Abstract

Objective To study heterogeneity between patients with glycogen storage disease type Ia (GSD Ia), a rare inherited disorder of carbohydrate metabolism caused by the deficiency of glucose-6-phosphatase (G6Pase).

Study design Descriptive retrospective study of longitudinal clinical and biochemical data and long-term complications in 20 GSD Ia patients. We included 11 patients with homozygous G6PC mutations and siblings from four families carrying identical G6PC genotypes. To display subtle variations for repeated triglyceride measurements with respect to time for individual patients, CUSUM-analysis graphs were constructed.

Results Patients with different homozygous G6PC mutations showed important differences in height, BMI, and biochemical parameters (i.e., lactate, uric acid, triglyceride, and cholesterol concentrations). Furthermore, CUSUM-analysis predicts and displays subtle changes in longitudinal blood triglyceride concentrations. Siblings in families also displayed important differences in biochemical parameters (i.e., lactate, uric acid, triglycerides, and cholesterol concentrations) and long-term complications (i.e., liver adenomas, nephropathy, and osteopenia/osteoporosis).

Conclusions Differences between GSD Ia patients reflect large clinical and biochemical heterogeneity. Heterogeneity between GSD Ia patients with homozygous G6PC mutations indicate an important role of the G6PC genotype/mutations. Differences between affected siblings suggest an additional role (genetic and/or environmental) of modifying factors defining the GSD Ia phenotype. CUSUM-analysis can facilitate single-patient monitoring of metabolic control and future application of this method may improve precision medicine for patients both with GSD and remaining inherited metabolic diseases.

Introduction

Glycogen storage disease type Ia (GSD Ia; OMIM #232200) is a rare inherited disorder of carbohydrate metabolism caused by mutations in the G6PC gene, resulting in deficiency of
glucose-6-phosphatase (G6Pase). The subsequently impaired hydrolysis of glucose-6-phosphate (G6P) to glucose and phosphate affects the final common pathway of glycogenolysis and gluconeogenesis (Bali et al. n.d.; Froissart et al. 2011). Symptoms and signs include severe fasting intolerance, failure to thrive, and hepatomegaly. Biochemically, the phenotype is characterized by non-ketotic hypoglycemia, hyperlactatemia, hyperuricemia, and hyperlipidemia (Bali et al. n.d.). Dietary management has greatly improved the life expectancy of GSD Ia patients, changing from an acute, fatal disease into a chronic disorder. Despite intensive dietary management, important long-term complications include the liver (hepatocellular adenomas and carcinomas), kidneys (proteinuria, renal insufficiency, stones), and bone (osteopenia, osteoporosis) (Bali et al. n.d.; Rake et al. 2002a, b).

Cross-sectional studies such as the European Study on Glycogen Storage Disease Type 1 (ESGSDI) focused on the complete cohort of GSD Ia patients, but longitudinal data on clinical heterogeneity between individual GSD Ia patients have been poorly documented. In contrast with the classical childhood GSD Ia phenotype, case reports illustrate patients with milder phenotypes, clinically presenting during late childhood with non-symptomatic hepatomegaly or adulthood with gouty arthritis and benign/malignant hepatic tumors (Takahashi et al. 2000; Shieh et al. 2011; Cassiman et al. 2010; Nakamura et al. 2001; Matern et al. 2002; Keller et al. 1998). Although these patients have not experienced clinically relevant fasting intolerance, their abnormal biochemical profiles resemble classical GSD Ia patients. In addition, observations in two siblings suggest that clinical heterogeneity cannot be solely explained by the G6PC genotype (Rake et al. 2000a).

Furthermore, data analysis has focused largely on traditional methods describing differences between groups by expressing means or medians. However, patient care for metabolic patients often is characterized by repeated clinical and biochemical measurements and their analysis can be complemented by inter-individual analysis methods, such as Cumulative Sum analysis (CUSUM-analysis).

This is a retrospective study of longitudinal clinical and biochemical parameters from (1) GSD Ia patients with homozygosity for different G6PC mutations and (2) patients within GSD Ia families carrying identical G6PC genotypes.

