Hollow nanostructures are paid increasing attention in many nanotechnology-related communities in view of their numerous applications in chemistry and biotechnology, e.g., as smart nanoreactors or drug-delivery systems. In this paper we consider irreversible, diffusion-influenced reactions occurring within a hollow spherical cavity endowed with a circular hole on its surface. Importantly, our model is not limited to small sizes of the aperture. In our scheme, reactants can freely diffuse inside and outside the cavity through the hole, and react at a spherical boundary of given size encapsulated in the chamber and endowed with a given intrinsic rate constant. We work out the solution of the above problem, enabling one to compute the reaction rate constant to any desired accuracy. Remarkably, we show that, in the case of narrow holes, the rate constant is extremely well-approximated by a simple formula that can be derived on the basis of simple physical arguments and that can be readily employed to analyze experimental data.

1 Introduction

Chemical processes at the nano-scale are central to many complex phenomena in a wide array of modern nanotechnological applications. For example, it has long been known that hollow nanostructures provide some advantages in a number of applications (fillers, pigments, coatings, catalysts, etc.) because of their lower density.$^1–5$ Furthermore, physical and chemical features of hollow nanostructures can nowadays be fashioned in a controllable manner for a wide range of sizes, shapes, materials, and structural properties of the shells, including thickness, porosity, and surface reactivity. As a consequence, increasing attention has been paid over the last decade to the elaboration of different engineering methods for manufacturing hollow nano-objects of various kinds.

Among many different nanostructures, hollow spheres and capsules have stimulated great interest because of their potential applications in controlled drug delivery systems,$^{6,7}$ artificial cells,$^8$ catalysis,$^{9,10}$ lithium batteries,$^11$ and as compartments for confined reactions.$^{10,12}$

It is clear that many important physical and chemical processes such as diffusion transfer and chemical reactions might be considerably influenced by spatial restrictions.$^{13–18}$ Hollow nanostructures find specific applications relative to their bulk counterparts mostly due to pronounced size-dependent effects emerging from the confined geometry of the reaction volumes. Nanochemical processes occurring in confined geometries usually take place within nano-scale reaction compartments (often referred to as nanoreactors), whose typical dimensions are greater than the relevant reactants sizes.$^{19,20}$ For example, typical nanoreactors for drug delivery consist of hollow spheres with reflecting walls and encapsulated prodrug particles that are needed for the local production of the appropriate drug. The spherical shells of such nanoreactors have one or several holes allowing small particles, reacting with prodrugs, to penetrate inside the nanoreactor by passive diffusion.$^6$ Other kinds of hollow spherical yolk-shell nanoparticles synthesized as delivery vehicles or nanoreactors rely on hierarchical porous structures.$^{21}$ or are engineered as thermostimative nano-catalysts.$^{13}$

Typical dimensions of reactants and compartments ensure that reactions occurring in hollow nanostructures and mesoporous materials are mostly diffusion-influenced. This kind of reactions play an important role in chemistry and biology, and appropriate mathematical theories are well established for reactions occurring in unbounded domains.$^{22,23}$ However, despite their great potential importance in many different applications, there are very few studies devoted to diffusion-influenced reactions occurring within hollow spheres.

To the best of our knowledge, this problem was first discussed by Adam and Delbrück.$^{24}$ Later Tachiya studied the kinetics of diffusion-controlled reactions between particles encapsulated within a micelle to describe luminescence quench-
ing and excimer formation. The theory of irreversible, diffusion-influenced quenching reactions of the type \( A + B^* \rightarrow A + B \) occurring at partially absorbing sinks within a spherical cavity and at the cavity surface were developed by Bug et al. Three possible schemes for the location of partially absorbing surfaces within a spherical cavity (acceptors in the center, at the surface and at both locations) were considered.

In another study, the somewhat similar problem of the description of a lipid molecule from a lipid vesicle and its incorporation into another vesicle at high acceptor concentrations was reduced to solving the diffusion equation inside two concentric spheres. To this end, perfectly absorbing boundary conditions were imposed on the large sphere and appropriate matching boundary conditions were used on the surface of the small sphere. Analogous calculations were performed by Lü and Bülow, who solved the diffusion equation in different hollow geometries featuring either impermeable or permeable inner cores.

