ABSTRACT

We report new single dish CO J = 6–5 line observations for the archetypal Ultra Luminous Infrared Galaxy (ULIRG) Arp 220 with the James Clerk Maxwell Telescope atop Mauna Kea in Hawaii. The J = 6–5 line is found to be faint, with brightness temperature ratios (6–5)/(1–0), (6–5)/(3–2) of 0.080 ± 0.017 and R_{65/32} = 0.082 ± 0.019, suggesting very low excitation conditions that cannot be reconciled with the warm and very dense molecular gas present in one of the most extreme starbursts in the local universe. We find that an optically thick dust continuum, with τν ≳ 1 for the bulk of the warm dust and gas in Arp 220, submerges this line to an almost black body curve, reducing its flux, and affecting its CO spectral line energy distribution at high frequencies. This also resolves the C+ line deficiency in this object, first observed by Infrared Space Observatory: the near absence of that line is a dust optical depth effect, not a dense photodissociation region phenomenon. Finally, we briefly comment on the possibility of such extreme interstellar medium (ISM) states in other ULIRGs in the distant universe, and their consequences for the diagnostic utility of high frequency molecular and atomic ISM lines in such systems. In the case of Arp 220, we anticipate that the now spaceborne Herschel Space Observatory will find faint high-J CO lines at ν ≳ 690 GHz that would appear as sub-thermally excited with respect to the low-J ones as a result of the effects of dust absorption.

Key words: galaxies: individual (Arp 220) – galaxies: ISM – galaxies: starburst – ISM: molecules

1. INTRODUCTION

Since the discovery of its enormous IR luminosity (L_{IR}(8–1000 μm) = 1.6 × 10^{12} L_{⊙}, Soifer et al. 1984; Emerson et al. 1984), representing ~99% of its bolometric luminosity, Arp 220 has been a study of extremes when it comes to the ISM conditions in intense starbursts in the local universe. A prominent member in a prominent class of galaxies (e.g., Sanders & Ishida 2004), the large IR luminosity and relative proximity (at D_{L} ≳ 77 Mpc, it is the nearest Ultra Luminous Infrared Galaxy, ULIRG), made Arp 220 an early target of numerous molecular line observations. Its large CO J = 1–0 line luminosity revealed a huge molecular gas reservoir (~10^{10} M_{⊙}; Young et al. 1984; Sanders et al. 1991; Solomon et al. 1997), while luminous transitions of heavy rotor molecules such as CS J = 1–0, and HCN, HCO+ J = 1–0 have demonstrated that, quite unlike typical quiescent spirals, most of the molecular gas in this spectacular merger is very dense, with n ≳ 10^{3} cm^{-3} (Solomon et al. 1990, 1992). Such studies have recently culminated in the most extensive molecular line survey ever conducted for such objects (Greve et al. 2009), making Arp 220 a galaxy with the best-studied molecular gas reservoirs in the local universe. High-resolution CO J = 1–0, 2–1 interferometer imaging reveals two compact (2r ≲ 0.3; 108 pc) gas concentrations ~1″ (360 pc) apart (Scoville et al. 1997; Downes & Solomon 1998; Sakamoto et al. 1999; Eckart & Downes 2001), whose intense starbursts dominate the IR luminosity of the entire system. Finally, a major advance was recently made with the imaging of the CO J = 3–2 emission (and the adjacent continua at 860 μm) of the warm and dense gas, that also implied substantial dust optical depths even at submillimeter wavelengths (Sakamoto et al. 2008).

We report single dish CO J = 6–5 observations of Arp 220 with the James Clerk Maxwell Telescope (JCMT) as part of a multi-J CO and HCN line survey of LIRGs (L_{IR} ≳ 10^{11} L_{⊙}) in the local universe. We demonstrate that an optically thick dust continuum at submillimeter wavelengths submerges this CO line to near-blackbody emission, and strongly affects the emergent CO spectral line energy distribution (SLED) and the C+ fine-structure line luminosity for this extreme starburst. Finally, we discuss whether similar ISM conditions are present in dusty starbursts in the distant universe, lowering their observed (high-J)/(low-J) CO ratios well below those typical of star-forming molecular gas, and thus limiting their diagnostic utility.

