In Brief
Catalysis-independent scaffolding by Tankyrase supports Wnt-β-catenin signaling. Scaffolding is mediated by AXIN-binding ankyrin repeat clusters and a polymerizing SAM domain. In a structure-function approach, Mariotti et al. show that polymerization supports Tankyrase PARP activity and enables avidity-dependent AXIN binding.

SUMMARY

The poly(ADP-ribose) polymerase (PARP) Tankyrase (TNKS and TNKS2) is paramount to Wnt-β-catenin signaling and a promising therapeutic target in Wnt-dependent cancers. The pool of active β-catenin is normally limited by destruction complexes, whose assembly depends on the polymeric master scaffolding protein AXIN. Tankyrase, which poly(ADP-ribosyl)ates and thereby destabilizes AXIN, also can polymerize, but the relevance of these polymers has remained unclear. We report crystal structures of the polymerizing TNKS and TNKS2 sterile alpha motif (SAM) domains, revealing versatile head-to-tail interactions. Biochemical studies informed by these structures demonstrate that polymerization is required for Tankyrase to drive β-catenin-dependent transcription. We show that the polymeric state supports PARP activity and allows Tankyrase to effectively access destruction complexes through enabling avidity-dependent AXIN binding. This study provides an example for regulated signal transduction in non-membrane-enclosed compartments (signalosomes), and it points to novel potential strategies to inhibit Tankyrase function in oncogenic Wnt signaling.

INTRODUCTION

Signal transduction often occurs through large and transient multi-protein complexes. Polymerizing proteins can nucleate the assembly of higher-order structures termed signalosomes, which enable locally increased protein concentrations for efficient, transient, and spatially confined processes (Bienz, 2014; Wu, 2013). Wnt-β-catenin signaling, which is dysregulated in most colorectal cancers, provides prominent examples for signalosomes (Bienz, 2014; Polakis, 2012). At basal signaling, a destruction complex (DC) composed of the scaffolding proteins AXIN and adenomatous polyposis coli (APC), glycogen synthase kinase 3 (GSK3), and casein kinase 1 (CK1) captures and phosphorylates β-catenin to initiate its degradation (Stamos and Weis, 2013). AXIN is the central and concentration-limiting component of the DC (Lee et al., 2003; Stamos and Weis, 2013). Microscopically, DCs manifest as dynamic puncta with a filamentous sub-organization, so-called β-catenin degradosomes, whose formation is dependent on AXIN polymerization (Fiedler et al., 2011; de la Roche et al., 2014; Martino-Echarri et al., 2016; Thorvaldsen et al., 2015).

The poly(ADP-ribose) polymerases (PARPs) Tankyrase (TNKS and ARTD5) and Tankyrase 2 (TNKS2 and ARTD6) regulate Wnt-β-catenin signaling (Huang et al., 2005). We shall refer to TNKS and TNKS2 collectively as Tankyrase where principles apply to both. Tankyrase binds and poly(ADP-ribosyl)ates (PARylates) AXIN, targeting it for PAR-dependent ubiquitination (PARdU) and degradation to stabilize transcriptionally active β-catenin (Callow et al., 2011; DaRosa et al., 2015; Huang et al., 2009; Morron et al., 2012; Zhang et al., 2011). Tankyrase buffers negative regulation of Wnt signaling by AXIN for robust pathway activation (Wang et al., 2016). Upon Wnt stimulation, AXIN PARylation by Tankyrase promotes its function in active signaling complexes (Yang et al., 2016).

The two Tankyrases are highly similar (Hsiao and Smith, 2008; Smith et al., 1998) (Figure 1A), sharing a set of five ankyrin repeat clusters (ARCs) for substrate binding (Guettler et al., 2011; Seimiya et al., 2004), a sterile alpha motif (SAM) domain (De Rycker and Price, 2004; De Rycker et al., 2003), and a catalytic PARP domain (Rippe et al., 2002). Tankyrase’s biological functions are complex (Haikarainen et al., 2014), and simultaneous loss of both Tankyrases results in embryonic lethality in mice (Chiang et al., 2008). Tankyrase contributes to telomere maintenance (Canudas et al., 2007; Dynek and Smith, 2004; Smith et al., 1998), which together with Wnt signaling is relevant to stem cell renewal, development, and certain types of cancer (Bernardes de Jesus and Blasco, 2013; Clevers et al., 2014). Given these functions and a dependency of BRCA1/2-deficient cancer cells on Tankyrase (McCabe et al., 2009), Tankyrase is a promising anti-cancer target (Haikarainen et al., 2014; Lehtiö et al., 2013; Riffell et al., 2012).

