class II young infrared source, i.e. a T Tauri star surrounded by an accretion disc, according to the definition of Lada (1987).
Fig. 1. Spectra (black line) in the Hα (upper panels) and lithium (lower panels) region of the Cepheus comoving stars, and the template spectra (red lines) of non-active lithium-poor reference stars broadened to the $v \sin i$ of the targets and Doppler-shifted according to their RV.

| TYC 4500-1478-1| 0.100  | 75                     | 130                     | 25.1                                     | -3.4                        | -8.8            | 3.2                         | -11.5                      | -4.1                        | 8.9                         | -14.6                      | -5.3                        |
| BD+78 19       | 0.092  | 90                     | 155                     | 23.2                                     | -2.8                        | -9.7            | 3.6                         | -12.7                      | -4.3                        | 9.8                         | -16.3                      | -5.5                        |

This classification is consistent with its Hα emission profile. Similar Hα line profiles are often observed in accreting TTS (Appenzeller et al. 2005). According to the concept of the magnetospheric accretion model, the large line width (several hundred km s$^{-1}$) is indicative of large-scale gas flows, while the inverse P Cygni profile traces the gas infall (Muzerolle et al. 2001; Kurosawa et al. 2006).

4.3. Kinematics and relation to Cep-Cas complex.

The spatial distribution of BD+78 853, TYC 4496-780-1, TYC 4500-1478-1 and, BD+78 19 is shown in Fig. 3 overplotted on the extinction map (Av) published by Dobashi et al. (2005), in a similar way to Fig. 2 of Tachihara et al. (2005). The position of the nearby young visual binary HIP 115147 and its comoving companion, discovered by Makarov et al. (2007), is also plotted together with the “isolated” young stars discovered by Tachihara et al. (2005). The closest prominent star-forming region is the Cep-Cas complex, which surrounds our stars. They are located in particular, at Galactic latitudes $14^\circ < b < 17^\circ$, on the west side of the Cepheus flare, a region of significant extinction outside the Galactic plane first recognized by Hubble (1934). Across the Cepheus flare region, Kun (1998) determined the distances to several dark clouds and concluded that the interstellar matter is concentrated at 200, 300, and 450 pc (although the whole Cep-Cas complex extends to 800 pc or so) separated roughly at regular intervals along Galactic latitudes. Olano et al. (2006) suggested that the Cepheus flare forms part of a large shell, 50 pc in radius, expanding at 4 km s$^{-1}$, that encloses an old supernovae remnant (Grenier et al. 1989), whose center can be located at $l = 120^\circ, b = 17^\circ$. The Cepheus flare is a region of active star formation as demonstrated by Kun et al. (2009), who discovered about 70 new PMS stars in the star-forming clouds.

All the four stars investigated by ourselves are projected in front of the void located between the dark clouds LDN 1333 (west), LDN 1241-1251 (east), and north of LDN 1259-1262. A group of seven stars, including TYC 4500-1478-1, located in this void and displaying typical T Tauri characteristics, was identified by Tachihara et al. (2005). For a few stars, including
The Tycho parallaxes are useless and one must rely on photometric distance estimates. To cover all the possibilities, we estimated for each star two distances that we assume to be a lower and upper limit. The lower limit was calculated for the hypothesis that the star is on the ZAMS. An age of 5 Myr would place our stars at distances mostly exceeding 250 pc, i.e. farther than the closest boundary of the Cepheus flare shell in that direction. This would contradict our photometric observations that no stars experience significant interstellar extinction. An age older than \( \approx 20-30 \) Myr would contradict the observational finding that, at this age, stars display no significant NIR excess. A good compromise is 15 Myr that we adopted in the following. The lower and upper limits to the distances \((d_{\text{ZAMS}}\text{ and } d_{15 \text{Myr}}\text{, respectively})\) are reported in Table 4.

As seen in the table, the ZAMS assumption would place our stars roughly within 100 pc of the Sun ruling out their association with the Cep-Cas complex whose CO clouds are farther away by nearly a factor of two. Needless to say that this assumption is also hardly compatible with the detection of the IR excess from an accretion disc around TYC 4496-780-1.

Despite the distance uncertainty, we consider these stars to be associated with the Cep-Cas complex, only on the basis of their proximity to this region, and adopt a distance of 200 pc for them, their relation to the cloud complex remains uncertain.