Recently, more sophisticated in silico schemes based on complex sets of coupled reaction-diffusion boundary problems have been introduced with the aim of understanding the cellular behavior of toxic foreign compounds. Methods motivated by homogenization techniques have been applied to make such problem treatable, yielding good agreement with experiments. Along similar lines, the theory of irreversible diffusion-controlled reactions has been applied to describe reactions between substrates and enzymes in a whole-cell model. However, the Smoluchowski reaction rate constant was used in this study, which is questionable when one takes into account the confined geometry of the cell and crowding effects.

Overall, many studies that investigated reactions within confined geometries did not take into consideration the structure of the outer surface, often featuring one of more apertures (e.g. circular pores). Generally speaking, diffusive problems in geometries of this kind are known as narrow escape problems. Recently, Sheu and Yang generalized the diffusive narrow escape problem to a gating escape model, describing the escape process of a Brownian particle out of a spherical cavity through a circular gate on the surface. The angular size of the aperture was described by a time-dependent function \( \theta_0(t) \), so that the gate behaves like an absorbing or reflecting patch in the open and closed states, respectively.

Remarkably, as it is done in Ref., absorbing boundary conditions are usually imposed on the gate/patch with the aim of modeling the diffusive escape of a particle from a confined volume through a hole on its surface. As a consequence, these theories cannot describe free diffusion of particles through the hole. In fact, this would necessitate that the model accommodate for both the diffusion from the inside to the exterior and in the opposite direction. Moreover, the mean first passage time approach is a powerful tool to study diffusion in compact domains but it is not appropriate for diffusion in a cavity connected with an outer, unbounded domain.

The problem of leakage of Brownian particles through a narrow pore studied in Ref. is much closer to the problem of free diffusion through a hole, as the flux density of the source on the boundary was taken into account. However, the flux of diffusing particles was given by a prescribed function and therefore it cannot describe free diffusion of particles through the hole. Along the same lines, Berezhkovskii and Barzykin studied the kinetics of diffusive escape from a cavity through a narrow hole in the cavity wall and successive reentry by a formal kinetic scheme for reversible dissociation.

The diffusion-influenced binding to a buried binding site connected to the surface by a channel studied in Ref. is the closest problem to the subject of our study that can be found in the literature. Nevertheless, this problem was only solved for the case of a conical pit with the aid of a constant-flux approximation or for all geometries where diffusion occurs in interior regions that are so narrow that the problem can be approximately considered as one-dimensional.

A thorough analysis of the literature showed that up to now there are no studies devoted to the theory of diffusion-influenced reactions occurring in hollow spheres connected through a circular hole to the unbounded outer space containing an excess of diffusing particles in the bulk. This is the problem that we solve in this paper.

The paper is organized as follows. In Section 2 we present a detailed formulation of the problem at issue. The solution of the problem is described in section 3, where we compute the reaction rate constant. In Section 4 we discuss our results and we show that our problem can be considered as equivalent to a much simpler one in the case of very small apertures. The main conclusions of the paper and possible extensions of the theory are given in Sec. 5. The appendix contains the details of the calculation and the explicit expressions of the matrix equations obtained by a dual series relations approach.

## 2 The problem

Let us consider particles \( B \) with bulk density \( \rho_B \) diffusing into a randomly distributed 3D system of hollow spheres with immobile reactants \( A \) (sinks) encapsulated inside them. We assume the hollow spheres to be either fixed in space or mobile but much larger than the size of \( B \) particles, so that they can be considered as immobile. For the sake of simplicity, we treat hollow spheres as infinitely thin identical spherical shells \( S_R \) of radius \( R \) comprising one spherical sink \( S_a \) of radius \( a \) \( (a \leq R) \) and reaction surface \( \partial \Omega_a \) each, and featuring an axially symmetric hole \( \partial \Omega_0 \) corresponding to a spherical cap of aperture \( \theta_0 \) (see Fig. 1). To make calculations simpler, we consider every sink to be concentric with the envelope hollow.
We note in passing that this constraint may be removed with the aid of reexpansion formulae methods.\footnote{We note in passing that this constraint may be removed with the aid of reexpansion formulae methods.} In this way the solution of more general problems with sinks at arbitrary locations inside the hollow spheres is also feasible.

