Abstract: Deoxidized oxygen free copper C12200, 1 mm in thickness, was welded to 1-mm thick AISI 304 stainless steel with disk laser. The butt-welded joints were produced with different welding parameters. Full factorial design of experiment (DoE) approach consisting of three factors and two levels was utilized. Laser powers used for welding were 1.3 and 1.9 kW and welding speeds of 20 and 30 mm/s. Two beam offsets were tested, namely, 100 µm toward copper side and 200 µm toward AISI 304 steel. It was found that beam offset possesses the largest influence on the welded joints’ tensile strength. Tensile strengths attained values more than 3.7 times higher in comparison to the AISI 304 steel beam offset. When lower laser power was used, the higher tensile strength was attained for copper sheet offset. Higher microhardness was observed when laser beam was offset to AISI 304 steel side. The average microhardness of the weld metal was higher than that of the weaker base material, copper sheet. Energy dispersive X-ray spectroscopy (EDS) analysis confirmed the heterogeneity in elemental composition across the welded joint interface, being lower when laser beam was offset to AISI 304 steel side. On the other hand, the copper content dropped to the average composition of weld metal at the distance of about 140 µm from copper-weld metal interface.

1. Introduction

Welding of dissimilar materials is nowadays a great challenge due to differences of the properties of materials to be welded [1–3]. One such combination represents copper to stainless steel welded joints, which are extensively utilized in the nuclear, power generation, automotive, and chemical industries [4,5]. There is a large mismatch in the thermophysical properties of the mentioned metals [6]. Copper is characterized by high thermal conductivity in comparison to AISI 304 stainless steel. Usually, it is necessary to preheat the copper in order to obtain full penetration across material thickness. Furthermore, the difference between melting points of selected materials are also distinct [7]. Because of the lower melting point of copper, the formation of liquation cracking in the heat affected zone (HAZ)
of stainless steel could be observed. This issue results from the penetration of copper liquid into the grains of HAZ and followed by reduction of the cohesion strength of stainless steel (SS) grains [8]. Laser beam welding is a promising technology to eliminate the mentioned issue. Because of lower heat input, the width of HAZ is expected to be minimal, resulting also in a narrower region of copper that underwent recrystallization [9]. Cheng et al. [6] studied the application of various filler materials for joining such combination of metals. They observed that maximum tensile strength of 80% of that of copper base material was attained when Cu-based filler material was used. The authors found that the fracture was observed in the heat-affected zone of copper due to grain coarsening and reduction of dislocation density resulting from annealing of the zone [6]. Similarly, various filler materials were studied also by Shiri et al. [10]. They found that welded joints without weld defects could be produced with Cu-based filler material. Tensile strength of the welded joint reached 96% of the tensile strength of copper [10]. The laser welded joints between copper alloy C21000 and AISI 304 stainless steel investigated by [11] exhibited the strength of 85% of the copper strength. The highest hardness was observed at the weld metal-stainless steel interface. The welded joints failed at the Cu-weld metal interface. In another study, local properties of gas tungsten arc welding (GTAW) of C21000 copper alloy to AISI 304 stainless steel welded joints produced with ERNiCu-7 filler material were investigated [12]. Meng et al. [13] conducted laser-arc hybrid welding and observed that, at the laser beam offset ranging from 0.5 to 1.0 mm toward Cu sheet, the weld metal consisted of a Cu-rich matrix with dispersion of Fe-based particles. Contrarily, Chen et al. [14] utilized laser beam offsetting to the stainless-steel sheet side. The tensile strength was dependent on the amount of melted copper. The maximum tensile strength reached 260 MPa. Fracture during tensile testing of welds occurred at the weld metal-copper interface, the HAZ of copper and weld metal [14]. Mannucci et al. [15] observed in weld metal various microstructures based on Cu content, namely, solid solution with the content of Cu ≥ 2 at. %, Cu-rich droplets with higher than 20 at. % of copper, and Cu-enriched zones between austenite cells (2 to 5 at. % Cu). Kar et al. [16] investigated the influence of beam oscillation on Cu-AISI 304 joints produced by electron beam welding and found that oscillation with optimum diameter resulted in an increase in impact strength and elongation in comparison to welds made without oscillation of electron beam. Contrarily, tensile strength of welds was similar to that produced without oscillation [16]. Zhang et al. [17] utilized electron beam welding QCr0.8 copper alloy to AISI 304 stainless steel with copper filler wire. The authors observed that the weakest region of the welded joint was the melted zone at the weld metal-copper side interface. Grain coarsening was observed in the mentioned zone [17]. Kuryntsev et al. [18] performed fiber laser welding with defocused beam in conduction mode, and beam offset to stainless steel side was realized. The authors found that the width of layer between stainless steel and copper ranged from 41 to 53 µm. The microhardness measured in this location ranged from 128 to 170 HV0.01 [18]. Guo et al. [19] evaluated the effect of beam offset during electron beam welding of copper to stainless steel. The microstructure of weld consisted of ε-phase dendrites and a small portion of γ-phase dendrites in the case of beam offsets toward copper side. Offset to stainless steel side resulted in the γ-dendrites’ formation with a small fraction of ε-phase [19]. Zhang et al. [20] studied the mechanism of the formation of welds between Ti alloy and stainless steel with the use of copper interlayer. They observed that at the interface between copper and stainless steel the weld was formed by dilution of copper and intermixing with stainless steel [20]. Similarly, the interfaces between copper filler material and AISI 304 stainless steel were studied within produced brazed joint by [21] and welded joint by [22]. Research has also focused on the welding of the mentioned combination of materials with explosive bonding [23,24]. In this study, we used DoE when disk laser welding copper to AISI 304 stainless steel with the goal of determining the most significant welding parameter from the microstructure, chemical composition, microhardness, and tensile strength point of view. Two beam offsets were tested, including offsets to the copper side and stainless-steel sheet side. A linear model for tensile strength based on laser power, welding speed, and beam offset was developed.
2. Materials and Methods