It is intriguing that Tankyrase, like AXIN, polymerizes (De Rycker and Price, 2004; De Rycker et al., 2003). Tankyrase polymerization is mediated by the SAM domain, a small helical fold highly prevalent in eukaryotes (Knight et al., 2011; Qiao and...
Bowie, 2005). The structural basis of Tankyrase polymerization and its function have remained unknown. Moreover, we currently lack insight into the regulation of Tankyrase activity.

Here we show that Tankyrase can induce Wnt-β-catenin signaling independently of its catalytic activity, through ARC- and SAM domain-dependent scaffolding. This redefines our view on pharmacologic inhibition of Tankyrase. Informed by crystal structures of the TNKS and TNKS2 SAM domains, we demonstrate that Tankyrase polymerization is critical for its function in Wnt signaling, required for full PARP activity, and necessary for efficient interaction with AXIN. We propose a model in which recruitment of Tankyrase to β-catenin DCs is promoted by avidity effects that arise from multivalency and polymerization inherent to the Tankyrase-AXIN complex.

**RESULTS**

**Tankyrase Requires ARCs and SAM Domain to Promote Wnt Signaling**

To explore the domain requirements of Tankyrase for Wnt-β-catenin signaling, we measured β-catenin/TCF/LEF-dependent transcription in reporter assays. While basal Wnt signaling in HEK293T cells is low (Li et al., 2012), expression of TNKS or TNKS2 activated the reporter in a specific, dose-dependent manner (Figure 1B; see Figure S1 for protein expression levels). Intriguingly, reporter activation by either TNKS or TNKS2 was not abolished but merely reduced by ≈50% when poly- and mono(ADP-ribosyl)ation were inactivated by point mutation (G1185WT1 and G1032WT2; Figures 1B and 1F) (Yu et al., 2005). Likewise, mutation of a glutamate that is part of the catalytic H-Y-E triad (E1291WT1 and E1138WT2) (Hottiger et al., 2010), or deletion of the PARP domain altogether, did not abolish reporter activation (Figures 1C and 1F). Concordantly, saturating concentrations of the Tankyrase inhibitor XAV939 reduced TNKS2-dependent reporter activation only to a level that also was conferred by PARP-inactive TNKS2 G1032WT2 (Figures 1D and S2A). This suggests that both catalysis-dependent and -independent functions of Tankyrase contribute to Wnt signaling.

We hypothesized that scaffolding through the SAM domain and ARCs contributes to signaling. Deletion of the SAM domain...
fully abrogated Tankyrase-dependent reporter activation (Figure 1B), as did deletion of all ARCs or mutation of ARCs 1, 2, 4, and 5 (mutant xx3xx) to prevent substrate binding (Guettler et al., 2011) without impairing catalysis (Figures 1E and 1F).

Our observations expand upon and are in line with previous deletion studies (Huang et al., 2009). ARCs and the SAM domain may collaborate in recruiting Tankyrase to AXIN and/or facilitate productive PARylation. Overexpression of Tankyrase-binding-deficient, but not wild-type (WT), AXIN1 impeded TNKS2-dependent Wnt signaling (Figure S2B). This is in agreement with Tankyrase activating Wnt-β-catenin signaling at the level of AXIN, and it illustrates the strong buffering capacity of Tankyrase toward AXIN (Huang et al., 2009; Wang et al., 2016).

Polymerization of TNKS and TNKS2 SAM Domains

AXIN binding by the Tankyrase ARCs is well understood (Guettler et al., 2011; Huang et al., 2009; Morrone et al., 2012). Conversely, it remains unclear how the SAM domain enables Tankyrase function in Wnt signaling and whether polymerization is involved. To study SAM domain polymerization, we performed ultracentrifugation sedimentation assays, in which polymers of purified SAM domains partition into the pellet (Figure 2A). While the TNKS2 SAM domain readily sedimented, that of TNKS did not, suggesting that TNKS SAM forms less stable polymers in vitro (Figure 2A). We observed filaments for both the TNKS2 and TNKS SAM domains by electron microscopy (EM), but TNKS SAM required higher concentrations to form visible filaments (Figure 2B). Based on a homology model (not shown), we generated a DH902/924RE T2 mutant of the TNKS2 SAM domain, which failed to sediment (Figure 2A).