Let us also assume that the system relaxation time for the diffusive flux of $B$ particles $t_B \propto (R-a)^2/D_i$ is small enough to neglect time-dependent effects. Hence, in the absence of external forces, the diffusion of particles $B$ with normalized number density $u(r) = \rho(r)/\rho_B$ is described by the steady-state diffusion equation

$$\nabla \cdot \left[ D(r) \nabla u(r) \right] = 0 \quad \text{in} \quad \Omega = \Omega^+ \cup \Omega^- \cup \partial \Omega_0$$  \hspace{1cm} (3)

which should be solved with the customary bulk boundary condition

$$\lim_{|r| \to \infty} u(r) = 1$$  \hspace{1cm} (4)

It is well known from the general theory of partial differential equations that the classical solution (twice continuously differentiable in $\Omega$ and continuous on $\overline{\Omega}$) of the stationary diffusion equation (3) does not exist in the whole domain $\Omega$.\footnote{Note that for $D_i = D_0$ the conditions (6) and (8) turn into continuity conditions for the concentration field $u(r)$.} Therefore one should consider the function

$$u(r) = \begin{cases} u^- (r) & \text{for} \quad \Omega^- \cup \partial \Omega^- \\ u^+ (r) & \text{for} \quad \Omega^+ \cup \partial \Omega^+ \end{cases}$$  \hspace{1cm} (5)

Accordingly, continuity of the concentration field across the hole should be enforced, i.e.

$$u^- \big|_{\partial \Omega_0^-} - u^+ \big|_{\partial \Omega_0^+} = 0$$  \hspace{1cm} (6)

Another condition on the hole can be derived by restricting to a small cylinder $\mathcal{C}_\varepsilon$ of section $\delta S \in \partial \Omega_0$ with its axis along the normal with height $\varepsilon \ll R$, i.e. $\mathcal{C}_\varepsilon = \{ r - \varepsilon < r < R + \varepsilon, \lowercase{\theta}, \varphi \} \in \delta S$. Using Gauss-Ostrogradsky theorem and Eq. (3) one has

$$\lim_{\varepsilon \to 0} \int_{\mathcal{C}_\varepsilon} \nabla \cdot \left[ D(r) \nabla u(r) \right] d^3 r =$$

$$= \int_{\delta S} \left[ D_i \frac{\partial u^+}{\partial r} - D_o \frac{\partial u^-}{\partial r} \right] dS = 0$$  \hspace{1cm} (7)

Since $\delta S$ is arbitrary, we obtain the following continuity condition for the local diffusion fluxes, holding at each point of the cap hole $\partial \Omega_0$,

$$\frac{\partial u^-}{\partial r} \big|_{\partial \Omega_0^-} = \chi \frac{\partial u^+}{\partial r} \big|_{\partial \Omega_0^+}$$  \hspace{1cm} (8)

where we have introduced the diffusion anisotropy parameter

$$\chi = \frac{D_i}{D_o}$$

Conditions (6) and (8) for $D_i \neq D_o$ are often called the weak discontinuity conditions for the concentration field $u(r)$.\footnote{Note that for $D_i = D_0$ the conditions (6) and (8) turn into continuity conditions for $u(r)$.} To
complete the set of boundary conditions, the two-sided surface of the hollow sphere is assumed to be reflecting both from the inside \( \partial \Omega_1^+ \) and from the outside \( \partial \Omega_1^- \), i.e.

\[
\frac{\partial u^+}{\partial r} \bigg|_{\partial \Omega_1^+} = \frac{\partial u^-}{\partial r} \bigg|_{\partial \Omega_1^-} = 0 \tag{9}
\]

2.1 The reaction rate constant

We are interested in the pseudo-first-order irreversible bulk diffusion-influenced reaction between sinks \( A \) (encapsulated in hollow spheres with a hole) and reactants \( B \) freely diffusing in 3D space

\[
A + B \xrightarrow{k_D} A \cdot B \xrightarrow{k_w} A + P \tag{10}
\]

where \( A \cdot B \) denotes the so-called encounter complex, \( k_D \) and \( k_{-D} \) are the association and dissociation diffusive rate constants, respectively, and \( k_w \) is the intrinsic rate constant of the chemical reaction occurring at the sink surface. Reactions of the kind (10) are customary dealt with by enforcing radiation boundary conditions\(^3\) at the reaction surface \( \partial \Omega_a \), i.e.

