ABSTRACT
Inclusion of the inductive electric field, \( \mathbf{E}_{\text{ind}} \), due to the temporally changing \( \mathbf{B} \), in magnetic explosions is discussed, with emphasis on solar flares. Several roles played by \( \mathbf{E}_{\text{ind}} \) are identified: on a global scale, \( \mathbf{E}_{\text{ind}} \) produces the electromotive force that drives the explosion; the associated \( \mathbf{E}_{\text{ind}} \times \mathbf{B} \) drift is identified with the inflow of magnetic field lines into a reconnection region; the polarization current, associated with \( \partial \mathbf{E}_{\text{ind}}/\partial t \), implies a \( \mathbf{J} \times \mathbf{B} \) force that accelerates this inflow; and the component of \( \mathbf{E}_{\text{ind}} \) parallel to \( \mathbf{B} \) accelerates the energetic electrons that cause hard X-ray emission and type III radio bursts. Some simple models that describe these effects are presented. A resolution of the long-standing “number problem” in solar flares is suggested.

Key words: acceleration of particles – magnetic fields – magnetic reconnection – Sun: flares

1. INTRODUCTION

As discussed in an accompanying paper (Melrose 2012), referred to as Paper I, magnetic explosions are intrinsically time-dependent phenomena, and must involve an inductive electric field, \( \mathbf{E}_{\text{ind}} \), and a displacement current \( \mathbf{J}_{\text{disp}} = \varepsilon_0 \partial \mathbf{E}_{\text{ind}}/\partial t \). These fields are not taken into account explicitly in conventional models for solar flares and other magnetic explosions; the physics associated with them is either treated in terms of quasi-electrostatic proxies or ignored. The following six roles for \( \mathbf{E}_{\text{ind}} \) and \( \mathbf{J}_{\text{disp}} \) need to be taken into account in models for magnetic explosions.

1. The electromotive force (EMF), \( \Phi = -\varepsilon_0 \partial \Psi_B/\partial t \), that drives the explosion-related current is determined by the rate of change of the magnetic flux, \( \Psi_B \), enclosed by the circuit around which this current flows.
2. The electric drift, \( \mathbf{u}_{\text{ind}} = \mathbf{E}_{\text{ind}} \times \mathbf{B}/|\mathbf{B}|^2 \), associated with the inductive field transports magnetic energy into the energy-release region: no mechanical driver is required.
3. The collective response of the plasma particles to the displacement current resultants in the polarization current, \( \mathbf{J}_{\text{pol}} = (e^2/\mu_0) \mathbf{J}_{\text{disp} \perp} \), where \( u_A \) is the Alfvén speed.
4. The \( \mathbf{J} \times \mathbf{B} \) force due to the polarization current accelerates \( \mathbf{u}_{\text{ind}} \), providing the link that allows the changing magnetic field to drive the magnetic energy release.
5. The Alfvénic energy flux that transports energy from the energy-release region to the acceleration region is set up by \( \mathbf{J}_{\text{pol}} \), transferring current across field lines and driving a vortex motion within the flux tube.
6. Acceleration by \( \mathbf{E}_I \) relies on \( \mathbf{E}_{\text{ind}} \) and \( \mathbf{J}_{\text{disp}} \) (Song & Lysak 2006).

The first of these roles is discussed in Paper I, and the other five are discussed in this paper.

A long-standing “number problem” concerns the acceleration of the electrons that produce hard X-rays (MacKinnon & Brown 1989): the number of accelerated electrons inferred from X-ray data exceeds the number available by a large factor, \( M = 10^6 \), assumed here. A way of resolving the number problem, by including a return current in the model for Alfvénic energy transport, is suggested in Section 5.

The argument for the inductive field being the flare driver is presented in Section 2. The role of the polarization current in driving this inflow is discussed in Section 3. The role of time-dependent fields in Alfvénic energy transport to the acceleration region is discussed in Section 4. Acceleration of electrons by \( \mathbf{E}_I \), including the number problem, is discussed in Section 5. The results are discussed and summarized in Section 6.

2. INDUCTIVE FIELD AS A FLARE DRIVER

In this section, it is assumed that the parallel component of the inductive field is screened by charges. The perpendicular component is interpreted in terms of the \( \mathbf{E} \times \mathbf{B} \) drift velocity, \( \mathbf{u}_{\text{ind}} \).

2.1. Inductive Drift

The assumption that the parallel component of the inductive electric field is screened implies the presence of a charge density, \( \rho \). This charge density is such that it produces a parallel electric field that is equal and opposite to the parallel component, \( \mathbf{E}_{\text{ind} \parallel} \), of the unscreened \( \mathbf{E}_{\text{ind}} \). The remaining (perpendicular) component of the inductively induced electric field has a nonzero divergence,

\[
\text{curl} \mathbf{E}_{\text{ind} \perp} = -\frac{\partial \mathbf{B}}{\partial t}, \quad \text{div} \mathbf{E}_{\text{ind} \perp} = \frac{\rho}{\varepsilon_0}.
\]

(1)