C12200 deoxidized oxygen-free copper with content of phosphorus and AISI 304 austenitic stainless steel with dimensions of $50 \times 100 \times 1$ mm were used as base materials. Chemical composition of base materials is given in Tables 1 and 2. Optical emission spectrometer Bruker Q4 TASMAN (Bruker, Madison, WI, USA) was used for the measurements of chemical composition of base materials. Chemical composition was measured in three locations and the average value was calculated. Mechanical properties of base materials are given in Tables 3 and 4. Weld surfaces were milled to achieve perfect contact of surfaces and cleaned with acetone. Butt joints were fabricated by solid state disk laser TruDisk 4002 (TRUMPF, Ditzingen, Germany). Based on preliminary tests in which 20 welded joints were produced, eight parameters’ setup was chosen for DoE calculations. In preliminary tests, laser powers ranged from 0.7 to 1.9 kW, welding speed was set to 30 mm/s, and beam offsets 100, 200, and 300 $\mu$m toward AISI 304 steel and the same offsets toward copper were utilized. Furthermore, initial welds were produced without beam offsetting. Three factors, i.e., laser power, welding speed, and beam offset, were evaluated. Because of a very narrow weldability window, each factor was set to two levels. Thus, DoE of $2^3$ type, full factorial was chosen. Influence of beam offset on tensile strength was assessed. Laser light cable with the diameter of 200 $\mu$m was used. The spot size was 200 $\mu$m. Laser beam was focused on the top surface of the materials to be welded. Positive beam offset was set to the AISI 304 steel side and negative beam offset was to copper side (Figure 1).

Argon 4.6 shielding was utilized for weld bead protection. Shielding gas flow rate was 18 L/min. Root shielding was ensured by He shielding with flow rate of 16 L/min. Welding parameters used for DoE trials along with calculated heat inputs are given in Table 5. DoE was carried out in Minitab 17.3.1 (Minitab, Ltd., Coventry, UK) statistical software. Heat input in disk laser welding was calculated according to the following equation [25]:

\[ Q = \frac{P}{v} \text{(J/mm)} \]  

(1)

where \( P \) is laser power in W and \( v \) equals to the welding speed in mm/s.

### Table 5. Welding parameters used for DoE.

The cross-sections and local microstructures of welded joints were documented by ZEISS LSM 700 laser scanning confocal microscope (Carl Zeiss Microscopy GmbH, Jena, Germany). Electrolytic etching in 10% oxalic acid solution was used to reveal microstructure of stainless steel and stainless steel-rich weld metal. Solution of 20 mL nitric acid and 20 mL distilled water was used for etching copper and copper-rich weld metal. JEOL JSM 7600 F scanning electron microscope with EDS detector (JEOL Ltd., Tokyo, Japan) was applied for the study of chemical composition in selected welded joints. EDS analysis was carried out on etched samples. Microhardness course across dissimilar metal-welded joints was measured by Buehler IndentaMet 1100 Series tester (Buehler, Lake Bluff, IL, USA) with the loading of 0.98 N. Distance between indents was 100 \( \mu m \). Totally, five rows of indents were constructed during measurements of microhardness map for sample No. 5. Distance between rows was set to 200 \( \mu m \). One row in the middle of the thickness was measured for sample No. 1. Dwell time was 10 s. Tensile strength test was carried out on LabTest 5.250 SP1-VM tensile testing machine (LABORTECH s.r.o., Opava, Czech Republic). The crosshead speed was 3 mm/s.
3. Results and Discussion