We next analyzed highly purified SAM domains by size exclusion chromatography with in-line multi-angle light scattering (SEC-MALS), which is more sensitive than the sedimentation assay. When analyzed at 0.5 mM, the TNKS2 SAM domain (theoretical molecular weight [MW] = 9 kDa) eluted as polydisperse assemblies of overall 1,965 ± 329 kDa, clearly indicating polymerization (Figure 2C). For 0.5 and 2 mM TNKS SAM, we detected polydisperse assemblies of 33.9 ± 1.8 kDa and 65.3 ± 2.3 kDa, respectively (Figure 2C), confirming that TNKS SAM also polymerizes, although to a lesser extent. We found that differential polymerization of the TNKS and TNKS2 SAM domains is largely due to a single amino acid difference (T1049T1 and R896T2, Figures S2 C, S2D, S3A, and S3B). However, transcription reporter assays with TNKS/TNKS2 SAM domain chimeras and interconverting point mutants (T1049R T1 and R896T T2) showed that both SAM domains equally enable Tankyrase to drive Wnt signaling (Figure S2E). Thus, the SAM domain may either promote Tankyrase function independently of its polymerization, or the lower polymerization of TNKS may still be sufficient for Wnt signaling under the assay conditions. In the latter case, a substantial impairment of
TNKS/TNKS2 polymerization would abrogate Tankyrase-dependent Wnt signaling.

Crystal Structures of TNKS2 and TNKS SAM Domains
To enable the generation of well-defined Tankyrase mutants, we crystallized the TNKS2 SAM domain. Since polymerization was likely to hinder crystallization, we used the polymerization-impaired DH902/924RE T2 mutant. Reasoning that the mutant domain would still retain most polymerization interface residues, polymer contacts would be recoverable at the high protein concentration during crystallization, as illustrated for other polymerizing SAM domains (Kim et al., 2001, 2002). We obtained well-diffracting crystals (1.53 Å) and solved the structure by molecular replacement (Table 1; Supplemental Experimental Table 1. Data Collection and Refinement Statistics

<sup>a</sup>Values for the highest-resolution shell are shown in parentheses.

<sup>b</sup>Rmerge and Rfree are as calculated in AIMLESS (Winn et al., 2011). High Rmerge and Rfree are attributable to the high-resolution cutoff (Karplus and Diederichs, 2012), multi-dataset merging, and anisotropy (see next footnote).

<sup>c</sup>The principal directions of anisotropy are as defined by symmetry (axes or planes), as analyzed in AIMLESS (Winn et al., 2011). For TNKS SAM crystal form 1, the anisotropy is pronounced along CC_d1 (along 0.91 hr–0.40 l), with CC_<sub>1/2</sub> falling below 0.30 at 3.0 Å.
The TNKS2 SAM domain, a 5-α-helix bundle similar to other SAM domains, formed a left-handed helix with a pitch of 46 Å, whose axis coincided with the crystallographic P6_5 screw axis (Figure 3A). The SAM domains interacted in the well-established end-helix (EH)-mid-loop (ML) binding mode (Qiao and Bowie, 2005) (Figures 3B and 3D). On the EH surface, basic electrostatic potential predominated while the ML surface was predominantly acidic, in line with the salt sensitivity of the polymer (Figures 3B and 3C). The closest approach between the two surfaces occurred around the N terminus of helix α5, where EH

Figure 3. Crystal Structure of the TNKS2 SAM Domain
(A) A structural representation of the TNKS2 DH902/924RE T2 SAM domain filament is shown.
(B) A pair of WT-rendered TNKS2 SAM domains from the filament, colored by Coulombic surface electrostatic potential, is shown.
(C) Ultracentrifugation sedimentation assay as for Figure 2A at increasing [NaCl] is shown.
(D) Detailed representation of a TNKS2 DH902/924RE T2 SAM domain pair. Interface residues are in stick representation with orange lines indicating contacts. Mutations required for crystallization are indicated.
surface residues A919T2, Y920T2, G921T2, and H922T2 engaged in a network of hydrogen bonds and van der Waals contacts (Figure 3D). H922T2 and A919T2 contacted the Q898T2 side chain. Y920T2 was the most buried side chain at the interface (125 Å2), interacting with various hydrophobic ML side chains (V903T2, I899T2, I915T2, and M907T2), which collectively formed a shallow pocket, as well as E911T2 and E897T2. In turn, E897T2 bound the protein main chain at A919T2 and Y920T2. The main chains of adjacent SAM domains interacted between G921T2 and E897T2/Q898T2. The interface opened up toward the outside of the filament. In its non-mutated form, D902T2 likely forms a salt bridge with R932T2, which may promote another salt bridge between K928T2 and E906T2. Surprisingly, despite its importance for TNKS2 SAM domain polymerization, R896T2 was not involved in any contact (Figure 3D).

