(Dated: September 11, 2009)

The Raman shift, broadening, and relative Raman intensities of bilayer graphene are computed as functions of the electron concentration. We include dynamic effects for the phonon frequencies and we consider the gap induced in the band structure of bilayer graphene by an external electric field. We show that from the analysis of the Raman spectra of gated bilayer graphene it is possible to quantitatively identify the amount of charges coming from the atmosphere and from the substrate. These findings suggest that Raman spectroscopy of bilayer graphene can be used to characterize the electrostatic environment of few-layers graphene.

I. INTRODUCTION

Graphene-based systems have recently attracted much attention from both the experimental and the theoretical point of view. Graphene is in fact characterized by a high carrier-mobility, which make those systems very exciting in view of future applications in nanoelectronics. In standard experimental setups, few-layers graphene (FLG) interacts with the environment through doping charges coming from the top ($n_{\text{top}}$) and from the bottom ($n_{\text{bot}}$) of the system. These charges determine the external electric field ($E = (n_{\text{top}} - n_{\text{bot}})\varepsilon/(2\varepsilon_0)$) and the total electron concentration ($n = n_{\text{top}} + n_{\text{bot}}$). $E$ and $n$ can thus be varied independently changing the charges from the two sides. $n_{\text{top}}$ and $n_{\text{bot}}$ can be intentionally induced by applying gate voltage differences between the system and the substrate, or via atoms/molecules deposition on top of the system. On the other hand, important unintentional doping charges are typically present. For instance, in FLG obtained by exfoliation on SiO$_2$, or epitaxially grown on SiC, a charge transfer occurs between the substrate and the system, giving rise to a finite $n_{\text{bot}}$. In analogy, an additional $n_{\text{top}}$ can be accidentally induced by the uncontrolled adsorption of molecules from the atmosphere. Among FLG, the bilayer graphene is particularly interesting because it becomes a tunable band-gap semiconductor under the application of an electric field perpendicular to the system. In this context, the determination of the electric field is crucial in order to control the band-gap. Moreover, in graphene charge impurities originating from the top or from the substrate are the main source of scattering which reduces conduction performances. Therefore, the determination of the charge transfer from the substrate or from the atmosphere is highly desirable for possible applications. Although experimental techniques allow to estimate the total electron concentration on the system, an accurate determination of the respective values of top and bottom charges has never been achieved so far, and can be particularly challenging, for instance, when doping is intentionally induced by deposition of molecules or polymeric electrolyte. In this work we use a tight binding (TB) model fitted on ab initio calculations to compute the Raman shift, broadening, and relative Raman intensity of the $G$ modes in bilayer graphene, as a function of the electron concentration, for different values of top charges. In particular, the screening properties of the system in presence of an external electric field are described using ab initio density functional theory calculations (DFT), including the GW correction, while a TB model is used to reproduce the DFT calculated, GW corrected, band structure in the full Brillouin zone. We show that from the measured Raman spectra of bilayer graphene it is possible to determine the external charge distribution and thus the external electric field and the actual carriers concentration. This result is especially relevant since it shows that Raman spectroscopy, which is already widely used to investigate graphene-based systems, can be used to characterize the electrostatic environment of the sample. Moreover, since the charges coming from the atmosphere and the substrate are not expected to depend on the number of layers, Raman measurements on bilayer graphene can also be used to determine the origin and the amount of the unintentional doping of monolayer and few-layers graphene in the same environment.

The Raman spectra of monolayer graphene are characterized by a doubly-degenerate $G$ peak ($E_{2g}$ mode) at around 1580 cm$^{-1}$. This mode shows a strong electron-phonon coupling, which induces a phonon renormalization when $n$ is varied. Therefore, Raman can be used to measure the total electron concentration. In bilayer graphene, in the absence of an external electric field the $G$ peak splits, as in graphite, in a doubly-degenerate Raman active mode ($E_{2g}$) and a doubly-degenerate, Raman inactive, infra-red active mode ($E_u$). The $E_{2g}$ mode is characterized by a symmetric in-phase displacement of the atoms in the two layers, whereas $E_u$ is characterized by an antisymmetric out-of-phase displacement of those atoms. Most Raman measurements on bilayer graphene show a single $G$ peak whose position is used, as in monolayer graphene, to measure the electron concentration on the system.
Interestingly, the splitting of the $G$ peak has been observed in the Raman spectra of bilayer graphene,\textsuperscript{15} and it has been recently attributed to symmetry breaking due to the application of an external electric field.\textsuperscript{32} Moreover, other experimental works recently reported on the infrared spectra of gated bilayer graphene.\textsuperscript{5,16,17,18,19} These findings suggest that a deep understanding of the behavior of a splitted $G$ mode in gated bilayer graphene could lead to quantify not only the total electron concentration $n$ but also the separate values of $n_{\text{top}}$ and $n_{\text{bot}}$.