3.1. Weld Bead and Root Appearance

Weld bead and weld root appearance for dissimilar welded joint No. 2 are given in Figure 2a,b. The width of the weld bead was 1.034 mm (Table 4). The surface of the weld bead was smooth. Lack of fusion on the copper side of root was observed due to low heat input. The surface of the weld bead No. 3 (Figure 2c) showed no defects. The mentioned welded joint was produced with a higher heat input of 65 J/mm. The welding speed decreased to 20 mm/s. The weld bead increased to 1.228 mm. Lack of fusion from the copper root (Figure 2d) was observed again from the weld root side, as a result of insufficient heat input. Furthermore, it was evident that the beam offset of 200 µm to AISI 304 steel was too large. In such cases, the temperatures sufficient to melt completely the copper are not high enough. Thus, the beam offset 100 µm toward copper side (weld No. 4) was tested. The width of the weld was 1.097 mm. Only the value of the beam offset was different in comparison to weld No. 2. There was not evident difference in the weld metal size, confirming that the beam offset had a similar effect on the weld width. Variation of offset to the copper side (weld No. 4) provided more uniform heat distribution, even though the heat input was only 43.3 J/mm, as in sample No. 2. In the case of weld No. 4, it was enough for formation of the uniform welded joint. Both the weld surface (Figure 2e) and the root (Figure 2f) exhibited a uniform and smooth surface. Welding speed decreased to 20 mm/s to increase heat input to 65 J/mm, in the case of weld No. 8. Welded joint No. 8 possessed a smooth weld bead pattern (Figure 2g,h). Weld sagging was observed on the AISI 304 side. The weld bead width was 1.063 mm. Measured widths for welded joints are summarized in Table 6.

Table 6. Measured width for dissimilar metal-welded joints.

| Welded Joint No. | Weld Width (mm) |
|------------------|-----------------|
| 1                | 1.969           |
| 2                | 1.034           |
| 3                | 1.228           |
| 4                | 1.097           |
| 5                | 1.249           |
| 6                | 1.246           |
| 7                | 0.89            |
| 8                | 1.063           |

In the next step, the laser power increased to 1.9 kW (weld No. 7). Since the beam offset was to the copper side, more copper was melted, resulting in higher intermixing of both metals (Figure 3a,b). This fact needs to be confirmed by EDS analysis. The measured weld bead width was 0.896 mm.
In the case of weld No. 4, it was enough for formation of the uniform welded joint. Both the weld surface (Figure 2e) and the root (Figure 2f) exhibited a uniform and smooth surface. Welding speed decreased to 20 mm/s to increase heat input to 65 J/mm, in the case of weld No. 8. Welded joint No. 8 possessed a smooth weld bead pattern (Figure 2g, h). Weld sagging was observed on the AISI 304 side. The weld bead width was 1.063 mm. Measured widths for welded joints are summarized in Table 6.

**Table 6.** Measured width for dissimilar metal-welded joints.

| Welded Joint No. | Weld Width (mm) |
|------------------|-----------------|
| 1                | 1.969           |
| 2                | 1.034           |
| 3                | 1.228           |
| 4                | 1.097           |
| 5                | 1.249           |

**Figure 2.** Weld bead and root appearance for joints produced with laser power of 1.3 kW, (a) weld bead and (b) weld root of weld No. 2, (c) weld bead and (d) weld root of weld No. 3, (e) weld bead and (f) weld root of weld No. 4, (g) weld bead and (h) weld root of weld No. 8.
Figure 3. Weld bead and root appearance for welded joints produced with laser power of 1.9 kW. (a) weld bead and (b) weld root of weld No. 7, (c) weld bead and (d) weld root of weld No. 5, (e) weld bead and (f) weld root of weld No. 6, (g) weld bead and (h) weld root of weld No. 1.

Welding speed decreased to 20 mm/s in the case of weld No. 5 (Figure 3c). The heat input increased to 95 J/mm. Weld bead width was 1.249 mm. The heat-affected zone width of copper increased as a result of the higher heat input used. Furthermore, high thermal conductivity of copper contributed to that fact. Discoloration on AISI 304 surface of the weld bead and root (Figure 3d) is a sign of insufficient shielding of the welded joint.