2. OBSERVATIONS, LINE, AND CONTINUUM FLUX ESTIMATES

We used the upgraded dual-channel W/D (620–710 GHz) receiver at the JCMT4 at 4092 m altitude atop Mauna Kea in Hawaii, operating single sideband (SSB), to observe the CO J = 6–5 line (ν_{rest} = 619.473 GHz) in Arp 220 on 2009 March 15 under dry conditions (T_{225GHz} ≲ 0.04–0.06). To ensure the flattest baselines possible, but also measure the corresponding dust continuum at λ_{obs} = 442 μm, we used the fastest beam switching mode available (continuum mode) with a beam switch frequency of f_{BW} = 4 Hz and a throw of 30″ (in azimuth). The ACSIS spectrometer5 was used at its widest mode of 1.8 GHz (~780 km s^{-1}) at 690 GHz and for separate tunings, yielding an effective bandwidth of 3.253 GHz (~1400 km s^{-1}). This was necessary in order to cover the widest known CO line in local ULIRGs (FWZI ~ 900–1000 km s^{-1}). The typical system temperatures were T_{sys} ~ 2500 K (including atmospheric absorption). The beam size at 691 GHz is Θ_{HPBW} = 8″. Good pointing with such

4 The JCMT is operated by The Joint Astronomy Centre on behalf of the Science and Technology Facilities Council of the United Kingdom, the Netherlands Organization for Scientific Research, and the National Research Council of Canada.

narrow beams is crucial and was checked every 45 minutes using both absolute W/D and differential pointing with the A 3 receiver (230 GHz), yielding $\sigma_x \sim \sigma_y \sim 1.4''$ (rms; Figure 1). The aperture efficiency at 690 GHz is $n_{\nu}^* \sim 0.32$, estimated from the Ruze formula for an 80% membrane transmission, an rms dish surface accuracy of $\sim 25$ $\mu$m, and $n_{\nu,0}^* \sim 0.68$ (aperture efficiency for a perfect dish with the illumination taper applied at the JCMT), and verified with observations of Venus. The flux calibration uncertainty is estimated with repeated observations of compact spectral line standards and is $\sim 25\%$.

Individual spectra were examined, edited for bad channels, and co-added (both W/D channels) to yield the final spectrum shown in Figure 2 overlaid with CO 3–2 (JCMT), and the HCN J = 1–0, CS J = 3–2 lines obtained with the IRAM 30 m telescope (from Greve et al. 2009). The agreement between overall FWZI’s and line centers is excellent although the high density tracer CS 3–2 line ($230$ GHz), yielding $\sigma_x \sim \sigma_y \sim 1.4''$ (rms; Figure 1). The aperture efficiency at 690 GHz is $n_{\nu}^* \sim 0.32$, estimated from the Ruze formula for an 80% membrane transmission, an rms dish surface accuracy of $\sim 25$ $\mu$m, and $n_{\nu,0}^* \sim 0.68$ (aperture efficiency for a perfect dish with the illumination taper applied at the JCMT), and verified with observations of Venus. The flux calibration uncertainty is estimated with repeated observations of compact spectral line standards and is $\sim 25\%$.

The agreement between overall FWZI’s and line centers is excellent although the high density tracer CS 3–2 line ($230$ GHz), yielding $\sigma_x \sim \sigma_y \sim 1.4''$ (rms; Figure 1). The aperture efficiency at 690 GHz is $n_{\nu}^* \sim 0.32$, estimated from the Ruze formula for an 80% membrane transmission, an rms dish surface accuracy of $\sim 25$ $\mu$m, and $n_{\nu,0}^* \sim 0.68$ (aperture efficiency for a perfect dish with the illumination taper applied at the JCMT), and verified with observations of Venus. The flux calibration uncertainty is estimated with repeated observations of compact spectral line standards and is $\sim 25\%$.

Individual spectra were examined, edited for bad channels, and co-added (both W/D channels) to yield the final spectrum shown in Figure 2 overlaid with CO 3–2 (JCMT), and the HCN J = 1–0, CS J = 3–2 lines obtained with the IRAM 30 m telescope (from Greve et al. 2009). The agreement between overall FWZI’s and line centers is excellent although the CO J = 6–5 line becomes weak toward the velocity range where the high density tracer CS J = 3–2 line ($n_{\nu,0}^* \sim 2 \times 10^5$ $\text{cm}^{-3}$) becomes especially strong (see discussion in Section 3). The integrated CO J = 6–5 line flux is estimated from

$$S_{\text{line}} = \int_{\Delta V} S_v dV = \frac{8k_B}{\eta_\nu^* \pi D^2} G(\sigma) \int_{\Delta V} T_A^* dV,$$

where $\Gamma_{\text{JCMT}} = 15.62$ (Jy $\text{K}^{-1}$), and

$$G(\sigma) = 1 + 8 \ln^2 \left( \frac{\sigma}{\Theta_{\text{HPBW}}} \right)^2,$$