We also crystallized the TNKS SAM domain, which again required a polymer-breaking mutation. TNKS SAM D1055R T1, equivalent to D902R T2, produced two crystal forms in space group P21, diffracting to 2.5 Å ( crystal form 1) and 2.9 Å ( crystal form 2), both with six molecules in distinct asymmetric units (Table 1; Figures 4A, 4B, and S4). The TNKS SAM domain was highly similar to that of TNKS2 (Figure 4C, left). For both TNKS crystal forms, non-crystallographic and crystallographic symmetry gave rise to left-handed helical filaments established by EH-ML contacts ( Figures 4A, 4B, and S4). The repeating unit consisted of six SAM domains with pitches of 83 and 79 Å, almost twice as long as for TNKS2 ( Figures 4A and 4B). Unlike for TNKS2, where protomer contacts relied on crystallographic symmetry only and were therefore uniform, the TNKS SAM EH-ML contacts varied substantially. This was apparent from the merely approximate 6-fold axial symmetry and the variable tilt and twist between adjacent SAM domains ( Figures S4 and 4C). The three crystal structures provided snapshots of 13 unique SAM domain pairs. Many contacts were shared between all EH-ML interactions, but a subset was specific to certain binding geometries, sometimes involving the same residue in alternative interactions ( Figures 4D and S4C). We conjecture that the variable relative orientations of SAM domains reflect filament flexibility ( Figure 2B). SAM-SAM interface residues were conserved across a wide range of phyla, including poriferans, indicating that polymerization is a common and ancient feature of Tankyrase ( Figures 4D and 4E).

Characterization of Polymer Contacts by Mutagenesis

We performed site-directed mutagenesis of the TNKS2 SAM domain and assessed polymerization by ultracentrifugation sedimentation. Mutations strongly, intermediately, or weakly abrogated sedimentation ( Figure 5A). In most cases, mutation of robust TNKS2 SAM contact residues (Y920T2, H924T2, E897T2, and V903T2) strongly impaired polymerization, as did mutation of E906T2, K913T2, and K928T2. Although situated close to the SAM-SAM interface, the latter three formed no explicit contacts in the TNKS2 SAM crystal structure ( Figures 3D and -D). However, the equivalent residues (D1059T1, K1066T1, and K1081T1, respectively) mediated binding between a subset of protomers in the TNKS SAM crystal structures ( Figures 4D and S4C). Thus, contacts not seen in all SAM-SAM pairs are still generally relevant, probably occurring in some, but not all, configurations of the flexible filament.

We used SEC-MALS and EM to validate strong mutations (V903W T2, E906K T2, K913E T2, Y920A T2, H924E T2, and a VY903/920WA T2 combination). Except for E906K T2 and K913E T2, all mutations conferred monomeric behavior ( Figures 5B and 5C). TNKS SAM K913E T2 and E906K T2 showed considerable residual polymerization ( Figures 5B and S3F); we hence re-assigned their polymer-breaking scores to intermediate. As for TNKS2 SAM, the TNKS SAM mutations V1056W T1, Y1073A T1, and VY1056/1073WA T2 strongly abrogated polymerization ( Figure 5B). Circular dichroism (CD) spectroscopy showed that the mutations did not impair SAM domain folding ( Figures S5A and S5B).

Combining SAM domains with strong mutations in opposite polymerization surfaces (ML: V1056W T1 and V903W T2; EH: Y1073A T1 and Y920A T2) gave rise to homo- and heterotopic dimers ( Figures S3D and S3E). This enabled us to assess the SAM-SAM binding affinities by isothermal titration calorimetry (ITC). TNKS and TNKS2 SAM domains bound homo- and heterotypically with comparable, low-micromolar affinities, typical for dynamic protein-protein interactions ( Figures 5D and S5C; see Discussion).

