BRIDGEMAN’S ORTHOSPECTRUM IDENTITY

DANNY CALEGARI

Abstract. We give a short derivation of an identity of Bridgeman concerning orthospectra of hyperbolic surfaces.

1. Introduction

In [1], Martin Bridgeman proves a beautiful identity concerning orthospectra of hyperbolic surfaces with totally geodesic boundary. Let $\Sigma$ be a hyperbolic surface with totally geodesic boundary. An orthogeodesic is a geodesic segment properly immersed in $\Sigma$, which is perpendicular to $\partial \Sigma$ at its endpoints. The set of orthogeodesics is countable, and their lengths are proper. Denote these lengths by $l_i$ (with multiplicity). Bridgeman’s identity is:

Theorem 1.1 (Bridgeman, [1]). With notation as above,

$$\sum_i L\left(1/\cosh^2(l_i/2)\right) = -\pi^2 \chi(\Sigma)/2$$

where $L$ is the Rogers’ dilogarithm function (to be defined below).

Treating the function $L$ as a black box for the moment, the identity has the form

$$\sum_i \ell(l_i) = \text{a term depending only on the topology of } \Sigma$$

The proof is very, very short and elegant. By the Gauss–Bonnet theorem, the term on the right is equal to $1/8$ of the volume of the unit tangent bundle of $\Sigma$. Almost every tangent vector on $\Sigma$ can be exponentiated to a geodesic on $\Sigma$ which intersects the boundary in finite forward and backward time (by ergodicity of the geodesic flow on a closed hyperbolic surface obtained by doubling; see e.g. [4]). If $v$ is such a tangent vector, and $\gamma_v$ is the associated geodesic arc, then $\gamma_v$ is homotopic keeping endpoints on $\partial \Sigma$ to a unique orthogeodesic (which is the unique length minimizer in its relative homotopy class).

The volume of the set of $v$ associated to a given orthogeodesic $\omega$ can be computed as follows. Lift $\omega$ to the universal cover, together with lifts of the boundary geodesics it ends on. The three together make a letter “H” in which $\omega$ is the crossbar; see Figure 1. Any $\gamma_v$ in the homotopy class of $\omega$ lifts to a unique geodesic segment in the universal cover with endpoints on the sides of the $H$. Therefore the volume of the set of such $v$ depends only on the geometry of the $H$, which in turn depends only on $l = \text{length}(\omega)$. This volume is $8\ell(l)$ with notation as above.

To complete the proof of Bridgeman’s identity therefore, it suffices to show $\ell(l) = L\left(1/\cosh^2(l/2)\right)$. Bridgeman derives this in several pages of calculations. The purpose of this note is to give a short derivation of this fact, using elementary hyperbolic geometry.

Date: June 29, 2010.
2. Derivation of $L$

The “ordinary” polylogarithms $Li_k$ can be defined by a Taylor series

$$Li_k(z) = \sum_{n=1}^{\infty} \frac{z^n}{n^k}$$

which converges for $|z| < 1$, and extends by analytic continuation. Taking derivatives, one sees that they satisfy the identities

$$Li_k'(z) = Li_k(z) - \frac{1}{z}$$

thereby giving rising to recursive integral formulae for these functions. The special case $Li_0(z)$ is the familiar geometric series for $z/(1 - z)$, so $Li_1(z) = -\log(1 - z)$ and

$$Li_2(z) = -\int \log(1 - z) \frac{dz}{z}$$

The Rogers dilogarithm is a “normalization” of $Li_2$ given by the formula

$$L(z) = Li_2(z) + \frac{1}{2} \log(|z|) \log(1 - z)$$

for real $z < 1$. One sees that the Rogers dilogarithm is obtained by symmetrizing the integrand for the integral expression for $Li_2$ under the involution $z \rightarrow 1 - z$:

$$L'(z) = -\frac{1}{2} \left( \frac{\log(1 - z)}{z} + \frac{\log(z)}{1 - z} \right)$$

A classic reference for this material is Lewin [5].