\[
\left[ 4\pi a^2 D_1 \frac{\partial u^+}{\partial r} - k_{int} u^+ \right] \bigg|_{\partial \Omega_a} = 0 \tag{11}
\]

Thus, we can consider that hollow spheres effectively act as sinks of infinite capacity according to the pseudo-first-order reaction scheme

\[
A + B \xrightarrow{k_w} A + P \tag{12}
\]

where the forward diffusion-influenced rate constant \( k_a \) is defined by the formula

\[
k_a = \int_{\partial \Omega_a} D_1 \frac{\partial u^+}{\partial r} \bigg|_{r=a} \, dS \tag{13}
\]

Using this rate constant one can approximately describe the kinetics of the effective reaction (12) as

\[
c_B(t) = c_B(0) \exp(-k_a c_A t) \tag{14}
\]

where \( c_A = \text{const} \) is the bulk concentration of hollow spheres, \( c_B(t) \) is the time-dependent effective bulk concentration of \( B \) particles. We stress that our schematization of the problem holds under the excess reactant condition \( \rho_a \ll \rho_B, \rho_a \) being the bulk density number of sinks. Our goal is to compute the rate constant (13).

Equation (5) with the boundary conditions (4), (6), (8) and (11) completely specify our mathematical problem. It is expedient in the following to use the dimensionless spatial variable \( \xi = r/R \). The problem at issue can be cast in the following form

\[
\nabla^2 u^+ = 0 \quad \text{in} \quad \Omega^+ \tag{15a}
\]

\[
\frac{\partial u^+}{\partial \xi} \bigg|_{\xi=\varepsilon} - hu^+(\varepsilon) = 0 \quad \text{for} \quad 0 \leq \theta < \pi \tag{15b}
\]

\[
\lim_{\xi \to 0^+} u^-(\xi) = 1 \tag{15c}
\]

\[
\frac{\partial u^-}{\partial \xi} \bigg|_{\xi=1^-} = 0 \quad \text{for} \quad \theta_0 < \theta < \pi \tag{15d}
\]

\[
u^+|_{\xi=1^-} - u^-|_{\xi=1^+} = 0 \quad \text{for} \quad 0 \leq \theta \leq \theta_0 \tag{15e}
\]

\[
\mathcal{X} \frac{\partial u^-}{\partial \xi} \bigg|_{\xi=1^-} - \frac{\partial u^-}{\partial \xi} \bigg|_{\xi=1^+} = 0 \quad \text{for} \quad 0 \leq \theta \leq \theta_0 \tag{15f}
\]

where \( \varepsilon = a/R \) and \( h = k_a R/(4\pi a^2 D_1) \). The limit \( h \to \infty \) corresponds to considering the boundary \( \partial \Omega_a \) as a perfectly absorbing sink. In this case the reaction (10) becomes diffusion-limited, as the chemical conversion from the encounter complex \( A \cdot B \) to the product \( P \) becomes infinitely fast with respect to the diffusive step leading to the formation of \( A \cdot B \).

3 The solution

We look for solutions in the form

\[
u^-(\xi) = 1 + \sum_{n=0}^{\infty} \frac{A_n}{\xi^{n+1}} P_n(\mu) \quad \text{for} \quad \xi \geq 1 \tag{16a}
\]

\[
u^+(\xi) = \sum_{n=0}^{\infty} \left[ \frac{B_n}{\xi^{n+1}} + C_n \xi^n \right] P_n(\mu) \quad \text{for} \quad \xi \leq 1 \tag{16b}
\]

where \( A_n, B_n \) and \( C_n \) are constants, \( \mu = \cos \theta \) and \( P_n(\mu) \) are Legendre polynomials of order \( n \). Inserting eq. (16b) in eq. (15b), we get

\[
C_n = a_n B_n \tag{17}
\]

with

\[
a_n = \frac{n+1+h\varepsilon}{\varepsilon^{2n+1}(n-h\varepsilon)} \tag{18}
\]