Full-Length Tankyrases Interact through EH and ML SAM Domain Surfaces

We assessed self-interaction of full-length Tankyrases in co-immunoprecipitation (co-IPs) with WT Tankyrases as bait. Robust homotypic binding of TNKS and TNKS2 was abolished by SAM domain deletion or mutation of both the ML and EH surfaces (VY1056/1073WA T1 and VY903/920WA T2), and it was reduced by mutation of either the ML surface (V1056W T1 and V903W T2) or EH surface (Y1073A T1 and Y920A T2) alone ( Figure 6A, left and center). We also detected heterotypic binding of TNKS and TNKS2 and confirmed its sensitivity to SAM domain mutations ( Figure 6A, right). The SAM domain previously was shown to confer high apparent molecular weight to TNKS in gel filtration experiments (De Rycker and Price, 2004). Using the VY1056/1073WA T1 and VY903/920WA T2 point mutants, we tested whether this reflects Tankyrase polymerization. WT TNKS and
TNKS2 eluted close to the void volume with subsequent trails (Figure S6A). Both deletion and point mutation of the SAM domain resulted in an elution delay and increased trailing with an emerging late elution peak. We detected endogenous TNKS in both the early and late peaks, suggesting that TNKS exists in heterogeneous polymerization states (Figure S6A), but we were unable to detect endogenous TNKS2. Collectively, co-IP and gel filtration showed that full-length Tankyrases homo- and heteropolymerize. Using both assays, we found no evidence for modulated polymerization of full-length TNKS or TNKS2 by the T1049R T1 or R896T T2 mutations, suggesting that differential polymerization may not occur in a full-length context or only under particular conditions (Figures S6A and S6B).

Polymerization Controls Tankyrase Subcellular Localization

To address if polymerization affects Tankyrase subcellular localization, we imaged HeLa cells expressing mCitrine- and mCherry-tagged TNKS or TNKS2. Since Tankyrase PARP activity was proposed to inhibit polymerization (De Rycker and Price, 2004), we compared vehicle- and XAV939-treated cells (Figure 6B). Both mCherry-TNKS and -TNKS2 displayed a punctate, predominantly cytoplasmic distribution, with more pronounced puncta upon XAV939 treatment (Figure 6B). In contrast, co-expressed mCitrine-tagged non-polymerizing EH/ML double mutants (VY1056/1073WA T1 and VY903/920WA T2) displayed mostly diffuse localization, even in the presence of XAV939 (Figure 6B; see Figure S6C for additional controls). This shows that polymerization enables the assembly of both TNKS and TNKS2 higher-order structures. In line with heteropolymerization, differentially tagged TNKS and TNKS2 colocalized (Figure S6D).

Polymerization Is Required for Tankyrase-Dependent Wnt Signaling

We tested how SAM domain mutations affect the ability of TNKS2 to drive Wnt signaling. We observed a correlation between the severity of the polymerization defect and diminished transcription reporter activity (Figure 6C). Likewise, strong polymer-breaking mutations abolished Wnt signaling induced by TNKS (Figure 6D). Transcription reporter assays using paired TNKS2 mutants with inactivated opposite SAM domain faces suggested that Tankyrase dimerization is insufficient to drive Wnt signaling (Figure S7A). A heterologous polymerizing SAM domain, that of D. melanogaster Polyhomeotic (Kim et al., 2002), only partially compensated for SAM domain loss in TNKS2; however, the partial rescue was dependent on polymerization (Figures S7B–S7E). In conclusion, SAM domain polymerization enables Tankyrase function in Wnt-β-catenin signaling.

Figure 5. Characterization of Tankyrase SAM Domain Mutants

(A) Ultracentrifugation sedimentation assays as for Figure 2A. Color coding indicates the degree of abrogated sedimentation. H924 T2, K928 T2, and E906 T2 charge reversals were more severe than changes to alanine.

(B) SEC-MALS of Tankyrase SAM domains, as in Figure 2C (Mw ± SD, D ± SD, n = 2). Color coding is as in (A). TNKS2 WT reference data, from the same experiment, are identical to Figure 2C. See Figure S5B for eluate analyses by SDS-PAGE and Figures S5A and S5B for CD spectroscopy.

(C) EM of TNKS2 SAM domains. Color coding is as in (A). See Figure S5F for further mutants. Scale bars, 50 nm.