On the other hand, the 15 Myr assumption would place them roughly at the distance of LDN 1333, LDN 1261, and LDN 1228, the vicinity are also labelled.

TYC 4500-1478-1, they found a lithium equivalent width close to that often measured at the Pleiades upper envelope, implying a PTTS or ZAMS evolutionary status for them. Although they consider these stars to be associated with the Cep-Cas complex, the distance assumption, the quantitative analysis excludes any possibility of a common origin with the Hyades supercluster, respectively. The loci of the young-disc (YD) and old-disc (OD) populations are also marked. The position of HIP 115147 is plotted as a filled square.

The distance of our stars is crucial in determining their origin and a possible association with the Cep-Cas complex. Unfortunately, the Tycho parallaxes are useless and one must rely on photometric distance estimates. To cover all the possibilities, we estimated for each star two distances that we assume to be a lower and upper limit. The lower limit was calculated for the hypothesis that the star is on the ZAMS. An age of 5 Myr would place our stars at distances mostly exceeding 250 pc, i.e. farther than the closest boundary of the Cepheus flare shell in that direction. This would contradict our photometric observations that no stars experience significant interstellar extinction. An age older than \( \approx 20-30 \) Myr would contradict the observational finding that, at this age, stars display no significant NIR excess. A good compromise is 15 Myr that we adopted in the following. The lower and upper limits to the distances \((d_{\text{ZAMS}}\text{ and } d_{15 \text{Myr}}\text{, respectively})\) are reported in Table 4.

As seen in this table, the ZAMS assumption would place our stars roughly within 100 pc of the Sun ruling out their association with the Cep-Cas complex whose CO clouds are farther away by nearly a factor of two. Needless to say that this assumption is also hardly compatible with the detection of the IR excess from an accretion disc around TYC 4496-780-1. On the other hand, the 15 Myr assumption would place them roughly at the distance of LDN 1333, LDN 1261, and LDN 1228.

Additional crucial information to elucidate their origin tentatively can be derived from kinematics. Because errors in the distances are the major uncertainties (proper motions and radial velocity errors are smaller than or equal to 2 mas and 1.5 km s\(^{-1}\) respectively), we computed the heliocentric space velocity components, \( U, V, W \), in a left-handed coordinate system, both with distances corresponding to ZAMS radii \((U_{\text{ZAMS}}, V_{\text{ZAMS}}, W_{\text{ZAMS}})\) and adopting the \( d_{15 \text{Myr}} \) distances \((U_{15 \text{Myr}}, V_{15 \text{Myr}}, W_{15 \text{Myr}})\), i.e. assuming that all stars are located in proximity to the closest clouds of the Cep-Cas complex. The RV values measured on our spectra and Tycho-2 proper motions have been used. The positions of our four stars and HIP 115147 in the \( U-V \) kine-matical diagram are shown in Fig. 4 together with the mean position of the major stellar kinematics groups (SKG) discussed in Montes et al. (2001b), namely the IC 2391 supercluster (~50 Myr), the Pleiades SKG (~100 Myr), the Castor SKG (~200 Myr), the Ursa Major (UMa) group (~300 Myr), and the Hyades supercluster (~600 Myr). Figure 4 readily shows that, whatever the distance is, all our stars share the same kinematics within a few km s\(^{-1}\) proving that they form a homogeneous MG with the same origin. We also note that both distances and kinematics seem to rule out an origin in common origin with HIP 115147.

To assess their membership to the aforementioned SKGs on more objective grounds, we used the probabilistic approach described in Klutsch (2008), i.e. we computed the probability \( P \) that a star with heliocentric velocities \( U, V, W \), and \( W \) has a Galactic motion compatible with a given SKG. Independently of the distance assumption, the quantitative analysis excludes any possible association with the oldest UMa and Hyades MGs \((P \approx 0)\), as expected from the high-lithium photospheric abundance of...
Table 5. Membership probability P (%) of our four stars to major MGs computed with the ZAMS (left) and 15 Myr assumption (right).