Further, the beam offset 200 µm to AISI 304 steel was evaluated (weld No. 6). The heat input was 63.3 J/mm. The weld bead width was 1.246 mm. Irregular surface appearance was observed (Figure 3e). Similarly, weld root appearance (Figure 3f) exhibited the same characteristic. It could be associated with the high reflectivity of laser radiation by copper surface, resulting in the instability of the keyhole during welding. Thus, the welding speed decreased to 20 mm/s. Weld surface and weld root No. 1 is shown in Figure 3g,h. The heat input increased to 95 J/mm. Similarly, weld bead width was raised to 1.969 mm. An undercut was observed at the copper side. Slight discoloration could be observed on the AISI 304 top surface. The process was more stable resulting from higher heat input; thus, the irregularities of the weld appearance were eliminated.
3.2. Analysis of Weld Cross-Sections

Cross-sections of selected welded joints are given in Figure 4. It is visible that the weld metal of all welded joints consists of two distinct zones, with the darker zone being closer to copper and the brighter one being closer to AISI 304 steel. Melted locations are characterized by asymmetric geometry due to large differences in thermal conductivities and laser absorptivity by surface of metals, as well [15].

Influence of laser beam offset on welded joint geometry is shown in Figure 4a,c. Welded joints were produced with the same welding speed and laser power.

Copper HAZ-weld metal interface of the weld No. 1 exhibited the characteristic of brazed joint. The joint was produced through so-called weld-brazing [26–28]. This is attributed to the larger beam offset to AISI 304 side. It resulted in melting of AISI 304 material followed by wetting of copper interface. High thermal conductivity of copper contributed to the weld-brazing effect. Contrarily, a typical welded joint interface could be seen on the steel side. Fusion zone of sample No. 5, where beam offset towards copper sheet was utilized, showed intermixing of both welded metals. Based on the cross-section, it was evident that beam offset had significant influence on welded joint geometry. Slight displacement of the welded materials on both samples can be seen.

Difference of laser power and, thus, heat input on bead geometry can be seen on samples No. 4 (Figure 4b) and No. 7 (Figure 4d). Higher heat input used for production of weld No. 7 resulted in a larger fusion zone.

Different welding speeds were used for production of weld No 5. and No. 7. Welding speed for sample No. 5 (Figure 4c) was 20 mm/s and for No. 7 (Figure 4d) it was 30 mm/s. Geometry of the fusion zone was similar in both cases. Sheets’ misalignment was observed in weld No. 5. Higher heat input of 95 J/mm resulted in the wider fusion zone. Fusion zone of copper was observed at the copper side. Increase in welding speed to 30 mm/s was used in the case of sample No. 7. Lower heat input of 63.3 J/mm used for production of weld No. 7 resulted in the narrowing of the weld metal. Nguyen et al. [29] observed that an increase in welding speed resulted in the reduction of porosity and cracking.
3.3. Analysis of the Microstructure

Copper base metal-HAZ-fusion zone transition of weld No. 1 is documented in Figure 5a. The microstructure of copper base metal is characterized by texture, i.e., the grains are elongated in the direction of rolling. Copper exhibited in the middle of its thickness the characteristic of recrystallization. On the right-middle side is the heat-affected zone and on the far right is the fusion zone. Grain size in the HAZ increased due to the higher temperatures near the fusion zone. Only stainless steel is melted by laser heating, which means welding for the stainless steel. Contrarily, copper did not melt. Only the small zone at the former upper edge of copper melted. For weld-brazing mode, there was a characteristic planar interface between copper and weld metal. The material of molten pool was wetting the copper side.

![Figure 5. (a) Copper base metal-HAZ-fusion zone transition of weld No. 1; (b) copper weld metal-AISI 304 weld metal interface; (c) weld metal-AISI 304 HAZ interface; (d) higher magnification of the zone marked in (c).](image)

The microstructure of the weld metal exhibited a dendritic characteristic. The weld metal consisted of two parts, a darker one and a brighter one. The brighter zone was formed by austenite dendrites. Interdendrite spacings were characterized by the presence of \( \delta \)-ferrite. Columnar dendrites were observed at the interface between the darker and brighter zones (Figure 5b). Furthermore, fine cellular dendrites were documented. The weld metal-HAZ of the stainless-steel side is shown in Figure 5c. The \( \delta \)-ferrite was observed at the interface. Columnar dendrites grew perpendicularly to the fusion line. Higher magnification of the mentioned zone is given in Figure 5d.