(D) ITC analysis for the indicated SAM domain pairs. Mutated surfaces are indicated by the star in the schematics. See Figure S5C for a second experiment.
HEK293T cells (avoiding AXIN overexpression to maintain limiting levels), and we assessed its binding to MYC2-TNKS2 (Figure 7D). AXIN1 robustly bound to TNKS2 and its catalytically inactive mutant G1032W. However, recovery of TNKS2 ΔSAMT2, V903W, Y920A, and the xx3xx mutant was strongly reduced (Figure 7D). Taken together, the microscopy and binding studies illustrate that SAM domain-mediated polymerization promotes Tankyrase interaction with AXIN in β-catenin degradasomes.

DISCUSSION

We propose a model in which multivalency, mediated by two Tankyrase-binding motifs in AXIN (Morone et al., 2012) and four AXIN-binding ARCs in Tankyrase (Guettler et al., 2011), combined with polymerization of both proteins, gives rise to avidity for efficient Tankyrase recruitment to DCs (Figure 7E). Additionally, Tankyrase polymerization supports auto-PARPylation and is expected to promote recruitment and activity of the E3 ubiquitin ligase RNF146, which also binds the ARCs (DaRosa et al., 2015). Our observation that Tankyrase-mediated scaffolding can drive Wnt-β-catenin signaling independently of catalytic PARP activity has important implications for the use of Tankyrase inhibitors to oppose oncogenic Wnt signaling.

The SAM-SAM contacts seen in our crystal structures are relevant to the full-length proteins. First, the SAM domains present their termini toward the filament periphery, compatible with protruding ARCs and PARP domains (Knight et al., 2011). Second, Tankyrase polymerization and its ability to activate β-catenin-dependent transcription correlate. Mutagenesis suggests that activation may require a TNKS- and TNKS2-specific polymerization threshold to be surpassed. Third, in co-IP, gel filtration, and light microscopy, full-length Tankyrases respond to mutation of the identified head-to-tail interfaces, in line with previous deletion studies (De Rycker and Price, 2004; Hatsugai et al., 2010). Tankyrase polymers display a punctate localization, as observed for other polymerizers, such as AXIN and Dishevelled in Wnt signaling (Fiedler et al., 2011). Polyhomo-erotic orthologs in transcriptional repression (Isono et al., 2013), and proteins of supramolecular organizing centers (SMOCs) in innate immune signaling (Kagan et al., 2014; Sherman et al., 2010). Puncta also were observed for endogenous Tankyrase in XAV939-treated colorectal cancer cells (de la Roche et al., 2014). Correlative light and EM showed that β-catenin DCs are a filamentous sub-organization (Thorvaldsen et al., 2015). That these filaments do not grow to substantial length in cells likely reflects their dynamic nature (Bienz, 2014), a view compatible with micromolar SAM-SAM affinities and nanomolar Tankyrase concentrations in cells (Hein et al., 2015). Compared to the TNKS2 SAM domain, that of TNKS polymerizes less efficiently. The higher molecular weight reported for chicken Tank SAMS polymers (De Rycker and Price, 2004) is based on elution volume, rather than static light scattering, and likely affected by the globular affinity tag and long flexible termini in the construct. Chicken MBP-Tnks SAM filaments are thus likely to be of similar length to the human TNKS2 SAM filaments analyzed here. R896T2, responsible for differential polymerization of isolated TNKS and TNKS2 SAM domains, or a basic residue is conserved across TNKS2 orthologs and Tankyrases from species lacking TNKS2 (Figure 4D). However, its role remains unclear. First, our crystal structures do not reveal how R896T2 contributes to polymerization. Although all crystal structures of polymerizing SAM domains to date support the EH-ML interaction mode (Harada et al., 2008; Kim et al., 2001, 2002; Leettola et al., 2014; Nanyes et al., 2014; Stafford et al., 2011), crystallization may impose constraints onto some aspects of filament architecture and conceal the role of R896T2. Second, TNKS and TNKS2 SAM domain affinities are similar by ITC, suggesting that the differences only become apparent in the context of WT filaments rather than pairs of mutant SAM domains. Third, the TNKS and TNKS2 SAM domains are mutually interchange-able for Wnt signaling, and the interconverting T1049R1 and R896T2 mutations do not appear to affect polymerization of the full-length proteins. Thus, differential polymerization may not occur in full-length Tankyrases or requires a yet unknown regulatory event. Given their heteropolymerization, the TNKS and TNKS2 pools may in fact not be separable.