with $\sigma \sim \sigma_x \sim \sigma_y$ the pointing residuals. The aforementioned factor corrects for the flux bias resulting when point-like sources are observed with single dish telescopes with given pointing rms errors (Condon 2001). This is usually insignificant for modern millimeter/submillimeter telescopes (e.g., at 345 GHz and the same pointing rms error: $G \sim 1.064$), yet it can become significant at very high frequencies, even for the excellent tracking and pointing of the enclosed JCMT. For our observations $G = 1.17$, and we use it to scale our measured CO J = 6–5 line and 442 $\mu$m dust continuum fluxes accordingly. We obtain $S_C65.65 = (1170 \pm 341)$ Jy $\text{km s}^{-1}$, and $S_{442,\mu m} = (3.71 \pm 0.96) Jy$ (using the line-free part of the spectrum and the scaling factor in Equation (1)), or equivalently $S_{134,\mu m} = (3.85 \pm 0.99) Jy$ (scaled by $S_c \propto \nu^2$). Regarding the continuum it is worth mentioning that Arp 220 is a submillimeter calibration source for SCUBA at the JCMT, where multiple images show a compact source at 450 $\mu$m ($\lesssim 5''$) with $S_{50Jy} = (2.77 \pm 0.06)$ Jy. The higher value of $S_{50Jy} = (6.3 \pm 0.8)$ Jy reported by Dunne & Eales (2001) is thus likely affected by calibration error (L. Dunne 2009, private communication). Finally, the CO J = 6–5 flux is in good agreement with that reported recently by Matsushita et al. 2009 of $S_{65.65} = (1250 \pm 250)$ Jy $\text{km s}^{-1}$ using the SMA. The full CO J = 6–5 flux is in good agreement with that reported recently by Matsushita et al. 2009 of $S_{65.65} = (1250 \pm 250)$ Jy $\text{km s}^{-1}$ using the SMA. For the purposes of this work we adopt $S_{65.65} = (1210 \pm 240)$ Jy $\text{km s}^{-1}$ (average: JCMT and SMA), $S_{134,\mu m} = (3.0 \pm 0.06)$ Jy (average: W/D, SMA, SCUBA calibrator database).

### 3. THE STATE OF MOLECULAR GAS AND DUST IN ARP 220

A large multi-J CO, HCN, HCO⁺, and CS line survey by Greve et al. (2009) makes Arp 220 the ULRIRG with the best-studied molecular gas properties, and allows us to place the measured CO J = 6–5 line in the best possible perspective. From that study it becomes apparent that densities for the bulk of the molecular gas in Arp 220 are very high: $n_{\text{crit}} \sim 10^{25}$ $\text{cm}^{-3}$, and thus the CO J = 6–5 transition is expected to be fully thermalized ($n_{\text{crit}} \sim 5.8 \times 10^5$ $\text{cm}^{-3}$). On the other hand, global dust continuum SEDs (e.g., Lisenfeld et al. 2000), and high resolution millimeter/submillimeter imaging (e.g., Downes & Eckart 2007; Sakamoto et al. 2008) yield typically

---

**Figure 1.** Distributions of pointing offsets obtained during all W/D observing periods. Values with $|\sigma| \lesssim 2''$ are those that apply to source observations, with any larger ones typically obtained after large changes in azimuth and elevation when the telescope changed sky sectors. The pointing offsets during Arp 220 observations are $\sigma_x \sim \sigma_y \sim 1''.4$ and $\sigma_x = (\sigma_x^2 + \sigma_y^2)^{1/2} \sim 2''$. 

[6] http://www.jach.hawaii.edu/JCMT/continuum/calibration/sens/potentialcalibrators.html

[7] A fringe pattern present on the short baselines has likely corrupted the SMA channel map spectrum (Figure 7 in Matsushita et al. 2009), and thus the SMA spectrum is not reproduced here. The reported SMA line flux has been corrected for that effect (S. Matsushita 2009, private communication).
ular gas reservoir. High dust optical depths at short submillimeter wavelengths provide the most plausible explanation for the faint CO $J = 6–5$ line, immersing it in a strong nearly blackbody (and thus almost featureless) dust continuum. Such large optical depths of dust continuum at far-IR wavelengths were first proposed for Arp 220 by Lisenfeld et al. (2000) where $\tau_{65} \sim 5–12$ has been deduced from its far-IR/submillimeter dust SED, with González-Alfonso et al. (2004) arriving at similar conclusions using a full Infrared Space Observatory Long Wavelength Spectrometer spectrum. This has culminated with the recent work of Sakamoto et al. (2008) where large optical depths are reported even at submillimeter wavelengths ($\tau_{65} \sim 1$). Their effect on the emergent CO line ratios can be easily shown using a simple model of an isothermal mixture of molecular gas and dust in LTE, where the continuum-subtracted source line brightness temperature is (e.g., Rohlfs & Wilson 1996, p. 320)

$$\Delta T_{b,co} = e^{-\tau_{d}} [J(v_{co}, T) - J(v_{co}, T_{CM})] \left(1 - e^{-\tau_{co}}\right), \quad (3)$$