Formula (13) leads to the reduced reaction rate

\[
k_a^* = \frac{k_a}{k_d^*} = \frac{1}{2} \int_{-1}^{1} \frac{\partial u^+}{\partial \xi} \bigg|_{\xi=\varepsilon} \, d\mu \tag{19}
\]

where \( k_d^* = 4\pi D_1 a \) is the internal Smoluchowski rate constant for an ideal spherical sink of radius \( a \). Inserting eq. (16b) in eq. (19) and making use of eqs. (17) and (18), we get

\[
k_a^* = \frac{B_0}{\varepsilon} \tag{20}
\]

So the problem is reduced to the calculation of the constant \( B_0 \). The mixed boundary-value problem (15a)-(15f) can be
solved with the method of dual series relations (DSR). DSR admit solutions in the form of an infinite-dimensional system of algebraic equations for a new set of unknown coefficients \(X_n, \ U_n\), that are linearly related to \(A_n, B_n\):

\[
Z_n = Z_n^0 + \sum_{m=0}^{\infty} M_{nm} Z_m, \quad (n = 0, \infty)
\]

(21)

Here \(Z_n = (X_n, Y_n)^T, Z_n^0 = (X_n^0, Y_n^0)\) and

\[
M_{nm} = \begin{pmatrix} M_{nm}^{11} & M_{nm}^{12} \\ M_{nm}^{21} & M_{nm}^{22} \end{pmatrix}
\]

(22)

where \(M_{ij}^{mn}\) are four infinite-dimensional matrices of known elements, functions of the relevant geometrical and physical parameters \(\epsilon, h\) and \(\chi\) (see appendix A for the details of the calculation and the explicit expressions of the matrices \(M_{mn}^{ij}\)). In particular, the expression for the rate as a function of the new coefficients is

\[
k_a = -\frac{Y_0}{\epsilon}
\]

(23)

### 4 Results and discussion

Let us start by considering the limit \(\epsilon \to 1\), that is, \(a \to R\). Furthermore, for the sake of simplicity, let us consider diffusion-limited reactions, \(i.e. h \to \infty\). This case corresponds to considering a perfectly absorbing circular patch on an otherwise reflecting sphere of radius \(R\). The rate constant for this system can be characterized by a steric factor \(f_R(\theta_0) \in [0, 1]\)

\[
f_R(\theta_0) = \frac{k_a}{k_s}
\]

(24)

where \(k_s = 4\pi D_0 R\) is the external Smoluchowski rate constant for an ideal spherical sink of radius \(R\). The steric factor \(f_R(\theta_0)\) can be calculated to any necessary accuracy with the DSR method. In particular, it was found that

\[
f_R(\theta_0) \sim \frac{1}{2\pi} (\theta_0 + \sin \theta_0) \quad \text{as} \quad \theta_0 \to 0
\]

(25)

In the general case \(a < R\), it is expedient to normalize the reaction rate constant \(k_a\) to the rate constant \(\epsilon k_s\). This is tantamount to characterizing the sink inside the spherical cavity through a normalized effective steric factor \(\hat{f}(\theta_0; \epsilon, \chi) \in [0, 1]\), defined as

\[
\hat{f}(\theta_0; \epsilon, \chi) := \frac{k_a}{k_R(\theta_0)} = \frac{k_a}{k_s f_R(\theta_0)} = \frac{\epsilon \chi}{f_R(\theta_0)} \left(\frac{k_a}{k_s}\right)
\]

(26)

The physical meaning of \(\hat{f}(\theta_0; \epsilon, \chi)\) is to gauge how effective is the inner sink of radius \(a\) in trapping a particle diffusing through the spherical cap hole with respect to the situation when the particle is instantaneously trapped the moment it touches the cap from the outside \((a = R)\). Indeed, as the sink grows to touch the internal wall of the cavity, one has

\[
\lim_{\epsilon \to 0} \hat{f}(\theta_0; \epsilon, \chi) = 1
\]

(27)

independently of \(\chi\), as the inner sphere merges with the outer one. Conversely, as the sink shrinks, one has

\[
\lim_{\epsilon \to 0} \hat{f}(\theta_0; \epsilon, \chi) = 0
\]

(28)

uniformly with respect to \(\chi\). In this case, the effective steric factor vanishes as there is no sink within the spherical cavity \(\mathcal{S}_R\).