Weld bead width of the sample No. 5 was 1.249 mm. The offset to copper side resulted in intermixing of both materials. It is noticeable that in the Figure 6a the weld does not exhibit any planar interface along the copper side, which confirms that both materials were metallurgically joined. Contrary to the previous welded joint, the copper was melted. Fine copper dendrites were observed at the interface (Figure 6b,d). The weld metal-AISI 304 interface was characterized by the same features...
as welded joint No. 5. The Δ-ferrite was detected at the interface (Figure 6c). A similar microstructure was observed by Mannucci et al. [15]. Their investigation was conducted with ytterbium doped yttrium aluminum garnet (Yb:YAG) laser. Contrary to our findings, the authors observed some hot cracking [15].

Figure 6. (a) Copper-HAZ-weld metal transition of weld No. 5; (b) higher magnification of copper-weld metal interface; (c) weld metal-AISI 304 HAZ interface; (d) fine copper dendrites zone at higher magnification.

3.4. EDS Analysis

EDS analysis was carried out in selected sites in weld metal for welded joint No. 5, in which beam offset to copper sheet was tested. The highest amount of copper was measured in Spectrum 4 (Figure 7). In direction to weld metal, at first, a dark zone was observed. In Spectra 2 and 6, a slightly lower amount of copper was detected. The content of element dropped to about half, i.e., about 48 at. %. In those sites, a higher amount of iron was detected. Also, Cr content increase was noticed. Spectra 1, 2, and 5 were specified by a higher amount of iron. In the white island, the composition was characterized by elemental intermixing. Iron content was 57 at. % in this zone. Furthermore, 21 at. % of copper and 16 at. % of chromium was detected. The bright sites toward the weld center were specific for their higher content of iron. The highest content was detected in Spectrum 3. This location belonged to the iron-rich side of the weld metal.
Figure 6. (a) Copper-HAZ-weld metal transition of weld No. 5; (b) higher magnification of copper-weld metal interface; (c) weld metal-AISI 304 HAZ interface, (d) fine copper dendrites zone at higher magnification.

3.4. EDS Analysis

EDS analysis was carried out in selected sites in weld metal for welded joint No. 5, in which beam offset to copper sheet was tested. The highest amount of copper was measured in Spectrum 4 (Figure 7). In direction to weld metal, at first, a dark zone was observed. In Spectra 2 and 6, a slightly lower amount of copper was detected. The content of element dropped to about half, i.e., about 48 at.%. In those sites, a higher amount of iron was detected. Also, Cr content increase was noticed. Spectra 1, 2, and 5 were specified by a higher amount of iron. In the white island, the composition was characterized by elemental intermixing. Iron content was 57 at. % in this zone. Furthermore, 21 at. % of copper and 16 at. % of chromium was detected. The bright sites toward the weld center were specific for their higher content of iron. The highest content was detected in Spectrum 3. This location belonged to the iron-rich side of the weld metal.

Figure 7. Locations of measurement of local chemical composition by means of EDS analysis (weld No. 5).

Chromium increased to 18 at. % and copper dropped to 12 at. %. Spectrum 5 contained 58 at. % of iron and a slightly lower content of chromium in comparison to Spectrum 3. Furthermore, copper was slightly higher than for Spectrum 3. Due to beam offsetting to copper side, intermixing of both metals occurred. Results of EDS point analysis in local sites of weld metal are given in Table 7.

| Spectrum | Cr   | Mn   | Fe   | Ni   | Cu   |
|----------|------|------|------|------|------|

Variation in the chemical composition across the weld cross-section for sample No.1 and sample No. 5 was observed. EDS measurements were carried out along the cross-section to determine the change of selected elements.

A line scan of elemental distribution across the fusion zone for the weld-brazing mode in sample No. 1 is shown in Figure 8a. Although very low solid solubility in copper-iron binary diagram and short thermal cycle during laser welding existed, Fe, Cr, and Ni diffused to the copper sheet, but also copper diffused to the weld metal [30]. A decrease in copper toward weld metal (WM) was observed. Contrarily, an increase of Fe, Cr, and Ni in the direction to the WM was recorded. Fusion was confirmed by the presence of pores (Figure 8a).

Line scans of the main alloying elements across the copper-fusion zone-AISI 304 interface of sample No. 5 are given in Figure 8b. A decrease of copper in the direction from base material (BM) to weld metal (WM) was observed. Conversely, an increase in the content of Fe, Cr, and Ni was documented. Greater heterogeneity was observed in comparison with sample No. 1. At the distance of approximately 130 µm, a decrease in Cu content was observed. It proved that copper penetrated to the larger distance from the interface due to the concentration of laser beam energy to the copper side. The distribution of investigated elements varied significantly across the entire cross-section of the dissimilar metal-welded joint, thus confirming heterogeneous composition of the weld metal. Noticeable fluctuation of the elemental composition distribution was observed.
For closer inspection of intermixing of welded materials in the fusion zone, elemental mapping of Cu, Fe, Cr, and Ni with better approximation was constructed (Figure 9). Visible intermixing of elements can be seen at the copper-fusion zone interface. Darker zones are expected to be originated from AISI 304 and brighter ones from the copper base material.