The inductive drift is the electric drift due to \( \mathbf{E}_{\text{ind} \perp} \):

\[
\mathbf{E}_{\text{ind} \perp} = -\mathbf{u}_{\text{ind}} \times \mathbf{B}, \quad \mathbf{u}_{\text{ind}} = \frac{\mathbf{E}_{\text{ind} \perp} \times \mathbf{B}}{|\mathbf{B}|^2}.
\]

(2)

Combining Equations (1) and (2) gives

\[
\frac{\partial \mathbf{B}}{\partial t} = \text{curl} (\mathbf{u}_{\text{ind}} \times \mathbf{B}),
\]

(3)

which is the equation for magnetic field lines moving with the velocity \( \mathbf{u}_{\text{ind}} \). The screening charge density is

\[
\rho = \varepsilon_0 |\mathbf{u}_{\text{ind}} \cdot \text{curl} \mathbf{B} - \mathbf{B} \cdot \text{curl} \mathbf{u}_{\text{ind}}|.
\]

(4)

2.2. Sweet–Parker-type Model

Consider any steady-state reconnection model, such as the Sweet–Parker-type model illustrated in Figure 1. Such a model involves an inflow of plasma and magnetic field into a current sheet, with this inflow being specified as a boundary condition. Physically, the inflow must be driven in order for fast reconnection to proceed, and in a steady-state model this requires a
mechanical driver acting across field lines, usually assumed to be a pressure gradient (Sato 1978; Haerendel 1994). However, the pressure gradient is much smaller that the available Maxwell stress, due to the \( \mathbf{J} \times \mathbf{B} \) force, and the latter is a more plausible driver, as proposed in Uchida’s quadrupolar model (Uchida 1996; Hirose et al. 2001) for an erupting filament. Here, it is suggested that the \( \mathbf{J} \times \mathbf{B} \) force acts as a driver under more general conditions, provided that the (artificial) steady-state assumption is abandoned.

A simple model that illustrates the role \( \mathbf{u}_{\text{ind}} \) plays in reconnection involves a magnetic field that varies globally as a function of time, \( f(t) \). The function \( g(t) = \frac{df(t)}{dt} \) can be regarded as simulating the rate of reduction in stored magnetic energy beyond the boundary of the steady-state region. In the simplest example of a planar geometry, let the magnetic field be along the \( z \)-axis, oppositely directed above and below the current sheet at \( x = 0 \). Assuming that the \( x \) - and \( t \)-dependencies are independent, one may write \( B_z(x, t) = f(t) b(x) \), with \( b(-x) = -b(x) \). One has

\[
E_{\text{ind}}(x, t) = -g(t) \int_0^x dx' b(x'), \quad g(t) = \frac{df(t)}{dt}. \tag{5}
\]

The inductive drift,

\[
\mathbf{u}_{\text{ind}}(x, t) = \frac{g(t)}{f(t) b(x)} \int_0^x dx' b(x'), \tag{6}
\]

is along the \( x \)-axis, with \( \mathbf{u}_{\text{ind}}(-x, t) = -\mathbf{u}_{\text{ind}}(x, t) \). For a decreasing field, \( g(t) < 0 \), the flow is directed toward the current sheet at \( x = 0 \). A generalization to allow the magnetic field lines to be curved in the \( x-z \) plane is \( B_z(x, z, t) = f(t) b_z(x, z) \). The inductive electric field is again along the \( y \)-axis,

\[
E_{\text{ind}}(x, z, t) = -g(t) \left[ \int_0^x dx' b_z(x', z) - \int_0^z dx' b_z(x, z') \right], \tag{7}
\]

and \( \mathbf{u}_{\text{ind}} \) has a component along the \( z \)-axis, such that \( \mathbf{u}_{\text{ind}} \cdot \mathbf{B} = 0 \). In both these simple models there is no parallel component of the inductive electric field, so that screening of the parallel component of the inductive field is not relevant, and one has \( \rho = 0 \).

### 2.3. Self-similar Model

A generalization is possible for the special case where the change in the magnetic field is self-similar. Specifically, a self-similar model corresponds to \( \mathbf{B}(x, t) = f(t) \mathbf{b}(x) \). The inductive electric field can then be written as \( \mathbf{E}_{\text{ind}}(x, t) = g(t) \mathbf{e}(x) \). The inductive drift is

\[
\mathbf{u}_{\text{ind}}(x, t) = \frac{g(t) \mathbf{e}(x) \times \mathbf{b}(x)}{f(t) |\mathbf{b}(x)|^2}. \tag{8}
\]

The assumed screening of the parallel component of \( \mathbf{E}_{\text{ind}} \) implies \( \mathbf{e} \cdot \mathbf{b} = 0 \) and requires \( \rho = 0 \). Introduction of the vector potential, \( \mathbf{a}(x, t) = g(t) \mathbf{a}(x) \), and the scalar potential, \( \phi(x, t) = g(t) \rho(x) \) in the Coulomb gauge, \( \nabla \mathbf{a}(x) = 0 \), one requires that \( \rho(x) \) depend on the distance, \( s \), along field lines, with \( \frac{d^2 \rho(x)}{ds^2} = r(x)/\epsilon_0 \). One has

\[
\mathbf{e}(x) = -\mathbf{a}(x), \quad \mathbf{b}(x) = \nabla \mathbf{a}(x). \tag{9}
\]