We now explain how to compute the volume of the set of vectors $v$ tangent to a geodesic $\gamma_v$ intersecting the left and right sides of the $H$ associated to an orthogeodesic $\omega$. The four ideal vertices of the $H$ span an ideal quadrilateral $Q$. The diagonals of this quadrilateral subdivide it into four semi-ideal triangles. We denote the left and right sides of the $H$ as $L$ and $R$, and the other two edges of $Q$ as $U$ and $D$. Similarly, denote the four triangles $T_L$, $T_R$, $T_U$ and $T_D$ labeled according to which edge of the quadrilateral they bound; see Figure 2 (the triangle $T_R$ is colored gray in the figure). The crossbar of the $H$ (corresponding to the orthogeodesic $\omega$ itself) is not depicted in the figure.

We identify the ideal circle with $\mathbb{RP}^1$ in such a way that the vertices of $Q$ are (in circular order) $0, x, 1, \infty$, where $\infty, 0$ are the ideal vertices of the gray triangle. Call $\alpha$ the (hyperbolic) angle of the gray triangle at its vertex. By elementary hyperbolic trigonometry, $x = (1 + \cos(\alpha))/2 = \tanh^2(l/2)$ where $l$ is the distance between $L$
and $R$ (i.e. the length of the given orthogeodesic). We use the parameters $l$, $x$ and $\alpha$ interchangeably in the sequel. We will compute $\ell$ implicitly as a function of $x$, and show that it is a multiple of the Rogers dilogarithm function, thus verifying Bridgeman’s identity.

Every vector $v$ in $Q$ exponentiates to a (bi-infinite) geodesic $\gamma_v$, and we want to compute the volume of the set of vectors $v$ for which the corresponding geodesic intersects both $L$ and $R$. The point of the decomposition in the figure is that for $v$ in $T_L$ (say), the geodesic $\gamma_v$ intersects $L$ whenever it intersects $R$, so we only need to compute the volume of the $v$ in $T_L$ for which $\gamma_v$ intersects $R$. Similarly, we only need to compute the volume of the $v$ in $T_R$ for which $\gamma_v$ intersects $L$. For $v$ in $T_U$, we compute the volume of the $v$ for which $\gamma_v$ does not intersect $U$ (since these are exactly the ones that intersect both $L$ and $R$), and similarly for $T_D$.

The crux of the matter is that these volumes can be expressed in terms of integrals of simple harmonic functions. Let $\chi_L$ denote the harmonic function on the disk which is 1 on the arc of the circle bounded by $L$, and 0 on the rest of the circle. This function at each point is equal to $1/2\pi$ times the visual angle (i.e. the length in the unit tangent circle) subtended by the given arc of the circle, as seen from the given point in the hyperbolic plane. Define $\chi_R$, $\chi_U$ and $\chi_D$ similarly. Then the total volume we need to compute is equal to

$$4\pi \left( \int_{T_L} 2\chi_R + \int_{T_U} (1 - 2\chi_U) \right)$$

(here we have identified $\int_{T_L} \chi_R = \int_{T_R} \chi_L$ by symmetry, and similarly for the other pair of terms). Let us approach this a bit more systematically. We introduce three functions $A(\cdot)$, $B(\cdot)$ and $C(\cdot)$ as follows. If $\alpha$ denotes as above the angle at the nonideal vertex of triangle $T_R$, we define

$$\int_{T_R} \chi_R = A(\alpha), \quad \int_{T_R} \chi_U = B(\alpha), \quad \text{and} \quad \int_{T_R} \chi_L = C(\alpha)$$