Surprisingly, Tankyrase can induce β-catenin-dependent transcription independently of its catalytic PARP activity. The underlying mechanism relies on ARC- and SAM domain-dependent scaffolding but remains incompletely understood. Inactive Tankyrase may have a direct role in establishing β-catenin degradasomes (Martino-Echarri et al., 2016). TNKS or TNKS2 over-expression, either at the mRNA or protein level, has been described in numerous malignancies, including gastric cancer (Gao et al., 2011; Matsutani et al., 2001), breast cancer (Gelmini et al., 2004), bladder cancer (Gelmini et al., 2007), astrocytoma (Tang et al., 2012), glioblastoma (Shervington et al., 2007), pancreatic cancer (Zhao et al., 2009), lung cancer (Busch et al., 2013), and colon cancer (Gelmini et al., 2006; Shebzukhov et al., 2008). Polymerization and thus catalysis-independent Tankyrase functions may prevail when Tankyrase is overexpressed. Therefore, the effectiveness of catalytic Tankyrase inhibitors may be limited when Tankyrase levels are high (see Figure 6). Tankyrase Requires Polymerization to Drive Wnt-β-Catenin Signaling

(A) Homo- and heterotypic interactions of TNKS and TNKS2 in HEK293T cells. FLAG2-Tankyrase were immunoprecipitated, and co-precipitation of MYC2-Tankyrases was assessed by SDS-PAGE and western blotting. TNKS2 expression is lower than TNKS, accounting for the weaker apparent TNKS2 self-association (Figure S1E). See Figures S6A and S6B for cell lysate fractionations and additional co-immunoprecipitations. (B) Tankyrase polymerization controls localization. Serum-starved HeLa cells expressing the indicated mCherry- and mCitrine-tagged Tankyrases were vehicle or XAV939 treated. See Figures S6C and S6D for controls and additional experiments. Scale bar, 10 μm.

(C and D) Tankyrase polymerization controls Wnt-β-catenin signaling. Transcription reporter assays for selected TNKS2 and TNKS SAM domain mutants, as for Figure 1C. Reporter activity was normalized to WT TNKS2 or TNKS (100%). Color coding reflects polymerization defects of the corresponding SAM domains as assessed by sedimentation, SEC-MALS, and EM (see Figure 5; n = 3 duplicate experiments; error bars, SEM). See Figure S1 for expression levels and Figure S7 for further data.
Crystals of TNKS2 SAM DH902/924RE T2 and TNKS SAM D1055R T1 were crystallized, structure determined, and analyzed for protein regulation. Roles of polymeric Tankyrase likely extend beyond Wnt signaling, given the high prevalence of Tankyrase-binding proteins (Guettlner et al., 2011). In analogy to SAM domain-containing transcriptional regulators (Isono et al., 2013), Tankyrase polymerization may facilitate protein regulation over an extensive physical range. Two such examples may be telomeres (Hsiao and Smith, 2008) and DNA repair sites (Nagy et al., 2016). Conversely, polymerization may suppress Tankyrase function in some cellular contexts. This study provides the tools to explore these questions.

EXPERIMENTAL PROCEDURES

The Supplemental Experimental Procedures are available in the Supplemental Information online.

Luciferase Reporters

HEK293T cells were transfected in technical triplicate with TOPFlash or FOPFlash reporter plasmids (Veeman et al., 2003), a reference Renilla luciferase reporter, and the indicated Tankyrase or AXIN constructs. One replicate was analyzed for protein expression. Cells were maintained in low serum (DMEM with 0.3% fetal bovine serum [FBS]) following transfection or treated with XAV939. Luciferase activities were measured 24 hr after transfection complex addition and Renilla luciferase activity used for normalization. Data were analyzed as detailed in the figure legends.

Protein Expression and Purification

SAM domains of human TNKS (1,018–1,093) and TNKS2 (867–940) were expressed in E. coli as His6-MBP-Asn10 fusion proteins, and they were purified by Ni affinity purification, tag removal, anion exchange, and SEC. Proteins were dialyzed into buffer with 200 mM NaCl prior to experiments. Proteins shown in Figures 3C and 5A were affinity purified. Proteins (Guettler et al., 2011) were dialyzed into buffer with 200 mM NaCl. TNKS2 SAM Y920A/T2 or TNKS SAM Y1073A/T1 (500 μM) was injected in 2-μl increments into TNKS2 SAM V903W/T2 or TNKS SAM V1056W/T1 (50 μM) or buffer, using an ITC200 MicroCalorimeter (MicroCal/GE Healthcare). Data were processed using Origin 7 (MicroCal/GE Healthcare) using a one-site binding model.