The parallel-screening condition becomes

\[
\mathbf{a}(x) \cdot \nabla \mathbf{a}(x) = 0. \tag{10}
\]

The flow (8) is along the direction of

\[
\mathbf{a}(x) \times \nabla \mathbf{a}(x) = \nabla \left[ \frac{1}{2} |\mathbf{a}(x)|^2 - [\mathbf{a}(x) \cdot \nabla] \mathbf{a}(x) \right]. \tag{11}
\]

The condition (10) restricts the form of a magnetic field that can evolve in a self-similar manner. Seeking a solution that is separable in Cartesian coordinates, one finds that Equation (10) is satisfied by

\[
\mathbf{a}(x) = (YZ, XZ, XY), \quad \mathbf{b}(x) = (X[Y' - Z'], Y[Z' - X'], Z[X' - Y']), \tag{12}
\]

where \( X = X(x), Y = Y(y), Z = Z(z) \) are arbitrary functions, and \( X', Y', Z' \) are their derivatives. The model corresponding to Equation (7) is reproduced by \( Y = 0 \), and the model corresponding to Equation (5) is reproduced by \( Y = 0, Z = 1 \).

These models all have a common feature: the inductively induced drift, \( \mathbf{u}_{\text{ind}} \), transports magnetic field lines toward the current sheet. This inflow is analogous to that in a steady-state model, but is explicitly dependent on the time derivative of \( \mathbf{B} \), and involves no mechanical driver.

### 3. ROLE OF THE POLARIZATION CURRENT

In this section, the role of the polarization current associated with a changing inductive electric field is discussed.

#### 3.1. Polarization Current

The presence of a time-dependent electric field in a plasma causes a charged particle, with charge \( q \) and mass \( m \), to drift across the magnetic field. This polarization drift is (Northrop 1963)

\[
\mathbf{v}_{\text{pol}} = \frac{m}{q} \frac{d\mathbf{E}_\perp}{dt}. \tag{13}
\]

In the following, \( d\mathbf{E}_\perp/dt \) is identified as \( \partial \mathbf{E}_{\text{ind},\perp}/\partial t \), whose curl is determined by \( \partial^2 \mathbf{B}/\partial t^2 \). The drift (13) depends on the sign of the charge, and summing over all charges it implies a current that is proportional to the displacement current. This current is referred to as the polarization current:

\[
\mathbf{J}_{\text{pol}} = \frac{\epsilon^2}{2 \mu_0} \epsilon_0 \frac{\partial \mathbf{E}_\perp}{\partial t}. \tag{14}
\]

The polarization current may be interpreted as the response of the plasma to the displacement current. An alternative derivation
of Equation (14) that shows this follows by considering the low-frequency response of a plasma. The susceptibility tensor for a magnetized plasma at very low frequency is approximately diagonal, with components \( \chi_{11} = \chi_{22} = c^2/v_A^2, \chi_{33} = -\omega_p^2/\omega^2 \), where \( \omega_p \) is the plasma frequency and the magnetic field is along the 3-axis. This tensor relates the polarization, \( \mathbf{P}/\varepsilon_0 \), to the electric field, with the current density related to the polarization by \( \mathbf{J} = \partial \mathbf{P}/\partial t \). Differentiating the perpendicular components with respect to time, assuming for simplicity that \( v_A^2 \) is a constant, and integrating the parallel component (with \(-\omega^2 \rightarrow \partial^2/\partial t^2\)) implies that the response can be rewritten in the form

\[
\mathbf{J}_\perp = \frac{c^2}{v_A^2} \varepsilon_0 \partial \mathbf{E}_\perp/\partial t, \quad \mathbf{J}_\parallel = \varepsilon_0 \omega_p^2 \mathbf{E}_\parallel.
\]  

(15)

This provides an alternative derivation of \( \mathbf{J}_{\text{pol}} = \mathbf{J}_\perp \). This alternative formalism allows one to include dissipation, through the conductivity tensor, with perpendicular component \( \sigma_\parallel \) and parallel component \( \sigma_\perp \), leading to additional terms, \( \sigma_\perp \partial \mathbf{E}_\perp/\partial t \), on the right-hand sides of the two equations (15), respectively.

On differentiating expression (2) for \( \mathbf{u}_{\text{ind}} \) with respect to time, neglecting the time dependence of \( \mathbf{B} \), the result becomes

\[
\eta \frac{d \mathbf{u}_{\text{ind}}}{dt} = \mathbf{J}_{\text{pol}} \times \mathbf{B},
\]

(16)

where \( \eta \) is the mass density. It follows that the polarization current provides the force that accelerates \( \mathbf{u}_{\text{ind}} \).

These results lead to the following interpretation of the energy inflow into the energy-release region. Magnetic energy is stored in a global current system, and some trigger causes \( \mathbf{B} \) to start decreasing in time. Once the energy release begins, \( \mathbf{J}_{\text{pol}} \) becomes nonzero, and the inflow is driven by the \( \mathbf{J}_{\text{pol}} \times \mathbf{B} \) force. The inflow transports energy over large distances to the (ill-defined) boundary of the energy-release region. Within the energy-release region the energy flow may be described by a steady-state model, with further acceleration by \( \mathbf{J}_{\text{pol}} \) being unimportant.