**Figure 8.** SEM image of area for EDS line analysis of the weld (a) No. 1 and (b) No. 5, elemental distribution across welded joint (c) No. 1 and (d) No. 5.

**Figure 9.** Elemental mapping across copper-weld metal interface (weld No. 5).
3.5. Microhardness Measurements

The distribution of microhardness across dissimilar metal-welded joint No. 1 is given in Figure 10. It is evident that an increase of microhardness from copper side to fusion zone was recorded. Contrarily, the drop of microhardness from AISI 304 stainless steel toward the fusion zone was attained. The average microhardness of copper is 65 HV0.1. The average microhardness of austenitic stainless steel is approximately 215 HV0.1. The mean microhardness of weld metal equals to 179 HV0.1. The course of microhardness proved the heterogeneity of the produced weld metal. As it arose from the course of microhardness, the hardness of the fusion zone was greater than the hardness of the weaker base material, i.e., copper. Kar et al. [16] observed during investigation of the effect of beam oscillation on the properties of dissimilar welds higher hardness of electron beam welds in comparison to copper. The nature of the hardness variation of weld metal was based on the amount of intermixing of copper in the weld metal [16]. In the work of Weigl and Schmidt [31], the highest value of an average hardness in the weld zone was documented with a lateral beam displacement of 100 µm into the stainless steel. The authors stated that this is associated to the amount of mixed copper and stainless steel [31].

![Microhardness Contour Plot](image)

Figure 10. The distribution of microhardness across copper-weld metal-AISI 304 stainless steel interface (weld No. 1).

Figure 11 shows the microhardness map for dissimilar metals-welded joint No. 5. This sample was welded with the same laser power and welding speed as the previous sample, but the beam offset was changed 100 µm to the copper side in this case. Microhardness contour plot derived from the microhardness measurements across the weld cross-section revealed that both base metals AISI 304 and copper had more uniform hardness distributions equivalent to their theoretically expected microhardness values. Additionally, the AISI 304 base metal and its heat-affected zone had similar microhardness due to the small heat input in laser welding, significantly eliminating the grain growth close to the weld metal. Although the heat input in laser welding was low, the drop of microhardness in copper HAZ was recorded. It was associated with the high thermal conductivity of copper, allowing the heat to spread to longer distance from the heat source. When taking into account that copper was as-rolled, the heating after deformation resulted in recrystallization [32] or grain growth (Figure 6a). It depended on deformation and the amount of heat. Dislocation density decreased and microhardness dropped as a result [6]. The mean microhardness dropped in the weld metal to the value of 140 HV0.1 in comparison to weld No. 1. This was associated to the higher intermixing with copper, resulting
in lowering the mean microhardness. The highest microhardness in Metal Inert Gas-Tungsten Inert Gas (MIG-TIG) both side arc welds was observed by Cheng et al. [6] in AISI 304 base material and was approximately 200 HV. The lowest microhardness was observed when ERCuSi-A filler wire was used for joining. Higher values were measured when ERCuNi-30 and ER304 filler wires were used in joining of copper to stainless steel [6].

3.6. Tensile Strength Results

Values of tensile strengths of welded joints for each sample are shown in Table 8. Samples with offset to the AISI 304 steel side reached lower values than welds produced with beam offset to copper side. Samples No. 2 and 6 possessed the lowest values of tensile strength, 66 and 70 MPa (Figure 12). This is due to the lack of fusion caused by high offset to the AISI 304 steel side. In this case, when the lower laser power of 1.3 kW was used, a slightly higher tensile strength was attained.

| Welded Joint No. | Tensile Strength [MPa] |
|------------------|------------------------|
| 1                | 162                    |
| 2                | 70                     |
| 3                | 166                    |
| 4                | 261                    |
| 5                | 236                    |
| 6                | 66                     |
| 7                | 256                    |
| 8                | 254                    |

Figure 11. Microhardness map for dissimilar metals-welded joint No. 5.

Table 8. Measured tensile strength for dissimilar metals-welded joints.
Table 8. Measured tensile strength for dissimilar metals-welded joints.

| Welded Joint No. | Tensile Strength [MPa] |
|------------------|------------------------|
| 1                | 162                    |
| 2                | 70                     |
| 3                | 166                    |
| 4                | 261                    |
| 5                | 236                    |
| 6                | 66                     |
| 7                | 256                    |
| 8                | 254                    |

Zhang et al. [17] evaluated also the influence of beam offset on tensile strength of electron beam welds between QCr0.8 copper alloy and AISI 304 steel. They used copper filler material with Sn as the main alloying element (0.62%). The authors observed that tensile strength dropped with the rise in the beam offset.