where $J(v, T) = h\nu/k_B \left[\exp(h\nu/k_B T) - 1\right]^{-1}$, and $\tau_d$ and $\tau_{co}$ are the dust continuum and CO line optical depths. Here it is important to point out that the equation above assumes a form identical to that for line absorption by a foreground dust screen only for an isothermal mixture of line-emitting gas and emergent dust (i.e., identical source functions). In such a mixture the high dust optical depths do not actually reduce the emergent line strength (as they would for a dust absorption “screen”) rather than make both continuum and spectral line emission rise up to a common blackbody SED, with Equation (3) simply expressing the diminishing line-continuum contrast. For a dust emissivity law $\tau_d(v) \propto v^\beta$ ($\beta = 1–2$), the brightness temperature ratio $CO(6–5)/(J + 1–J)$ transition would then be

$$R_{65/J+1,J}^{(int)} = \exp \left[ -\tau_d(v_{J+1,J}) \left(\left(\frac{v_{65}}{v_{J+1,J}}\right)^\beta - 1\right) \right] \times R_{65/J+1,J}^{(obs)}, \quad (4)$$

where $R_{65/J+1,J}^{(obs)}$ is the “intrinsic” line ratio corresponding to $\tau_d = 0$. For CO $J = 3–2$ (also tracing the warm star-forming molecular gas as the $J = 6–5$ line) and its corresponding continuum emission (Sakamoto et al. 2008) has deduced $\tau_d(v_{32}) \sim 1$. For $n(H_2) = 10^5$ cm$^{-3}$ and a typical $T_{kin} = (65–90)$ K our large velocity gradient (LVG) code yields $R_{65/J+1,J}^{(int)} \sim 0.85–0.90$. Inserting these values into Equation (4) yields $R_{65/J+1,J}^{(obs)} \sim 0.042–0.32$ (for $\beta = 1–2$), comfortably encompassing the observed value, and demonstrating how substantial submillimeter dust optical depths can suppress (high-J)/(low-J) CO line ratios. The larger suppression of CO $J = 6–5$ in the eastern nucleus of Arp 220, contributing mostly to the “horn” at $\sim 5600$ km s$^{-1}$ of the CO line profiles, is then a likely result of the larger gas densities (and thus correspondingly larger dust optical depths). This is clearly indicated by the rising CS $J = 3–2$ line emission (Figure 2) and the larger HCN(4–3)/CO(3–2) ratio (Figure 3) toward $\sim (5500–5600)$ km s$^{-1}$ than toward $\sim (5300–5400)$ km s$^{-1}$, the latter range associated with the western nucleus.

Thus, the CO $J = 6–5$ line (and partially even $J = 3–2$) is affected by a dust continuum rising to an almost black body curve from IR out to short submillimeter wavelengths. This is further indicated by the observed ratio $S_{33} / S_{65} \sim 5.45 \pm 0.82$ (for the two nuclei: $S_{65} = (0.55 \pm 0.082)$ Jy; from Sakamoto et al. 2008), which is close to the black body

![Graph showing temperature vs. velocity for Arp 220](image-url)

**Figure 2.** Arp 220: $a = 15^h34^m57^s24$, $\delta = +23^\circ 30^\prime 11^\prime 2$ (2000). Top: CO $J = 6–5$ (thick line), overlaid to CO $J = 3–2$ (thin line), with resolutions of $\Delta V_{ch} = 27$ km s$^{-1}$ ($J = 6–5$) and $\Delta V_{ch} = 23$ km s$^{-1}$ ($J = 3–2$), and centered at $cz = 5450$ km s$^{-1}$ (LSR). The thermal rms error across the line-free part of the spectrum is $\delta T^*_b \sim 12$ mK for both lines. Bottom: the CO $J = 6–5$ line overlaid with HCN $J = 1–0$, and CS $J = 3–2$ lines, obtained with the IRAM 30 m telescope (adapted from Greve et al. 2009).

$T_{dust} \sim (65–120)$ K. For the high gas densities in this system: $T_{kin} \sim T_{dust}$, and the CO line emission should be peaking at $J_{max} \sim [2k_B T_{kin}/E_c]^{1/2} \sim 5–7$ ($E_c / k_B \sim 5.5$ K). Clearly the $J = 6–5$ transition should not only be luminous but quite possibly the most luminous CO line in this system, with typical brightness temperature ratios of $R_{65/J+1,J} \sim 0.80–0.95$ for $J + 1 = 1–5$, even for the lowest possible $T_b = 65$ K and $n(H_2) = 10^5$ cm$^{-3}$.