### 3.2. Energy-release Region

The conversion of magnetic energy into the energy in nonthermal particles is assumed to occur in two stages: conversion of magnetic energy into an Alfvénic flux in an energy-release region, and conversion of the Alfvénic flux into energetic particles in a remotely located acceleration region. The energy conversion in the first of these regions is discussed here.

Conversion of magnetic energy into another form requires some dissipation, but the dissipation need not be energetically significant. Reconnection is effective only around a magnetic null (Priest & Forbes 2000), and the Sweet–Parker model illustrated in Figure 1 shows the inflow and outflow in such a region. To be effective in a solar flare, reconnection must be fast (compared with the Sweet–Parker rate), and the geometry is similar for fast reconnection models. Numerical simulations show that fast (Petschek) reconnection can occur only if the resistivity is localized (Biskamp & Schwarz 2001; Udensky 2003) and anomalous (Kulsrud 2001, 2005), in which case the reconnection region is on a micro scale (Paper I). A statistically large number of such reconnection sites is needed, and this requires multiple local magnetic nulls (Lazarian & Vishniac 1999). Although dissipation is an essential ingredient in reconnection, the energy dissipated in converting the magnetic energy into kinetic energy or an Alfvénic flux is arbitrarily small for arbitrarily small regions of anomalous resistivity. It is assumed here that magnetic energy conversion occurs without significant dissipation in the energy-release region.

The energy flow into the energy-release region is inductively driven, as discussed above. Within the energy-release region, a steady-state model relates the energy outflow to the inflow. The outflow can be in three forms: kinetic energy, magnetic energy transported due to field lines frozen into the flow, and an Alfvénic flux. In conventional flare models, such as the CSHKP model, the downward moving newly closed field lines ultimately join the underlying closed magnetic structure. This requires that they slow down, reducing the kinetic energy in the flow. The length of the reconnected flux tubes decreases, and the magnetic energy associated with the current flowing along these field lines reduces as they are dragged into their final location. This implies that both the kinetic energy initially in the outflow and the magnetic energy transported by the outflow decrease. It is assumed here that the definition of the energy-release region is extended to include this further energy conversion. It follows that the relevant energy emerges as an Alfvénic flux, propagating along the newly closed field lines. These remarks support earlier suggestions that the outflowing energy is Alfvénic (Emslie & Sturrock 1982; Haerendel 1994; Fletcher & Hudson 2008; Kontar et al. 2011); however, there is no detailed model that includes all these effects. A specific model for the Alfvénic energy transport away from the energy-release region is presented in the next section.

### 4. ALFVÉN ENERGY TRANSPORT

In this section, a specific (coaxial) model is developed for the Alfvénic transport of energy from the energy-release region to the acceleration region. Although highly idealized, this model shows how the large power released can be transported over large distances.

#### 4.1. Setting Up the Alfvénic Flux

The magnetic energy inflow into the energy-release region is balanced by an Alfvénic outflow. A complication in developing simple models for the inflow and outflow is geometric: the inflow is plausibly modeled using Cartesian coordinates, and far from the energy-release region the Alfvénic flow is more appropriately modeled using cylindrical coordinates. Rather than attempt to formulate a more general geometry that covers both regions, Cartesian and cylindrical geometries are simply assumed for the inflow and outflow, respectively.

Consider a cylindrical model for a flux tube of radius \( R \) with radial coordinate \( r < R \), azimuthal angle \( \phi \), and axial distance \( z \) (Melrose 1992). The magnetic field is twisted due to the current, and it has components \( B_\phi, B_z \). For simplicity the twist is assumed to be small, \( |B_\phi| \ll |B_z| \). The pre-flare current is assumed to be force-free, implying \( J_\phi/J_z = B_\phi/B_z \), and the assumption that the twist is small allows one to calculate \( B_\phi \) in terms of \( J_z \) and ignore \( J_\phi \). It is convenient to write the radial dependence of the current density in the form \( J_z(r) = J_0 j_1(\xi) \), with \( \xi = r/R \) a dimensionless radial distance. The function \( j_1(\xi) \) describes the current profile in the flux tube prior to the flare. Prior to the flare, there is no electric field, no plasma motion, and no energy flux. At the onset of the flare, the inductive electric field is set up, and this is identified as a radial field, \( E_r \propto g(t) \). The displacement current, \( \varepsilon_0 \partial E_z/\partial t \propto dg(t)/dt \), drives a radial polarization current, \( J_r \propto dg(t)/dt \). This radial
current transfers current across magnetic field lines, changing the radial current profile as a function of time, concentrating the current density at smaller radial distances, thereby increasing $B_\phi$ at $r < R$.

The radial electric field implies a vortex motion, $u_\phi \approx -E_r/B_z \propto g(t)$, where $B_\phi$ is assumed to be independent of time within the cylinder. During the onset of the energy release, $u_\phi$ increases in magnitude, driven by the force $-J_B \propto d g(t)/dt$. The vortex motion increases the twist, $B_\phi/B_z$. Thus, the onset of the energy release launches a propagating twist, which may be interpreted as an Alfvénic front that sets up the Alfvénic flux. The front and the subsequent energy flux propagate at the Alfvénic speed $v_A$.