Stress-strain curve for samples No. 1 and 5 is documented in Figure 13. There was a large difference in achieved values. Tensile strength of weld No. 1 was 162 MPa, and that of sample No. 5 reached 236 MPa. With the only difference being beam offset, results suggest that offset had large influence on tensile strength of produced welds. Singh et al. [7] observed that the tensile strength reached the value of 194 MPa when GTAW process with offsetting 1.25 mm to copper side was used.
A more pronounced difference was in the case of welds Nos. 6 and 7. Both samples were welded with laser power of 1.9 kW and a higher welding speed of 30 mm/s. In this case, a lower heat input was used for fabrication of welded joints. The only difference was the beam offset to the opposite sides. Beam offset of 200 $\mu$m to the AISI 304 side was used for sample No. 6 and 100 $\mu$m to the C12200 side for sample No. 7. In this case, the difference in values was even more significant. For sample No. 6 tensile strength was only 66 MPa, and for sample No. 7 it was 256 MPa. The strength value was more than 3.8x higher than that for sample No. 6. Such significant difference confirmed that offset to the C12200 side had important influence on tensile strength of the welds.

3.7. Fracture Surfaces

Fracture surfaces after tensile testing of weld No. 5 are given in Figure 14a–d. The fracture was observed at the HAZ of copper sheet. The surface is characterized by transgranular fracture. Secondary cracking was not documented. The characteristic of fracture exhibited typical features of ductile type. Dimples of various sizes were observed at the surfaces. In local sites, very fine dimples were observed. Furthermore, zones with coarse dimples were observed. The presence of larger dimples resulted from the coarser structure of HAZ, where the peak temperatures were developed. Ramachandran et al. [11] observed at copper HAZ of mainly coarse dimples after impact testing. The authors found that larger dimples resulted in a drop of fracture toughness of copper HAZ [11]. Zhao et al. [35] studied beam offset in welding titanium TA2 to 301L stainless steel with and without copper interlayer. Analysis of the fracture surface revealed the presence of copper-rich and Cu-Ti compounds when Cu interlayer was used. The mentioned phases were the locations characterized by brittle fracture in their study [35].
3.8. Statistical Analysis Results

The linear dependence of tensile strength of welded joints on welding parameters is given in Equation (1). This mathematical relationship possesses the coefficient of correlation $R^2 = 99.92\%$, confirming the important correlation between tensile strength of welded joints and welding parameters (laser power, welding speed, and beam offset). The probability plot of tensile strength of dissimilar metals’ welds proved the normal distribution (Figure 15a). Half the samples were expected to have tensile strength lower than 200 MPa. For the other half of the samples there was more than 50% probability that their tensile strengths would reach more than 200 MPa. All the measured values must lie in the marked area. That corresponded with the actual measured tensile strengths. Analysis of variance for tensile strength of welded joints’ results are given in Table 9. The $p$-value < 0.05 means significant influence on the weld strength. Beam offset exhibited the $p$-value = 0.02, confirming its significance. Other welding parameters possessed higher $p$-values, welding speed 0.064, and laser power 0.358.

The influence of individual welding parameters on the tensile strength is given in Figure 15b. As it arose from the measured values, the beam offset had the highest impact on the tensile strength of welds.
The main effects plot for tensile strength of welds is shown in Figure 15c. It is obvious that laser power had negligible effect on the tensile strength. As expected from previous results, the beam offset possessed positive influence on the overall tensile strength. Based on DoE, the dependence of tensile strength on individual welding parameters was calculated. Regression equation in uncoded units is as follows:

\[
\text{Tensile strength (MPa)} = 343.8 - 0.0482 \times LP (W) - 4.70 \times WS (\text{mm/s}) + 0.398 \times O (\mu m) + 0.00142 \times LP (W) \times WS (\text{mm/s}) + 0.000031 \times LP (W) \times O (\mu m) - 0.03583 \times WS (\text{mm/s}) \times O (\mu m)
\]