The integral we want to evaluate can be expressed easily in terms of explicit rational multiples of $\pi$, and the functions $A, B, C$. These functions satisfy obvious identities:

$$C(\alpha) = \int_{T_R} 1 - A(\alpha) - 2B(\alpha) = \pi - \alpha - A(\alpha) - 2B(\alpha)$$

and

$$A(\alpha) + B(\pi - \alpha) = \pi/3$$
where the last identity comes by observing that we are integrating a certain function over an ideal triangle, and observing that the average of this function under the symmetries of the ideal triangle is equal to the constant function $1/3$. In particular, we see that we can express everything in terms of $A$. After some elementary reorganization, we see that the contribution $V(\alpha)$ to the volume of the unit tangent bundle of the surface associated to this particular orthogeodesic is

$$V(\alpha) = \pi^2(8 - 16/3) - 4\pi\alpha - 8\pi(A(\alpha) - A(\pi - \alpha))$$

It remains to actually compute $A(\alpha)$. To do this it makes sense to move to the upper half-space model, and move the endpoints of the interval to 0 and $\infty$. The harmonic function is equal to 1 on the negative real axis, and 0 on the positive real axis. It takes the value $\theta/\pi$ on the line $\arg(z) = \theta$. The area form in the hyperbolic metric is proportional to the Euclidean area form, with constant $1/\text{Im}(z)^2$. In other words, we want to integrate $\arg(z)/\pi\text{Im}(z)^2$ over the region indicated in figure 3, where the nonideal angle is $\alpha$, and the base point is 0.

$$\text{Figure 3.}$$

If we normalize so that the circular arc is part of the semicircle from 0 to 1, then the real projection of the vertical lines in the figure are 0 and $x$.

There is no elementary way to evaluate this integral, so instead we evaluate its derivative as a function of $x$ where as before, $x = (1 + \cos(\alpha))/2$. This is the definite integral

$$A'(x) = \int_{y=\sqrt{x-x^2}}^\infty \frac{\tan^{-1}(y/x)}{\pi y^2} dy$$

Integrating by parts gives

$$A'(x) = \frac{\alpha}{\pi \sin \alpha} + \frac{1}{\pi} \int_{y=\sqrt{x-x^2}}^\infty \frac{x}{y(y^2 + x^2)} dy$$

This evaluates to $A'(x) = (\alpha/\pi \sin \alpha) - 1/\pi(\log(1-x)/2x)$. Thinking of $V(\alpha)$ as a function of $x$, we get

$$V'(x) = -4\pi d\alpha/dx - 8\pi(A'(x) + A'(1 - x)) = -8L'(x)$$

Comparing values at $x = 0$ we see that $V(x) = 8L(1 - x)$ (where we use the symmetry of $L'$ under $x \rightarrow 1 - x$). Substitute $x = \tanh(l/2)$ and the identity is proved.

Remark 2.1. The paper [3] by Dupont and Sah relates Rogers dilogarithm to volumes of $\text{SL}(2,\mathbb{R})$-simplices, and discusses some interesting connections to conformal field theory and lattice model calculations. They cite an older paper of Dupont for
the explicit calculations; these are somewhat tedious and unenlightening; however, he does manage to show that the Rogers dilogarithm is characterized by the Abel identity. In other words, Dupont shows:

Lemma 2.2 (Dupont [2], Lemma A.1). Let \( f : (0, 1) \to \mathbb{R} \) be a three times differentiable function satisfying

\[
f(s_1) - f(s_2) + \frac{s_2}{s_1} - f \left( \frac{1 - s_1^{-1}}{1 - s_2^{-1}} \right) + f \left( \frac{1 - s_1}{1 - s_2} \right) = 0
\]

for all \( 0 < s_2 < s_1 < 1 \). Then there is a real constant \( \kappa \) such that \( f(x) = \kappa \mathcal{L}(x) \) where \( \mathcal{L}(x) \) is the Rogers dilogarithm (up to an additive constant).

Our geometric argument can be reformulated in homological algebraic terms, though since its virtue is its simplicity, we have not pursued this.

3. Acknowledgments

Danny Calegari was supported by NSF grant DMS 0707130. I would like to thank the anonymous referee for useful comments, and Martin Bridgeman for a beautiful talk at Caltech in which he explained his identity. I would also like to thank Hidetoshi Masai for catching some errors in an earlier version of this paper.