4.2. Change in Axial Current Profile

Let the current profile when the Alfvénic flux is established ($g(t) \to 1$) be described by $j_2(\xi)$. As the current profile changes at $z = 0$, it may be described by $j_1(\xi)[1 - g(t)] + j_2(\xi)g(t)$, with $g(t) = 0$ prior to the onset of the energy release, and with $g(t) \to 1$ after the initial transient phase. At points $z > 0$ the changing current profile is described by

$$J_z = J_0 \left[ j_1(\xi)[1 - g(t - z/v_0)] + j_2(\xi)g(t - z/v_0) \right].$$

The axial component of the Poynting vector, which describes the energy flux, is $S_z = E_z B_\phi/\mu_0$. The azimuthal component of the magnetic field, before and after the Alfvénic flux is set up, is

$$[B_\phi(r)]_{1,2} = \frac{\mu_0 I_0}{\pi R} b_{1,2}(\xi),$$

$$b_{1,2}(\xi) = \frac{1}{\xi} \int_0^\xi d\xi' \xi' j_{1,2}(\xi'),$$

with $I_0 = \pi R^2 J_0$. The radial electric field is related to $B_\phi$ through $\partial E_r/\partial z = \partial B_\phi/\partial t$, and assuming $E_r \propto g(t - z/v_0)$, this gives

$$E_r = v_0 (B_{\phi 2} - B_{\phi 1})g,$$

with $g = g(t - z/v_0)$ and $B_{\phi 1,2} = [B_\phi(r)]_{1,2}$. The Poynting flux is then

$$S_z = \frac{v_0}{\mu_0} [B_{\phi 2} - B_{\phi 1}] [g B_{\phi 2} + (1 - g) B_{\phi 1}] g.$$

After an initial transient phase, the Alfvénic flux approaches a constant value $v_0 [B_{\phi 2} - B_{\phi 1}] B_{\phi 2}/\mu_0$.

4.3. Coaxial Model

A simple model for the current profile has $j_1(\xi)$ independent of $\xi$, and $j_2(\xi)$ equal to one constant for $\xi < \xi_1$ and another constant for $\xi_1 < \xi < 1$, as illustrated in Figure 2. (An arbitrary force-free cylindrical current profile can be approximated by a set of concentric rings with the current density a constant within each ring, with a solution for $B_\phi$ involving Bessel functions of the first and second kind; Melrose et al. 1994.) It is convenient to introduce the current, $I_{\text{in}}$ in the inner region, $r < R_1$, and the current, $I_{\text{out}}$ in the outer region, $R_1 < r < R$, with $I_{\text{in}} + I_{\text{out}} = I_0$, where $I_0$ is the current in the flux tube prior to the onset of the flare.

After the onset phase, as $g(t)$ approaches unity, the current density is assumed to approach the constant values $a J_0$ for $\xi < \xi_1$ and $b J_0$ for $\xi_1 < \xi < 1$. This model involves three parameters, $a, b, \xi_1$, only two of which are independent, with $(a - b)\xi_1^3 = 1 - b$. For $g(t) \to 1$, this model gives, in terms of Equation (18),

$$b_2(\xi) = \begin{cases} a\xi^2/(2, & \xi < \xi_1, \\ b\xi^2/(2, & \xi_1 < \xi < 1. \end{cases}$$

With $b_1(\xi) = \xi/2$, Equation (19) with Equation (18) gives

$$E_r = -\frac{\mu_0 v_0 I_0}{\pi R} \left\{ \frac{(a - 1)\xi^2}{(1 - b)(1 - \xi^2)/2}, \quad \xi < \xi_1, \right. $$

Introducing the potential $\Phi(r)$, such that $E_r = -d\Phi(r)/dr$, Equation (22) with $\Phi(0) = 0$ implies

$$\Phi(r) = -\frac{\mu_0 v_0 I_0}{4\pi R} \left\{ \frac{(a - 1)\xi^2}{(1 - b)[\ln(\xi^2/\xi_1^2) + 1 - \xi^2]}, \quad \xi < \xi_1, \right. $$

The power at $r < \xi R$ in the Alfvénic flux is

$$2\pi R^2 \int_0^R d\xi' \xi' S_\phi(\xi') = \frac{\mu_0 v_0 I_0^2}{4\pi} (1 - b)^2 s(\xi),$$

$$s(\xi) = \begin{cases} (a - 1)\xi^4/(2 - b^2), & \xi < \xi_1, \\ \ln \frac{\xi^2}{\xi_1^2} - \frac{\xi^2}{1 - b} - b \frac{\xi^4 - \xi_1^4}{2(1 - b)}, & \xi_1 < \xi < 1. \end{cases}$$

The model involves two independent parameters, $b$ and $\xi_1$, with $a$ related to them by $(a - b)\xi_1^3 = 1 - b$. There is zero Alfvénic flux for $b = 1$, corresponding to the initial
current profile; the power increases with decreasing $b$, as the current becomes more concentrated near the axis. For $b = 0$, corresponding to all the current in the inner region $r < \xi_1 R$, the power in the Alfvénic flux is of the order of $I_0 \Phi_0$ with $\Phi_0 = \Sigma_A l_0$, which is consistent with the total power released in a flare. In this way, the model shows how the released magnetic energy can be transported along field lines in a quasi-stationary manner. The parameter $b$ can be negative, as discussed in the next section in connection with a return current and the number problem.