In Vitro PARylation

MYC2-TNKS2 and derivatives were expressed in HEK293T cells and immunoprecipitated. PARP activity assays were performed with 1 mM NAD+ and 5 μCi 32P-NAD+ for 30 min at 30°C. PAR chains were detached and analyzed essentially as described previously (Alvarez-Gonzalez and Jacobson, 1987; Panzeter and Althaus, 1990). Immunoprecipitates and in vitro reactions were analyzed by western blotting and autoradiography, respectively.

Co-IPs

HEK293T cells were transfected with the indicated Tankyrase or control constructs. For Figure 7D, cells were serum starved to match luciferase assays. Immunoprecipitates with anti-AXIN1 (C76H11 clone, Cell Signaling Technologies) or control IgG (sc-2027, Santa Cruz Biotechnology) were captured on Protein A/G magnetic resin (Thermo Scientific/Pierce). For Figures 6A and S6B, IPs were performed with anti-FLAG M2 affinity gel (Sigma). Lysates and immunoprecipitates were analyzed by SDS-PAGE and western blotting.

Fluorescence Microscopy

HeLa or SW480 cells were transiently transfected with the indicated Tankyrase constructs. Cells in DMEM containing 0.3% FBS were treated either with DMSO vehicle or 2 μM XAV939 for 20 hr directly after transfection. Cells were fixed by the addition of 4% formaldehyde. Cells were immuno- and DAPI-stained as indicated.

ACCESSION NUMBERS

The accession numbers for the structure coordinates and experimental structure factors reported in this paper are PDB: 5JRT, 5JU5, and 5JTI.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures, seven figures, and one table and can be found with this article online at http://dx.doi.org/10.1016/j.molcel.2016.06.019.
AUTHOR CONTRIBUTIONS

C.M.T., L.M., P.P., M.R., and S.G. generated DNA constructs, L.M. and C.M.T. purified proteins, L.M. crystallized proteins, with N.C. collected diffraction data, and with N.C. and S.G. determined crystal structures. L.M. and C.M.T. performed ultracentrifugation assays. L.M. performed SEC-MALS, CD, and ITC. L.M. and F.B. performed EM and with E.M. analyzed the data. C.M.T. and S.G. performed luciferase reporters. M.R. performed PARP activity assays. M.R. and M.R. performed co-immunoprecipitations. M.R. and S.G. performed lyseate fractions and fluorescence microscopy. P.P. contributed to protein purification, ultracentrifugation, and EM. S.G. designed the study together with the other authors and supervised the research. S.G. wrote the manuscript with input from all authors.

ACKNOWLEDGMENTS

We thank members of the S.G. team and the Divisions of Structural and Cancer Biology for helpful comments. We are grateful to Tina Daviter (ISMB Biophysics Centre, Birckbeck College) for assistance with CD spectroscopy, Kevin Jackson for advice on SEC-MALS, Chris Richardson for IT support, Fredrik Wallberg for assistance with microscopy, and Jane Sandiddall for laboratory support. We thank the staff at beamline I03 of the Diamond Light Source for their support during crystallographic data collection. We thank Alan Ashworth and Chris Lord for reagents and helpful discussions, Chris Bakal for HeLa cells, and Marc de la Roche for advice on AXIN immunofluorescence. We thank Frank Sichieri and the late Tony Pawson for support during the initial stages of this study. We are grateful to Mariam Biez for valuable advice. We thank Scott Gradia, Robert Rottapel, Randall Moon, Frank Sichieri, Karen Cowill, Oliver Rocks, Robert Kingston, and Richard Treisman for plasmasid. This work was supported by Cancer Research UK through a Career Establishment Award to S.G. (C47521/A16217) and The Institute of Cancer Research (ICR, L.M. is supported by an ICR studentship. E.M. is supported by Cancer Research UK (C12209/A16749).

**Note Added in Proof**

While this study was in press, DaRosa et al. reported a model for the TNKS SAM domain polymer, supported by biophysical evidence. The findings are in agreement with this study.