### 3.1. High Dust Optical Depths at Submillimeter Wavelengths

Our measured CO (6–5)/(1–0) and (6–5)/(3–2) brightness temperature ratios for Arp 220 are $R_{65/10} = 0.080 \pm 0.017$ and $R_{65/32} = 0.082 \pm 0.019$ (CO $J = 1–0$, 3–2 fluxes from Greve et al. 2009), suggesting impressively low excitation: the average properties of its molecu-
Figure 3. HCN $J = 4–3$ (thin line) overlaid to CO $J = 3–2$ (thick line) spectrum, with resolutions of $\Delta V_{\text{lin}} = 22–23$ km s$^{-1}$ (HCN $J = 4–3$, CO $J = 3–2$). The CO and HCN emission of the denser eastern nucleus corresponds to the feature centered at $\sim 5500–5600$ km s$^{-1}$ where the HCN/CO line ratio is the largest (Greve et al. 2009). The thermal rms errors across the line-free part of the spectra $\delta T = 0.6$ mK (HCN $J = 4–3$) and $\delta T = 1.2$ mK (CO $J = 3–2$).

value of $(860/434)^2 = 3.93$. Indeed from

$$S_{434\mu m}/S_{860\mu m} = \left(\frac{v_{434}}{v_{860}}\right)^2 \left[1 - \exp\left(-\frac{v_{434}}{v_{860}}\beta \tau_{860}\right)\right]^{1}/\left[1 - \exp\left(-\tau_{860}\right)\right],$$

and $S_{434\mu m}/S_{860\mu m} = 5.45$ we find $\tau_{860} \sim 1.25$ (for $\beta = 2$), while for $S_{434\mu m}/S_{860\mu m} = 6.27$ (+$\sigma$ of the measured value) the minimum optical depth is $\tau_{860} \sim 0.95$. Dust optical depths large enough to bring all this about are certainly present in Arp 220 (Sakamoto et al. 2008), while the globally suppressed $J = 6–5$ line further demonstrates that much of the large molecular gas mass in this system is “cloaked” by these high dust optical depths rather than only small sub-regions around, e.g., an active galactic nucleus (AGN; Downes & Eckart 2007). If this is typical for ULIRGs, it can modify the emergent CO SLEDs, and affect the diagnostic value of molecular lines at high frequencies for such extreme systems, a possibility further discussed in Section 4.

Finally, we note that the average state of the molecular gas in Arp 220, as indicated by the HCN, CS, and HCO$^+$ lines, is so highly excited that even CO $J = 6–5$ line fluxes up to $\sim 3$ times higher would leave $R_{65/32}$ well below what is expected of such gas and is typically observed in starbursts (see Figure 5 in Section 4.2), still suggesting substantial dust optical depths at short submillimeter wavelengths suppressing high-$J$ CO line emission.

3.2. Arp 220: the $C^+$ line Luminosity Deficit Resolved

For a $\tau_{850} \gtrsim 1$ “cloaking” the bulk of the gas and dust in Arp 220, and conservatively assuming $\beta = 1$, yields $\tau_{58} \gtrsim 5.4$ at the emission wavelength of the $C^+$ fine structure line. This is more than enough to almost completely suppress this strong ISM cooling line into a featureless black body dust continuum, favoring large dust optical depths as the cause for its weakness among the other explanations proposed (e.g., Malhotra et al. 1997). Indeed the faint CO $J = 6–5$ line, besides corroborating the high dust optical depths at IR/submillimeter wavelengths in Arp 220, also makes them the most likely cause of its $C^+$ line luminosity “deficit” (found in ULIRGs, with Arp 220 having the largest; Luhman et al. 1998, 2003). It does so by negating a prominent alternative explanation for the $C^+$ line suppression, namely very dense photodissociation regions (PDRs; where precipitous $C^+$ recombination would remove it from the ISM). This is because CO $J = 6–5$ is a different spectral line (governed by different physics and chemistry than $C^+$) and one that ought to be luminous if that alternative explanation held. Indeed, for dense PDRs immersed in strong far-UV radiation fields high-$J$ CO lines are expected to be very luminous and an alternative cooling “channel” to that of the suppressed $C^+$ line, balancing the tremendous ISM heating expected in ULIRGs (Papadopoulos et al. 2007). Finally it must be noted that if high dust optical depths at short submillimeter wavelengths are responsible for suppressing both the high-$J$ CO and the $C^+$ lines in ULIRGs, it follows that the starburst systems with dust-suppressed (high-$J$)/(low-$J$) CO line ratios will also be those with small $L(C^+)/L_{IR}$.