## II. COMPUTATIONAL DETAILS

In order to calculate the electron-phonon coupling (EPC) component of the phonon frequencies, broadenings, and relative Raman intensities as functions of $n$ and $n_{\text{top}}$, we consider the $\Gamma$ phonon self-energy\textsuperscript{26,27} projected onto the subspace of the two $E_{2g}$ and the two $E_u$ modes:

$$\Pi_{\mu\nu}(n_{\text{top}}, n) = \frac{\hbar}{M \omega_0 N_k} \sum_{k,i,j} D_{ij}^{\mu} D_{ji}^{\nu} (f_{ki} - f_{kj}) \left( \epsilon_{ki} - \epsilon_{kj} + \hbar \omega_0 + i\eta \right),$$ \hspace{1cm} (1)

where the sum is on the electron wave vector $k$ and the electronic $\pi$ bands $i, j$, $\mu, \nu = 1, 4$ are the phonon indexes, $N_k$ is the number of $k$ vectors, and $f_{ki}$ is the occupation of the electron state $|ki\rangle$ with energy $\epsilon_{ki}$. $D_{ij}^{\mu}$ is the EPC and $\Delta H^{\mu}$ is the Hamiltonian derivative with respect to the atomic displacement corresponding to the $\mu$ phonon. $\eta$ equals $0.009$ eV and $M$ is the atomic mass.

From the phonon self-energy one can calculate only frequency variations due to changes in the electron concentration and in the band structure. In order to obtain the absolute frequencies we use the following $4 \times 4$ matrix:

$$\Omega_{\mu\nu}(n_{\text{top}}, n) = \left( \omega_0 + \Delta \omega(n) - \Pi_0 + i \frac{\gamma_{\text{an}}}{2} \right) \delta_{\mu\nu} + \Pi_{\mu\nu}(n_{\text{top}}, n),$$ \hspace{1cm} (2)

where $\omega_0=1581.5$ cm$^{-1}$ is the experimentally measured frequency of the Raman active $G$ peak in bilayer graphene, in absence of doping and electric field.\textsuperscript{14} $\gamma_{\text{an}}$ is the contribution to the broadening of the $G$ modes in graphene and graphite from the anharmonic phonon-phonon interaction, whose value is estimated to be 1.8 cm$^{-1}$.\textsuperscript{26} $\Pi_0$ is the phonon self-energy of the doubly degenerate $E_{2g}$ mode calculated for $n = 0$ and $n_{\text{top}} = 0$, and it is given by $\Pi_0 = \text{Re} \left[ u_{\mu}^k \Pi_{\mu\nu}(0,0) u_{\nu}^k \right]$, where $k = 1, 2$ corresponds to the two $E_{2g}$ modes and $u_{\mu}^k$ are the corresponding eigenvectors. In presence of doping charge the lattice parameter changes and the corresponding variation of the $G$ modes frequencies can be obtained for zero electric field by ab initio calculations.\textsuperscript{29} $\Delta \omega(n) = -5.75 \times 10^3 \Delta a(n)$ cm$^{-1}$, where $\Delta a(n)$ is the relative variation of the lattice parameter, as in Eq.(2) of Ref.\textsuperscript{26} In this work we do not include in the phonon calculations the effects due to direct interaction of the system with adsorbates and with the substrate donating doping charge. However, as shown for intercalated graphite,\textsuperscript{36,37} we assume that this is not relevant also for the in-plane vibrational modes of bilayer graphene.

The eigenvalues of $\Omega_{\mu\nu}$ are of the form $(\omega_i + i \gamma_i / 2)$, where $\omega_i$ is the frequency of phonon $i$ and $\gamma_i$ is the full width half maximum (FWHM), given by the EPC and the anharmonic phonon-phonon interaction. In the general case of finite $n$ and $n_{\text{top}}$ the four eigenmodes of $\Omega_{\mu\nu}$, $\epsilon_{\mu}$, are still two by two degenerate, but they are a superposition of the $E_{2g}$ and $E_u$ eigenmodes of the unbiased bilayer graphene. Their relative Raman intensities $I_{\mu R}$ are calculated as:

$$I_{\mu R} = \frac{\sum_{k,i=1,2} |\epsilon_{\mu,i}^{(1)}|^2}{\sum_{k,i=1,2} \sum_{k'=1,2} |\epsilon_{\mu,i}^{(2)}|^2},$$ \hspace{1cm} (3)

where $\sum I_{\mu R} = 1$.

We have shown that the screening properties of bilayer graphene under the application of an external electric field are characterized by inter- and intra-layer polarizations.\textsuperscript{26} Most of the calculations of the band gap as a function of $n$ and $n_{\text{top}}$ are based on TB models\textsuperscript{6,18} which usually consider only the inter-layer polarization, resulting in an overestimation of the band gap. In the present work the band structure of the $\pi$ electrons $|\epsilon_{ki}\rangle$ and $|\epsilon_{kj}\rangle$ in Eq.(1) is obtained using the scheme presented in Ref.\textsuperscript{32} The band gap is computed by ab initio DFT calculations, including the $GW$ corrections, and both inter- and intra-layer polarizations are fully taken into account. The full band structure of gated bilayer graphene is then computed using a TB model, which is able to reproduce all the important features of the DFT calculated, $GW$ corrected bands, including the electron-hole asymmetry.