The parameter $\xi_1$ determines the inner radius, $\xi_1 R$, and is limited by two requirements. First, the drift speed of the electrons, $a_{\|} / \xi_1 c$, relative to the ions must not exceed the threshold for the development of an instability that leads to the onset of anomalous resistivity. Second, the twist $B_\theta / B_z$ must not exceed the threshold (of order unity) for the current-carrying region to become kink unstable.

4.4. Inclusion of the Displacement Current

The displacement current is usually ignored in MHD, and it is important to include it in discussing acceleration by $E_\parallel$. This was emphasized by Song & Lysak (2006), who derived two coupled equations for the $t$ and $z$ derivatives of the parallel components of the net current density and the vorticity, $\Omega = \text{curl} u$. In the cylindrical model assumed above, the parallel vorticity is $\Omega_\parallel = r^{-1} \partial [ru_\phi(r)] / \partial r$.

Neglecting terms that are not important in the present discussion, the equations derived by Song & Lysak (2006) are

$$\frac{\partial J'_\parallel}{\partial t} \approx \frac{B_r}{\mu_0} \frac{\partial \Omega_\parallel}{\partial z}, \quad \mathbf{J'} = \mathbf{J} + \varepsilon_0 \frac{\partial \mathbf{E}}{\partial t}, \quad (25)$$

where the net current $\mathbf{J'}$ includes the displacement current, and with

$$\left(1 + \frac{c^2}{v_A^2}\right) \frac{\partial \Omega_\parallel}{\partial t} \approx \frac{\mu_0 e^2}{B_z} \frac{\partial J'_\|}{\partial z}. \quad (26)$$

On differentiating either Equation (25) or Equation (26) with respect to $t$ and using the other, one finds that $J'_\parallel$ and $\Omega_\parallel$ satisfy the equation for an Alfvén wave propagating at $v_0 = v_A/(1 + v_A^2 / c^2)^{1/2}$. This justifies the assumption made above that the temporal variation $g(t)$ at $z = 0$ propagates away as $g(t - z/v_0)$ at $z > 0$.

5. ACCELERATION/DISSIPATION REGION

The acceleration of electrons in a solar flare is an outstanding unsolved problem. In this section, the ingredients needed to solve this problem within the framework of the generic model are discussed. The acceleration mechanism is assumed to be analogous to the mechanism for auroral electrons, due to $E_\parallel$, in a region remote from the energy-release region.

5.1. Requirements on the Acceleration Region

The following macroscopic requirements are plausible for the acceleration region.

1. The Alfvénic flux, incident on top of the region, decreases to zero at the bottom of the region.
2. The potential is across field lines at the top of the region, is zero at the bottom of the region, and is partially along field lines within the region, producing $E_\parallel$.
3. Electrons are accelerated by $E_\parallel$ to $\varepsilon = e\Delta \Phi$, $\Delta \Phi = \Phi / M$, with $M \gg 1$.
4. The available power, $I_0 \Phi_0$, is transferred to electrons, accelerated at the rate $\dot{N} = M I_0 / e$.

The most challenging of these constraints is the large value of $M$, which may be interpreted in terms of the “number problem” as the number of times an individual electron would need to be re-accelerated.

These requirements apply specifically to the upward current regions above each footprint, such that the energetic electrons propagate downward. As in a substorm, acceleration also occurs in the nearby downward current regions where electrons are accelerated upward (Ergun et al. 2003).

5.2. Dissipation of the Alfvénic Flux

As the Alfvénic flux enters the acceleration region, the energy begins to be dissipated by accelerating electrons. The associated reduction in the Alfvénic flux requires some mechanism that allows the current profile to revert to its initial form ($j_2(\xi)$ must revert to $j_1(\xi)$). The decrease in $E_r \propto g(t - z/v_0)$ across the acceleration region requires that $g(t - z/v_0)$ decrease as a function of $\xi$, and this implies that it is changing as a function of $t$. The resulting displacement current causes a (radial) polarization current, and this redistributes the current to larger radii (allowing $j_2(\xi)$ to revert to $j_1(\xi)$). The mechanism that causes $E_r$ to change is identified as the dissipation process that results in the acceleration of electrons, with the specific mechanism dependent on the details of the microphysics.