4. HIGH DUST OPTICAL DEPTHS IN ULIRGS: FROM THE IR TO THE SUBMM

The discovery of dust continuum optical depths that in ULIRGs can remain substantial even out to short submillimeter wavelengths is the culmination of a series of studies successively “pushing” the $\tau_{1} \gtrsim 1$ limit longward in wavelength for these remarkable systems (Condon et al. 1991; Solomon et al. 1997; Lisenzfeld et al. 2000; Sakamoto et al. 2008). Condon et al. were the first to point out that high dust extinction at far-IR wavelengths is needed to explain radio continuum sizes of ULIRGs that are smaller than their minimum IR black-body emission sizes. They argued that re-radiation of the IR light from a compact starburst by dust “layers” further out that remain optically thick at far-IR wavelengths can yield larger effective IR-continuum source sizes than the true starburst sizes (revealed by radio continuum). For the compact gas disk configurations in ULIRGs (expected in mergers and their dissipative gas motions) such large dust optical depths can make both IR “colors” and ISM line ratios at short submillimeter wavelengths viewing-angle dependent and thus much reduce their AGN-versus-starburst diagnostic power. This is indeed the case for IR colors where “IR-cool” ULIRGs may not be lacking an AGN but instead host AGN that are heavily obscured along the particular line of sight observed (Condon et al. 1991), while in nearly face-on ULIRG/quasi-stellar object systems (e.g., Mrk 231) such AGN remain visible with their warm IR colors discernible through smaller dust optical depths. It now seems that molecular line diagnostics at short submillimeter wavelengths may suffer from similar effects.

4.1. The Diagnostic Power of Far-IR/Submillimeter ISM Lines Revisited

A general effect of high dust optical depths at short submillimeter wavelengths on the CO SLEDs would be to make them appear “cooler” than those typical for star-forming gas. Thus, dust-suppressed CO (high-$J$)/(low-$J$) ratios can be hard to discern from those typical of genuinely low-excitation gas. High dust optical depths at short submillimeter wavelengths in ULIRGs are particularly troubling for ISM lines whose physics makes them diagnostic of deeply “buried” AGN versus starbursts as the energy source of their prodigious IR luminosities.
This is especially true for line frequencies of $v \gtrsim 690$ GHz whose ratios, when unaffected by dust absorption, offer the best discrimination between the various ISM excitation mechanisms, such as X-rays from a deeply buried AGN (Meijerink & Spaans 2005), or far-UV photons from their starbursts (Meijerink et al. 2006). In such cases, ratios of lines adjacent in frequency (e.g., HCO$^+$/HCN for the same rotational level) will have to be used as AGN/starburst discriminators. Finally, high dust optical depths at short submillimeter wavelengths can affect molecular line observations of ULIRGs at high frequencies with the upcoming Herschel Space Observatory. For Arp 220 in particular faint and apparently sub-thermally excited CO lines are to be expected at $v \gtrsim 690$ GHz (Figure 4), and this will also affect high-$J$ transitions of any molecules tracing the star-forming gas phase (e.g., HCN).

4.2. Evidence for High Dust Optical Depths at submillimeter Wavelengths in Distant Starbursts

Low (high-$J$)/(low-$J$) CO line ratios quite atypical of star-forming molecular gas have been measured in some of the most IR-luminous ($L_{IR} \sim 10^{11}\ L_\odot$) starbursts in the distant universe (Tacconi et al. 2006), a Ly-break galaxy whose CO($7–6$)/(3–2) brightness temperature ratio is $R_{76/32}$ = 0.030 (Baker et al. 2004), and in a submillimeter-bright ULIRG at $z = 1.44$ where $R_{54/32}$ = 0.16 (Papadopoulos & Ivison 2002). However, the wealth of molecular line data for Arp 220 that allowed its low CO (6–5)/(3–2) ratio to be attributed to large dust optical depths at short submillimeter wavelengths is not available yet for high redshift systems. Thus, as discussed in the previous section, “cool” CO line ratios can be due to either low-excitation gas or to high dust optical depths.