In order to compute $\Delta H^{\mu}$ one needs to calculate the derivative of the tight binding Hamiltonian with respect...
FIG. 2: (Color online) Raman shift in bilayer graphene for $n_{\text{top}} = n_{\text{bot}}$ and for $n_{\text{top}} = -n_{\text{bot}}$. Calculated values of the shifts are connected by lines. For a given value of $n$ (panel a) or $n_{\text{top}}$ (panel b) there are two phonon modes represented with two rectangles. The height of the rectangles is the FWHM and the areas are proportional to the relative Raman intensities (i.e. the integrated area of each peak) of the two modes. Thus, the ratio of the widths of the two rectangles is equal to the ratio of the maximum heights of the two Raman peaks. When the ratio is less than 0.1, the mode with the smallest intensity is colored in gray (red), otherwise is black. Circles are experimental results from Ref. 17 and the errorbars represent the experimental FWHM.

III. RESULTS

In Fig. 2a we show the calculated Raman shift as a function of $n$, for the case $n_{\text{top}} = n_{\text{bot}}$, where the external electric field and the band-gap are kept fixed to zero, as theoretically studied in Ref. 31. In this case the $E_{2g}$ and $E_u$ modes do not mix by symmetry. Analogously to monolayer graphene, the Raman active modes show a singularity when the Fermi energy is half of the phonon energy. In Fig. 2b we show the calculated Raman shifts for the case $n_{\text{top}} = -n_{\text{bot}}$, as a function of $n_{\text{top}}$. This is a special situation where the external electric field is varied while $n$ is kept fixed to zero, as realized in recent infra-red experiments. 5,17 In this case, the mixing between $E_{2g}$ and $E_u$ modes is weak due to the antisymmetric allocation of charges in the two layers. The Raman active modes show a singularity in the frequency and a divergence in the

FIG. 3: (Color online) Raman shift in bilayer graphene as a function of the electron concentration $n$, for different values of $n_{\text{top}}$. See the caption of Fig. 2.
unintentional \( n_{\text{top}} \) and \( n_{\text{bot}} \) arising from the atmosphere and the substrate can be present at zero gate voltage. By comparing the experimental and calculated Raman shifts as a function of \( n \) for different \( n_{\text{top}} \), we estimate a total electron concentration at zero gate voltage \( n^0 = -1.8 \times 10^{13}\text{cm}^{-2} \). In Fig.4a and -b we show the ratio between the relative Raman intensities of the highest and lowest mode, and the Raman shifts, respectively, as a function of the electron concentration \( n \), for different values of \( n_{\text{top}} \). The former one strongly depends on \( n_{\text{top}} \), while the frequency shifts have a weaker dependence. The best agreement between theory and experiments indicates an unintentional charge coming from the atmosphere \( n_{\text{top}}^0 = -0.25 \times 10^{13}\text{cm}^{-2} \). From our estimate of \( n^0 \), we deduce an unintentional charge from the substrate \( n_{\text{bot}}^0 = n^0 - n_{\text{top}}^0 = -1.55 \times 10^{13}\text{cm}^{-2} \). The agreement between experimental data and theoretical results is good. However, we notice that the slope of the theoretical curves is underestimated with respect to the experimental ones. This could be possibly due to local desorption of molecules and doping variation induced by the laser light, or to hysteresis effects in the doping dependence on gate voltage.

Finally, in the right side of Fig.2-b, we compare our theoretical results to the experimental frequencies and broadenings from recent infra-red measurements in Ref.12, where the doping charge is kept fixed to zero and the electric field is varied. The agreement is excellent with our lower frequency mode. In our calculations, the lower mode has a weak projection on \( E_u \). However, this mode is strongly coupled with the electrons, as testified by the large FWHM. Such coupling enhances the effective charges associated with \( E_u \) and increases the infra-red activity. Indeed, in Fig.3 of Ref.12, the measured infra-red intensity is maximum when the band-gap equals the phonon energy (about 0.2 eV), i.e. when the FWHM and thus the coupling of the mode with the electrons are maximum, while it decreases when the FWHM decreases.

IV. CONCLUSIONS

In summary, we have computed the Raman spectra of gated bilayer graphene, which is strongly influenced by the interaction with the environment. We claim that by the analysis of the splitting of the \( G \) mode in Raman measurements it is possible to estimate the amount of unintentional charges coming from the atmosphere and from the substrate. Here we compare our calculations with the only experimental data available on the \( G \) mode splitting in bilayer graphene, and we give an estimate of the unintentional charges coming from the environment in this experiment. In order to facilitate the comparison of new experimental results with our theoretical calculations, we provide as additional material a set of computed Raman shifts, FWHM, and relative Raman intensities as a function of \( n \), for different values of \( n_{\text{top}} \).