To be specific, suppose the dissipation is attributed to localized anomalously resistive regions developing along the current path. The enhanced resistivity causes the current to be partly deflected around the region (Melrose 1992; Parker 1993). There is a maximum dissipation rate that occurs for $R_\text{eff} \approx R_A$ (Melrose 1992). For $R_\text{eff} \ll R_A$ most of the current passes through the resistive region with little dissipation, and for $R_\text{eff} \gg R_A$ most of the current is deflected around the resistive region, again with little dissipation. The deflection of current around the anomalously resistive region changes the current profile. A region of anomalous resistivity also introduces $E_\perp = J_2 / \sigma_\perp$, where $\sigma_\perp$ is the anomalous conductivity. Thus, turning on a region of anomalous resistivity has both the required qualitative effects: redistributing the current to larger radii, and setting up $E_\perp$.

5.3. Return Current and the Number Problem

The number problem (MacKinnon & Brown 1989) presents an important difference between flares and substorms. In both cases, the power is $I \Phi$ with $N = M / e$ and $\varepsilon = e\Phi / M$, but with a large multiplicity ($M = 10^6$ with the fiducial numbers assumed here) in flares and $M$ of order unity in substorms. In substorms, inverted-V electrons are accelerated in an auroral cavity (Benson & Calvert 1979), and as a result of “charge starvation” the flux tube contains essentially only the energetic electrons (Ergun et al. 2000). In flares, the multiplicity is conventionally interpreted in terms of a return current replacing the electrons in the acceleration region $M$ times. An alternative interpretation is that the acceleration region and the hard X-ray source are co-located, and the same electrons are accelerated (and lose their energy emitting X-rays) a total of $M$ times (Brown et al. 2009).

If the coaxial model developed above is driven hard enough, it can adjust to maximize the power released. If no return current is allowed, $b \geq 0$, the limiting case is when all the current is confined to the inner region, which becomes as small as possible. This corresponds to $I_\text{in} = I_0$, $I_\text{out} = 0$, $a \xi_1^2 = 1$, and $b = 0$. 
When a return current is allowed, $b < 0$, an even larger power is possible. For $b < 0$, $I_{\text{out}}$ has the opposite sign to $I_{\text{in}}$, and corresponds to a return current for $\xi > \xi_1$, as illustrated in Figure 2. It follows from Equation (24) that the power increases with increasing $|b|$ for $b < 0$. The model becomes untenable for $b$ large and negative. Nevertheless, this case gives an indication of how the number problem can be resolved. To show this, let us assume $b \approx -M$ and explore the implications.

According to Equation (24), the power in the Alfvénic flux increases $\propto (1 - b)^2 \approx M^2$ for $-b = M \gg 1$. This can be attributed to the combination of two effects. First, the total current flowing in the region $r < \xi_1 R$ is much greater than $I_0$, with (all but $I_0$ of) this direct current being provided by recycling the return current, which closes across field lines in the photosphere and in the energy-release region. Second, the large current $I_{\text{in}} \approx M I_0$ implies a correspondingly large cross field $\Phi \approx M \Phi_0$, which is implicit in the assumption of Alfvénic flux. With $M \approx 10^6$, the extremely large values of $I$ and $\Phi$ are not tenable. In the coaxial model the direct current flows in a single current channel, at $r < \xi_1 R$, and relaxing this assumption opens the possibility of formulating a model that can resolve the number problem.

Suppose that the direct current is of the order of $M I_0$ flowing in $M$ parallel channels, each carrying a current $I_0$. The return current flows between these channels, and is of magnitude $(M - 1)I_0$. If the potential associated with each channel is $\Phi_0 / M$, with $\Phi_0 = \Sigma A I_0$, the Alfvénic flux in each channel transports a power $I_0 \Phi_0 / M$, giving the total power $M I_0 \Phi_0$ after summing over the $M$ channels. In the acceleration region, this power is transferred to electrons with energy $\epsilon = e \Phi_0 / M$ at a rate $I_0 / e$ in each channel, resulting in $M I_0 / e$ electrons per second with this energy from the $M$ channels. The implied cross-field potential in any given channel is $\Phi_0 / M \approx 10^4 \text{ V}$, consistent with the observed energy, $\epsilon$, of the order of 10 keV. The total cross-field potential $\Phi_0$ breaks up into potentials $\Phi_0 / M$ across $M$ separate current channels, whose existence is allowed by the large return current.

Although these arguments are heuristic, they give a clear indication of how the number problem can be resolved. A detailed model incorporating these ideas is needed to make further progress.
5.4. Development of $E_{||}$

An understanding of acceleration by $E_{||}$ involves two complementary aspects: the macroscopic electrodynamics associated with the development of $E_{||}$, and the microphysics associated with the specific (local and transient) structures with $E_{\perp} \neq 0$. Acceleration by $E_{||}$ is widely accepted for auroral electrons in a substorm (Block & Falthammar 1990), where $E_{||}$ can be observed in situ (Mozer & Kletzing 1998), and also for Io-related electrons in Jupiter’s magnetosphere (Su et al. 2003). However, the microphysics involved in setting up and maintaining $E_{||}$ is inadequately understood, with none of the many suggested mechanisms being entirely satisfactory (Borovsky 1993). As remarked in Paper I, in auroral acceleration $E_{||}$ is highly structured on the micro scale, with individual structures being modeled as, for example, phase-space holes (Ergun et al. 1998) and kinetic Alfvén waves (Chaston et al. 2003). Discussion of acceleration by $E_{||}$ in the solar corona also emphasizes microphysics (Bian et al. 2010). The viewpoint adopted here is that important aspects of acceleration by $E_{||}$ can be understood in terms of the macroscopic electrodynamics, independent of the microphysics that sustains $E_{||}$. This view was expressed by Haerendel (1994), who argued that the appeal to microphysics (double layers and anomalous resistivity) is required only to support other arguments that require the appearance of $E_{||}$.