Dominant amounts of low-excitation and star formation (SF)-idle gas extending well beyond star-forming galactic nuclei are indeed well-known features of star-forming spirals in the local universe and even of archetypal starbursts such as M 82 (Weiss et al. 2004). However, recent high-resolution CO imaging of submillimeter-bright galaxies (SMGs) at high redshifts finds no evidence for such low-excitation extended molecular gas reservoirs (Tacconi et al. 2006; Iono et al. 2009), yet it also measures CO (6–5)/(3–2), (7–6)/(3–2) line ratios of $\lesssim 0.35$ in many such systems. In one extreme such case, the most compact SMG (SMM J044307+0210 at $z = 2.5$) has the lowest such line ratio of $R_{76/32} \sim 0.13$ (Tacconi et al. 2006). Indicatively, for nearby star-forming galactic nuclei such CO line ratios are $\sim 0.8–0.9$ (Mao et al. 2000; Bayet et al. 2006), and values of $\lesssim 0.30$ are typical of low-excitation SF-quiescent gas. In Figure 5, we show the $R_{65/32}$ ratios for star-forming and quiescent environments in the local universe along with those available for systems at high redshifts. From this it becomes obvious that (1) nearby starburst environments behave as expected, tracing the entire range of $R_{65/32}$ values typical for star-forming molecular gas, and (2) several high luminosity SMGs ($L_{IR} > 10^{12}\ L_\odot$) fall well below this range, and well into that typical for low-excitation SF-idle environments. In some SMGs $R_{65/32}$ falls even below the minimum value of $\sim 0.3$, expected for the dense and cold starless cores with minimum temperatures of $T_{kin} \sim 10\ K$ (set by Galactic cosmic rays), and densities of $n(H_2) \sim 10^5\ cm^{-3}$. Indicatively $R_{65/32}$ for Arp 220 would remain below that value even for a CO $J = 6–5$ line flux that is $\sim 3$ times higher than the one observed.

In order to better quantify this we conduct LVG radiative transfer modeling of the CO line ratios reported for SMGs by

---

8 If a “neighboring” CO line ratio (e.g., $R_{65/32}$) rather than $R_{65/32}$ is available for a high-$z$ system, we obtain the average value and range of $R_{65/32}$ by using the available one to find compatible LVG solutions over $T_k = (30–110)\ K$, \(\langle n(H_2) \rangle = (10^2–10^7)\ cm^{-3}\), assuming also $K_{uv} \sim 1$. 

---

Figure 4. CO SLED of Arp220 and the effects of dust (see Section 4.1), where $t_{line}$ is given in solar luminosities. The red bars denote the 5σ–1 hr detection limits for the SPIRE-FTS on Herschel, evaluated using the observatory integration time calculator and assuming that all the line flux is contained in one (CO $J = 4–3$ up to $J = 7–6$), two (CO $J = 8–7$ up to $J = 10–9$) and three resolution elements (CO $J = 11–10$). It is clear that CO lines above $J = 6–5$, 7–6 can be faint and appear as sub-thermally excited, while very high-$J$ transitions such as $J = 10–9, 11–10$ will be undetectable.

Figure 5. CO (6–5)/(3–2) ratio vs. $L_{IR}(40–400\ \mu m)$ for quiescent systems (diamonds), nearby starburst galaxies or starburst nuclei (triangles), and SMGs (stars). The ULIRGs Arp 220, Mrk 231, the star-forming region in Orion A, and the SF-quiescent Galactic Center are also shown. The shaded areas mark the $R_{65/32}$ range for typical star-forming gas in LIRGs (hatched), and the extreme star-forming environments of ULIRGs (cross-hatched). The first was estimated from LVG models for $T_{kin} = (30–100)\ K$, $\langle n(H_2) \rangle = (10^5–10^6)\ cm^{-3}$ and $K_{uv} = 1$ (fully encompassing the typical conditions of star-forming gas), while the second narrower range is obtained from LVG solutions constrained by the HCN(3–2)/(1–0) average brightness temperature ratio of $(R_{32/10}(HCN)) = 0.55$ of nearby ULIRGs (from Krips et al. 2008; Gracía-Carpio et al. 2008). The dotted line marks the lowest possible $R_{65/32}$ for dense and cold GMC cores ($\langle n(H_2) \rangle > 10^5\ cm^{-3}$, $T_{kin} = 10\ K$) where both transitions would be fully thermalized and optically thick, and which is also the limit below which only gas with $n(H_2) < 10^3\ cm^{-3}$ can be found. CO data: Galactic Center: Fixsen et al. 1996; Orion A: Marrone et al. 2004; Mrk 231: Papadopoulos et al. 2007; Arp 220: this work; SMGs: Tacconi et al. 2006; Papadopoulos & Ivison 2002; nearby starbursts: Wild et al. 1992, Mao et al. 2000, Bradford et al. 2003, Bayet et al. 2006.