In Fig. 2, we plot the normalized effective steric factor as a function of the inner sink size \(a\) for different values of the angular aperture of the circular hole. As the aperture decreases, \(\hat{f}\) feels less and less the dependence on \(a\), which appears to be limited to two boundary layers in the vicinity of \(a = 0\) and \(a = R\). Between the two boundary layers, the effective steric factor is nearly constant.

In view of the Gauss-Ostrogradsky theorem, this tantamount to saying that for small patches the inner sphere feels a constant flux on the surface \(r = R\). Hence, the rate does not depend on the surface used for evaluating the integral (19).

The value of \(\hat{f}\) within the plateau is a measure of how much the whole system is less effective in trapping a tracer particle from the exterior with respect to the patched sphere \(\mathcal{S}_R\). Therefore, it is a measure of the portion of incoming particle flux through the hole that does not reach the inner sink, e.g. the flux that escapes back to the exterior through the aperture in the cavity.

Interestingly, we see that the such value increases when the outside diffusion coefficient decreases with respect to the inside (increasing \(\chi\)). Recalling that the single-particle diffusion decreases in crowded environment due to the volume occupied by crowding agents, we conclude that, in order to reach diffusively the inner target more effectively through the hole, the inner medium should be less densely populated than the outside. This can be rationalized in terms of a reduced escape probability towards the exterior due to crowding. A different way to picture this effect is to recall that in the limit \(\chi \to \infty\) the continuity condition (15) turns the spherical hole into a perfectly reflecting patch from the interior. Again, no particles allowed to escape outside the spherical cavity.

The plateau value of the effective steric factor for small \(\theta_0\) is proportional to the fraction of flux that reaches the inner sink at equilibrium, \(\Phi_{in}\), while its complement to one is proportional to the flux \(\Phi_{out}\) that leaves the inside of \(\mathcal{S}_R\). As \(D_i/D_o\) increases, we see that \(\Phi_{out}\) goes to zero, meaning that
Fig. 2 (Color online) Plot of the normalized effective steric factor (26) as a function of the radius of the inner sphere for different sizes of the spherical cap hole and different values of $\chi$. The inner encapsulated sphere is taken as perfectly absorbing, i.e. the calculations are performed for $h \rightarrow \infty$. The flux through the hole that reaches the sink is proportional to $D_0 / (D_1 + D_o)$, while the incoming flux into the cavity is proportional to $D_1$. We can thus surmise that, when the rate into the sink becomes independent of its size $a$ for small values of $\theta_0$, the fractions of flux reaching the sink and leaking back through the hole are approximately given by $D_1 / (D_1 + D_o)$ and $D_o / (D_1 + D_o)$, respectively. This leads us to conjecture that the value of the effective steric factor (26) for sinks occupying the bulk region of the cavity, i.e. the plateau shown in Fig. 2 is given by

$$\hat{f}_{\text{plat}} = \frac{D_1}{D_1 + D_o} = \frac{\chi}{1 + \chi} \quad (29)$$

Fig. 3 shows that Eq. (29) yields a perfect interpolation of the plateau values, confirming the validity of our simple physical reasoning.

4.1 Rationalizing the results through a simplified effective model

From the above discussion it should be clear that, for small $\theta_0$, we may model our system as a single sphere of radius $R$ endowed with a partially absorbing surface, characterized by an effective intrinsic reaction rate constant $k_{\text{eff}}$. This means that our boundary problem, for small values of the hole aperture,
should become equivalent to the following reduced problem

\[
\frac{d}{d\xi} \left( \xi^2 \frac{du}{d\xi} \right) = 0 \tag{30a}
\]

\[
\left( \frac{du}{d\xi} - h_{\text{eff}} u \right)_{\xi=1} = 0 \tag{30b}
\]

\[
\lim_{\xi \to \infty} u(\xi) = 1 \tag{30c}
\]

The parameter \( h_{\text{eff}} / k_s \) gauges the effective absorbing power of the sphere \( \mathcal{S} \). This should depend on the steric factor \( f_R(\theta_0) \), which guarantees that only a portion of the surface is potentially absorbing by construction, and on \( \chi = D_i / D_o \). It is easy to check that the rate constant \( k \) for the above reduced problem is given by

\[
\frac{k}{k_s} = \frac{h_{\text{eff}}}{1 + h_{\text{eff}}} \tag{31}
\]