where \(LP\) means laser power in W, \(WS\) is welding speed in mm/s, and \(O\) is laser beam offset in \(\mu m\).
As it follows from the abovementioned equation, beam offset $O$ and two-way interaction of laser power $LP$ and beam offset $O$ possessed positive influence on the overall tensile strength. Based on ANOVA results, the $p$-value for $LP \times O$ interaction was higher than 0.05, indicating no significance of its influence on the tensile strength. In general, the main laser welding parameters are laser power, welding speed, and focus position. In our study, the focus position was set to 0 mm, meaning that the maximum power density was on the top of the materials to be welded. Especially, it is useful in the case of welding copper where higher reflectivity of radiation can be expected. The higher heat input resulted in the formation of a larger weld pool. However, when a lower heat input was used, the differences in weld metal width were minimum, i.e., not dependent on the offset direction. Thus, controlling the weld metal composition could be done by beam offsetting. Higher amounts of elements originating from stainless steel results in intermixing and higher tensile strength of welded joints. So, when affecting the chemical composition, i.e., dilution of welded metals, it could be very beneficial to apply beam offsetting. The diameter of the focused laser beam was 200 $\mu$m. In the case of a higher beam offset to the AISI 304 steel, the power from the laser beam was concentrated not onto the copper part. The large part of the energy of the laser beam was utilized to melt the stainless steel. Due to the heat dissipating from the molten pool, diffusion could occur at the interface of weld metal-copper, forming a brazed interface. In this case, the reflectivity influence was negligible when the beam was offset to the stainless-steel side. Nguyen et al. [29] observed disconnections at the interface in the case of offsetting the laser beam 0.25 mm toward stainless steel. It is also necessary to consider different thermal conductivities of welded materials. The thermal conductivity of copper is much higher than that of stainless steel. As it follows from iron-copper binary diagram, the mutual solubility was very low. Another very important fact is that no intermetallic compounds were formed. Cheng et al. [6] observed the copper fusion boundary, the so-called unmixed zone, as a result of insufficient intermixing [6]. For the abovementioned case, also the microhardness reflected the higher values originating from steel chemical composition. Directly at the brazed interface, a darker zone was observed. The distribution of Cr, Ni, and Fe was like that in the bright zone.

A different situation was in the case of beam offsetting toward copper. The part of energy of the laser beam was utilized to direct melting of both materials. The brazed interface disappeared. The molten pool was formed by direct heating and melting of both materials. Meng et al. [13] observed that molten metal flowed out of the molten metal center. These actions resulted in intermixing of both molten materials, resulting in the formation of Fe-Cu-based compounds. The darker parts of the weld metal (Figure 6b) were characterized by the content of 48 at. % of copper and 36 at. % of iron. This was associated also with lower microhardness in comparison to when only stainless steels are joined. Bernatskyi et al. [36] carried out laser welding in various spatial positions of T-joints of austenitic stainless steel. The authors observed higher microhardness in weld metal after carrying out technological implementations [36]. The microhardness of copper-stainless steel depends on the amount of intermixed materials. When beam offset to AISI 304 was used, the microhardness was slightly higher than that in the welded joint produced with beam offset to copper. It was associated with the fact that in the case of beam offset to steel, the weld metal is characterized by an Fe-rich matrix. Contour plot of tensile strength vs. welding speed and beam offset is documented in Figure 15d. To attain welds with tensile strengths above 250 MPa, it is recommended to apply beam offset close to or the same as 100 $\mu$m toward copper and use the welding speed of 25 mm/s and above. In our case, the welded joint made with offset 100 $\mu$m to the copper side and welding speed of 30 mm/s possessed the tensile strength higher than 250 MPa. That agreed with sample No. 4 that was welded with these parameters and achieved tensile strength of 261 MPa.

4. Conclusions

The influence of disk laser welding parameters on the microstructure and mechanical properties of copper-AISI 304 stainless steel was investigated by means of light microscopy, electron microscopy
including EDS analysis, microhardness measurements, and tensile testing. Based on the reached results, the following can be stated:

- DoE results showed that beam offset had the highest influence on tensile strength of dissimilar metals’ welds and p-value for beam offset was lower than 0.05.
- Beam offset 100 µm toward copper resulted in 3.7 times higher tensile strength of welded joint in comparison to welds produced with offset to AISI 304 steel.
- When offset to copper sheet was used, higher tensile strength was attained when lower heat input was used.
- EDS analysis confirmed the heterogeneity in elemental composition across welded joint interface. The heterogeneity in elemental composition across welded joints was lower when laser beam was offset to AISI 304 steel side. On the other hand, the copper content dropped to the average composition of weld metal at the distance of about 140 µm from copper-weld metal interface.
- Fracture after tensile testing was observed at the copper HAZ in the case of application of beam offset toward copper.
- Microhardness increase from copper toward weld metal was observed. The mean microhardness of austenitic stainless steel was about 215 HV0.1 and that of weld metal equaled to 179 HV0.1 when beam offset to AISI 304 steel was used. The averaged microhardness of the weld dropped to 140 HV0.1 in the case of beam offset to copper.