---
Tacconi et al. (2006). For \( R_{65/32} \lesssim 0.3 \) and \( R_{76/32} \lesssim 0.15 \) we find no solutions within \( T_{\text{kin}} \sim (40–90) \text{K}, n(H_2) \gtrsim 10^4 \text{cm}^{-3} \), and \( K_{\text{vir}} \sim 1 \) (self-gravitating gas phase), the parameter space typical for star-forming gas. The \( K_{\text{vir}} \) parameter is

\[
K_{\text{vir}} = \left( \frac{dV}{d\nu} \right)_{\text{LVG}} \sim 1.54 \frac{\text{[CO}/H_2]}{\sqrt{\alpha A_{\text{co}}} \left( \frac{n(H_2)}{10^3 \text{cm}^{-3}} \right)^{-1/2}}
\]  

(\( \alpha \sim 1–2.5 \), depending on the cloud density profile) and quantifies the kinematics of the gas responsible for the CO emission, with \( K_{\text{vir}} \sim 1 \) (within factors of \( \sim 2–3 \) indicating a virialized gas phase and \( K_{\text{vir}} \gg 1 \) an unbound one (e.g., Greve et al. 2009). Only for \( R_{65/32} \sim 0.3 \) are there solutions \( T_{\text{kin}} = [40 \text{K}, (65–80) \text{K}], n(H_2) = 10^4 \text{cm}^{-3} \), i.e., typical for star-forming gas, except that \( K_{\text{vir}} = [4, 11] \) indicates unbound gas motions. The low CO (high-\( J \))/(low-\( J \)) line ratios found in some distant starbursts are thus not compatible with the typical conditions of warm and dense star-forming gas. Hence, unless one is willing to postulate dominant amounts of cold and/or diffuse gas in some of the most spectacular starbursts in the universe, high dust optical depths at rest-frame submillimeter wavelengths are the only other way of suppressing such (high-J)/(low-J) line ratios. Finally, it is unlikely that Arp 220 will be the only ULIRG, near or far, where this happens making its CO SLED appear “cool” and atypical of its vigorously star-forming dense gas.

In summary, high dust optical depths at short submillimeter wavelengths in extreme starbursts could then seriously impact

1. the detectability of CO \( J + 1 \rightarrow J, J + 1 > 6 \) lines of starbursts in the local or distant universe with Herschel and ALMA, respectively;
2. the diagnostic power of high-frequency molecular and atomic line ratios (e.g., deduced densities and temperatures, AGN-induced X-ray dominated regions versus starburst-related PDRs); and
3. the thermal balance in the molecular ISM of ULIRGs (with \( C^+ \) and high-J CO line cooling diminished, dust continuum maybe the dominant cooling “channel”).

We will further explore these issues in a future paper that will include the entire suite of CO lines observed for the LIRGs in our sample and their corresponding molecular SLEDs for heavily dust obscured environments.

5. CONCLUSIONS

We report measurements of the high-excitation CO \( J = 6–5 \) line and its adjacent dust continuum at 442 \( \mu \text{m} \) of the prototypical ULIRG Arp 220 with the JCMT in Hawaii. Our findings can be summarized as follows.

1. The CO \( J = 6–5 \) line is very faint, with CO \((6–5)/(1–0), (6–5)/(3–2) \) brightness temperature ratios of \( R_{65/10} \sim R_{65/32} \sim 0.08 \), much lower than those expected from the warm and dense star-forming gas that is present in this extreme starburst.
2. High dust optical depths with \( \tau(v \gtrsim 350 \text{GHz}) \gtrsim 1 \) are responsible for the faint CO \( J = 6–5 \) line in Arp 220 and will strongly modify its emergent CO SLED. We anticipate that for this ULIRG the now spaceborne Herschel Space Observatory will observe faint and apparently subthermally excited CO lines beyond \( \sim 690 \text{GHz} \).
3. The \( C^+ \) and the CO \( J = 6–5 \) line luminosity “deficits” in this system have the same cause: high far-IR/submillimeter dust optical depths.

4. The low CO (high-J)/(low-J) line ratios found also in several starbursts at high redshifts could also be due to high dust optical depths at short submillimeter wavelengths, though in individual objects this can be hard to distinguish from large reservoirs of genuinely low-excitation molecular gas.

5. High dust optical depths at far-IR/submillimeter wavelengths can affect the diagnostic power of molecular and atomic lines in the spectral regime where it is expected to be the greatest, making their intensity ratios depend on differential absorption and viewing angle rather than underlying gas excitation conditions.

Note added in proof. Recent results from Herschel Space Observatory suggest a CO \( J = 6–5 \) line-integrated flux 2–2.5 times higher than that measured by the JCMT and the SMA. Pending solution of various calibration issues with the Herschel FTS instrument, we note that such values still leave our main conclusions intact (Section 3.1).

We thank Telescope System Specialist Jim Hoge as well as the entire supporting team of the James Clerk Maxwell Telescope for conducting a superb set of measurements on 2009 March 15 that made this work possible. Moreover, we thank Dr Satoki Matsushita for informing us about some issues with the SMA data, and Dr Loretta Dunne for discussions regarding SCUBA calibration issues. P.P.P. thanks Dr Xilouris of the National Observatory of Athens for helpful discussions, and assistance with gathering/plotting literature data. Finally, we thank the anonymous referee for his/hers pointed and clear suggestions that led to critical improvements of the original manuscript.