Recalling the definition (26), we see that eqs. 31 and 29 fix the effective reactivity of the reduced model, i.e.

\[
h_{\text{eff}} = \frac{\chi f_R(\theta_0)}{1 + \chi [1 - f_R(\theta_0)]} \tag{32}
\]

5 Conclusion and perspectives

In this paper we investigated an irreversible, diffusion-influenced reaction occurring within a spherical cavity endowed with a circular hole on its surface. Importantly, our model is not limited to small values of the angular aperture \( \theta_0 \) of the hole on the cavity surface. In our model, \( B \) particles can freely diffuse inside and outside the cavity through the hole, and react at a spherical boundary \( A \) encapsulated in the cavity and endowed with a given intrinsic rate constant. This model is relevant for chemical and biochemical reactions occurring in hollow nano-structures, which are intensively studied for a wide array of nanotechnological applications.

We work out the solution of the above problem, enabling one to compute the reaction rate constant for the encapsulated sphere within the cavity to any necessary accuracy.

Remarkably, we find that, for small values of the hole aperture, the rate constant \( k_{\text{eff}} \) becomes independent of the size of the inner reactive sphere. In this case, the rate is simply proportional to the fraction of diffusive flux that is actually absorbed by the sink and thus does not leak back through the hole into the bulk. We show how this situation can be encapsulated in a simple effective model, whose theoretical prediction provides a simple yet powerful formula, i.e.

\[
k_{\text{eff}} = k_s f_R(\theta_0) \frac{\chi}{1 + \chi} \tag{33}
\]

Here \( \chi = D_i / D_o \) is the ratio of the inside to outside diffusion coefficients, \( k_s = 4\pi D_o R \) is the outside Smoluchowski rate constant into the spherical cavity and \( f_R(\theta_0) \simeq (\theta_0 + \sin \theta_0) / (2\pi) \) is the steric factor that characterizes the rate into the cavity when the hollow sphere is modeled as a perfectly absorbing patch (the hole) on an otherwise reflecting surface. Eq. (33) is a key result of this paper.

Future follow-ups of this work may include extending our mathematical framework to diffusion-influenced reactions with two axially symmetric hollow spheres and to situations where the encapsulated sink is no longer concentric with the hollow sphere but lies at an arbitrary location in the interior.[41]

A

In this appendix we describe in detail the solution of the mixed boundary-value problem (15a)-(15e) with the method of dual series relations (DSR).

The constants $A_n$ and $B_n$ can be determined by imposing the boundary conditions (15d) and the two continuity conditions (15e) and (15f). Recalling eq. (17), we get the two following coupled DSRs

\[
\sum_{n=0}^{\infty} \{ (1 + \alpha_n) B_n - A_n - \delta_{n0} \} P_n(\mu) = 0, \quad 0 \leq \theta \leq \theta_0 \tag{34a}
\]

\[
\sum_{n=0}^{\infty} (n+1) A_n P_n(\mu) = 0, \quad \theta_0 < \theta < \pi \tag{34b}
\]

\[
\sum_{n=0}^{\infty} \{ (n+1) A_n - \chi [n(1-\alpha_n) + 1] B_n \} P_n(\mu) = 0, \quad 0 \leq \theta \leq \theta_0 \tag{34c}
\]

\[
\sum_{n=0}^{\infty} [n(1-\alpha_n) + 1] B_n P_n(\mu) = 0, \quad \theta_0 < \theta < \pi \tag{34d}
\]

where $\delta_{n0}$ is the Kronecker delta. The above DSRs can be cast in canonical form by defining

\[
X_n = \left( \frac{n+1}{2n+1} \right) A_n \tag{35a}
\]

\[
Y_n = \left( \frac{n(1-\alpha_n) + 1}{2n+1} \right) B_n \tag{35b}
\]

which gives

\[
\sum_{n=0}^{\infty} X_n P_n(\mu) = G(\theta) \tag{36a}
\]

\[
\sum_{n=0}^{\infty} (2n+1) X_n P_n(\mu) = 0 \quad \theta_0 < \theta < \pi \tag{36b}
\]