One argument that an $E_{||}$ must appear is that the downward Alfvénic flux, transporting the released magnetic energy, has a large $E_{||}$ and associated vortex motion, $u_r$, and these cannot be sustained through the denser chromospheric and photospheric plasma. As illustrated in Figure 3 for the auroral application, the surfaces of constant potential, corresponding to $E_{||}$, must close above the conducting ionosphere or chromosphere, implying that $E_{||}$ must develop. Another argument is that line-tying, associated with the inertia of the denser regions of the ionosphere or chromosphere, precludes the vortex motion driven from above being maintained. The energy in the Alfvénic flux must be reflected, absorbed, or converted into another form somewhere above the boundary where line-tying becomes effective. This implies that along a given field line, $u_r$ must not reduce to zero, and this violates the frozen-in condition. The development of $E_{||}$ is essential to allow a decoupling between two regions in relative motion perpendicular to $B$, called fracturing by Haerendel (1994, 2007). These arguments imply that there must be a region with $E_{\perp} \neq 0$ irrespective of the specific microphysics that sustains $E_{||}$. In the model suggested above in connection with the return current and the number problem, the cross-field potential is $\Phi_0/M$, and the implication is that this leads to a parallel potential $\Phi_0/M$ along field lines in the acceleration region. The microphysics involved in how $E_{||}$ develops is not directly relevant: the system must find some form of microphysics to satisfy the macroscopic requirements.

6. DISCUSSION AND CONCLUSIONS

In this paper and in Paper I, a generic model for magnetic explosions is formulated, based on magnetospheric substorms, and applied to solar flares. Three ideas are central to the generic model: the separation into different scales (global, macro, micro) and into different (energy-release, acceleration, current-closure) regions; the insistence that the intrinsic time dependence be included explicitly (through $\mathbf{E}_{\text{ind}}, \mathbf{u}_{\text{ind}}, \mathbf{J}_{\text{disp}}, J_{\text{pol}}$); and, that the electron acceleration is due to a parallel electric field, $E_{||}$.

What triggers a flare is an unsolved problem. The recognition that the inflow into the energy-release region is driven by the changing magnetic field offers a new way of thinking about the trigger. Prior to a flare the magnetic structure is in a steady state, with any pressure gradients balanced by the $\mathbf{J} \times \mathbf{B}$ force, with a very small angle between $\mathbf{J}$ and $\mathbf{B}$. Once a flare is triggered, the unbalanced Maxwell stress, mediated by $\mathbf{E}_{\text{ind}}$ and $\mathbf{J}_{\text{disp}}$, drives the energy release, without requiring a mechanical force. The trigger can be a perturbing pressure gradient that initiates inflow into the energy-release region, causing $\mathbf{B}$ to start to change with time. The changing $\mathbf{B}$ can then take over, driving the magnetic energy into the energy-release region and powering the explosion.

It is assumed that the energy release occurs in two stages, involving two widely separated regions with an Alfvénic flux transporting the energy between them (Fletcher & Hudson 2008). The energy transport is modeled in terms of an Alfvénic energy flux associated in a current-carrying flux tube. A coaxial model is developed in which the direct current becomes strongly concentrated near the axis of the cylinder. A limiting case of this model is when all the current is confined to narrow channel, and in this limit the total power released can be transported Alfvénically from the energy-release region to the acceleration region.

The “number problem” has presented a formidable challenge to all theories of electron acceleration in flares: the hard X-ray data implies either that the number of electrons accelerated is $M$ times the number available, or that the available electrons are re-accelerated $M$ times, with $M$ of the order of $10^6$. The observations required electrons with an energy $e\Phi_0/M$ accelerated at a rate $N = M I_0/e$, such that the total power, $I_0 \Phi_0$, is that released in the flare. Based on the coaxial model developed here, it is suggested that the number problem may be resolved by incorporating three changes. First, the single direct current channel is replacement by $M$ current channels, each carrying a current $I_0$. Second, there is a return current of magnitude $(M - 1)I_0$ that flows between these channels, with the current lines closing in the photosphere and the energy-release region. Third, the cross-field potential associated with each channel is $\Phi_0/M$, and this potential develops along field lines in the acceleration region.

Another feature of the model is that there are both upward and downward current regions at each footpoint of the flaring flux tubes. The energetic electrons that produce hard X-rays as they precipitate are attributed to acceleration in the upward current region, and the electrons that escape to produce type III radio bursts are attributed to acceleration in the downward current region. These electrons do not come from a single distribution and need not have the same properties. Energetic ions, accelerated downward in the downward current region, are necessarily slightly displaced from the electrons accelerated downward in the upward current region. Such effects need to be treated quantitatively in a detailed model.

I thank Iver Cairns and Mike Wheatland for helpful comments.