| # | Name            | IC 2391 | Pleiades | Castor |
|---|-----------------|---------|----------|--------|
| 1 | BD+78 853       | 0.0 / 4.7 | 15.9 / 36.9 | 59.6 / 41.7 |
| 2 | TYC 4496-780-1  | 0.0 / 0.3 | 8.9 / 22.7  | 33.4 / 28.2 |
| 3 | TYC 4500-1478-1 | 0.0 / 0.1 | 11.3 / 50.5 | 33.2 / 32.8 |
| 4 | BD+78 19        | 0.0 / 0.3 | 17.4 / 65.9 | 28.6 / 20.0 |

our stars. Table 5 suggests a possible link with the Castor MG, which is, however, again not supported by the very high-lithium abundance measurements, hardly compatible with a 200 Myr old MG. With a less than 5% probability, the IC 2391 MG origin is highly improbable. We are left with the Pleiades SKG for which the probabilities rise from ≳15% for the ZAMS assumption to ≳40% for the 15 Myr assumption. However, as recalled by Makarov et al. (2007), this stream includes isolated stars, groups, and associations of diverse ages in the range from 1 Myr to about 200 Myr, which by itself, does not shed light on the origin of our stars.

We finally consider a possible link with the Cep-Cas complex. Projected on the sky, the closest dark clouds to our stars are LDN 1251 and LDN 1241 at both 5–8° east of them and about 300 pc from the Sun (Kun et al. 2008). The average proper motions of LDN 1251, as estimated thanks to its cloud membership discovered by Kun et al. (2009), are μα = 1.9 ± 1.7 and μδ = 0.5 ± 1.3 mas yr−1. The angular distance of 5–8° corresponds to 25–40 pc at the cloud distance. With a proper motion of about 21 mas yr−1 relative to LDN 1251, nearly aligned in the east-west direction and corresponding to a velocity of about 30 km s−1 at the cloud distance, they should have travelled for 0.8–1.3 Myr from their parental cloud. The closest cloud on the approaching side of the expanding shell (namely LDN 1228, d ≃ 180 pc, Kun et al. 2008) is about 10° east of our stars (≃ 30 pc at the cloud distance). By completing the same calculations for LDN 1251/1241, we found an escape velocity (v_esc) from LDN 1228 of about 22 km s−1 and a travel time of about 1.3 Myr. These estimates do not allow us to exclude that these stars are “runaway” objects that originated in LDN 1251, LDN 1241, or LDN 1228. Nevertheless, although a close encounter with massive stars can result in high velocity “runaway” stars, Sterzik & Durisen (1998) found that 60% of the runaways have speeds larger than 3 km s−1 but that this fraction steeply decreases, becoming smaller than 5% for v_esc > 10 km s−1. Both the high escape velocities and the common space motions cast doubt on the “runaway” hypothesis being applicable.

The more plausible explanation of how these “isolated” TTS formed is given by the “in-situ” model (Feigelson 1996). This scenario would support the conclusion of Tachihara et al. (2005) although the lack of accurate distances does not allow us to draw firm conclusions about the origin of this group of stars. The advent of GAIA mission, with its unprecedented astrometric precision, will certainly shed light on this open issue. Similar conclusions have been reached in the Taurus (Magazzu et al. 1997), Chamaeleon-Musca (Mizuno et al. 1998) and Lupus (Tachihara et al. 2001) SFRs although no accreting TTS have been found outside these SFR’s cores.

5. Conclusion

We have reported the discovery of four comoving very young stars located in a region devoid of dark matter and molecular clouds. On the basis of its Ho profile and infrared excess, one of the stars investigated has been tentatively classified as a Class II young, infrared source, i.e. a TTS surrounded by an accretion disc. Owing to the distance uncertainty, we cannot assert that these stars are completely unrelated to the Cep-Cas star-forming region. However, their kinematics prove that they form a homogeneous comoving group of stars with the same origin. Their off-cloud positions imply that they are very good “isolated” TTS candidates. The “runaway” hypothesis is highly improbable because of their kinematical properties. Our conclusions raise a question about the applicability of the “in-situ” star-formation scenario to very low-mass cloud environments. TYC 4496-780-1 could be a TW Hya analog, although a little bit older, and its comoving companions may represent the peak of the iceberg of a young loose association.

Acknowledgements. We are grateful to the OHP night assistant staff in conducting our Key Program, and those of the OAC observatories for their support and help with the observations. We thank Luigia Santagata of INAF-Catania for the English revision of the text. This research made use of SIMBAD and VIZIER databases, operated at the CDS, Strasbourg, France. This publication uses ROSAT data.