\[
\sum_{n=0}^{\infty} Y_n P_n(\mu) = F(\theta) \tag{36c}
\]

\[
\sum_{n=0}^{\infty} (2n+1) Y_n P_n(\mu) = 0 \quad \theta_0 < \theta < \pi \tag{36d}
\]

with

\[
G(\theta) = \sum_{m=0}^{\infty} \left[ \frac{X_n}{2(m+1)} + \beta_m Y_m \right] P_m(\cos \theta) - \frac{1}{2} \tag{37a}
\]

\[
F(\theta) = \sum_{m=0}^{\infty} \left[ \frac{2m+1}{\chi} X_m - 2m Y_m \right] P_m(\cos \theta) \tag{37b}
\]

and

\[
\beta_m = \frac{(1+\alpha_n)(2m+1)}{2m(1-\alpha_n)+1} \tag{38}
\]

The DSRs (36a), (36b), (36c), and (36d) admit a formal solution in the form of the infinite-dimensional system of algebraic equations

\[
X_n = \frac{\sqrt{2}}{\pi} \int_0^{\theta_0} d\cos \theta \sin \theta \frac{d}{d \mu} \int_0^{\mu} G(\theta) \sin \theta d\theta \tag{39a}
\]

\[
Y_n = \frac{\sqrt{2}}{\pi} \int_0^{\theta_0} d\cos \theta \sin \theta \frac{d}{d \mu} \int_0^{\mu} F(\theta) \sin \theta d\theta \tag{39b}
\]

The integrals appearing in eqs. (39a) and (39b) can be computed explicitly by noting that

\[
\int_0^{\mu} P_m(\cos \theta) \sin \theta d\theta \frac{d}{d \mu} = \frac{2\sqrt{2}}{m+1} \sin \left( m + \frac{1}{2} \right) \mu \tag{40}
\]

which finally gives

\[
X_n = \sum_{m=0}^{\infty} (M_{nm}^{11} X_m + M_{nm}^{12} Y_m) + X_n^0 \tag{41a}
\]

\[
Y_n = \sum_{m=0}^{\infty} (M_{nm}^{21} X_m + M_{nm}^{22} Y_m) + Y_n^0 \tag{41b}
\]

where

\[
M_{nm}^{11} = \frac{1}{2(m+1)} \Phi_{nm}, \quad M_{nm}^{12} = \frac{(1+\alpha_n)(2m+1)}{2m(1-\alpha_n)+1} \Phi_{nm} \tag{42a}
\]

\[
M_{nm}^{21} = \frac{2m+1}{\chi} \Phi_{nm}, \quad M_{nm}^{22} = -2m \Phi_{nm} \tag{42b}
\]

\[
X_n^0 = -\Phi_{n0}^0, \quad Y_n^0 = 0 \tag{42c}
\]

\[
\Phi_{nm} = \frac{\pi}{m+n+1} \int_0^{\theta_0} \left[ \sin(m+n+1)\theta_0 \right] \frac{d}{d \mu} \left[ \frac{\sin(m-n)\theta_0}{m-n} + \sin(m-n)\theta_0 (1-\delta_{nm}) + \theta_0 \delta_{nm} \right] \tag{42d}
\]

Note that $\Phi_{nm} = 0$ for $\theta_0 = 0$, which gives $Y_0 = 0$. Hence the rate vanishes in this limit, as it should. The other interesting limit is $\theta_0 = \pi$, when the larger external sphere no longer exists. In this case it is easy to see that $Y_0 = (\alpha_0 + 1-\chi)^{-1}$. However, in the limit $\theta_0 = \pi$, one has to consider $D_1 = D_0 = D$, as the separation between the two spatial domains $r < R$ and $r > R$ becomes immaterial. Hence, recalling eqs. (18) and (23), we get

\[
k = \frac{1}{k_s} = \frac{1}{1-\delta_{nm}} \chi \tag{43a}
\]

where $k_s = 4\pi D u$, which is the correct result for a partially absorbing sphere with intrinsic reaction rate constant $k_{in}$. The limit of fully absorbing sphere $k = k_s$ is recovered in the limit $k_{in} \to \infty$.