**Patients and methods**

**Patients** The Medical Ethical Committee of the University Medical Center Groningen approved the study protocol (MEC 2014/342). Data were studied from GSD Ia patients followed by two centers. Patients were selected based on G6PC genotypes/mutations and the availability of sufficient data. For all GSD Ia patients in this study the diagnosis was genetically confirmed and displayed according to the reference sequence NM_000151.3.

**Clinical and biochemical data** Longitudinal data on clinical and laboratory data and long-term complications were retrieved from the paper and electronic files before 01–02-2016.

Clinical parameters included height, weight, weight for height, BMI, and data of the prescribed diets. Height and BMI were recorded at last check-up and compared with Dutch standard growth diagrams (LUMC-TNO 1997 in cases A, B, and C and families I-III; LUMC-TNO 2010 in case D). For the patients from the University of Florida, biometric data were compared to the standard growth diagrams from the CDC 2000. Target height range was determined accordingly for all patients.

Biochemical parameters included blood concentrations that are closely related to metabolic control (i.e., lactate, uric acid, triglycerides (TG), and cholesterol) and urine parameters (i.e., creatinine, albumin and total protein) as mentioned in the published guidelines(Rake et al. 2002a; Kishnani et al. 2014).

Long-term complications were recorded at the last check-up. Liver adenoma(s) was defined as one or more focal lesions detected by standard imaging techniques. Nephropathy was defined as micro albuminuria (either 30–300 mg/24 h, or if previous data was not available albumin/creatinine >3.5 and >2.5 for females and males, respectively) and/or proteinuria (protein/creatinine >45 mg/mmol). Bone mineral density was evaluated by dual-energy X-ray absorptiometry scan (DEXA). Osteopenia was defined as bone mineral density T-scores between −1.0 and −2.5 SDs determined at one site. Osteoporosis was defined as bone mineral density T-scores of −2.5 SDs or lower determined at one site. The values are compared to the ideal or peak bone mineral density of healthy 30-year old adults.

**Statistical analysis** Statistical analysis was performed using Microsoft® Excel for Mac Version 15.19.1 and Graphpad Prism version 5.03 for Windows (San Diego, CA, USA, [www.graphpad.com]). Differences between groups were studied using either Mann-Whitney U test (in families I, II and IV) or Kruskal-Wallis test followed by Dunn’s multiple comparison (in patients with homozygous G6PC mutations and family III). Differences were considered statistically significant at $p < 0.05$.

To display subtle variations for repeated measurements with respect to time for individual patients, CUSUM-analysis graphs were constructed. CUSUM-analysis is a method in which each measurement is seen as a deviation from the mean value of the parameter over time. The cumulative effect of the deviations of each measurement to the mean is made visible as CUSUM-analysis graphs. However, in our retrospective analysis, interpretation of CUSUM-analysis was complicated because time intervals between TG measurements were not constant, which means
that periods of high measurement density would have a dispro-
portional effect in the CUSUM-analysis. To correct for different
time intervals, the TG values were interpolated to equidistant
intervals \( t = 0.01 \text{ year, approximately } 3.65 \text{ days} \). This
interpolation interval was chosen to make the calculation of the
CUSUM easier. After calculating average blood TG concentra-
tions (\( \text{TG}_{\text{avg}} \)), for each value \( \Delta \text{TG} \) was calculated as \( \Delta \text{TG} = \text{TG}_n - \text{TG}_{\text{avg}} \). At the first time point CUSUM equals \( \Delta \text{TG} \). For serial
measurements at time point \( n \), CUSUM is calculated as \( \Delta \text{TG} + \text{CUSUM}_{n-1} \).

**Results**

Twenty GSD Ia patients were included from 14 families, 12
males and eight females. Median age was 21.5 years (range
4.2–43.0).

**Differences between GSD Ia patients with homozygosity
for different G6PC mutations**

Parameters of 11 patients with homozygosity for different
G6PC mutations are presented in Table 1 (UMCG; patients
A-D) and Table 2 (UF; patients E-K). Figure 1 presents (1)
longitudinal data of blood TG concentrations and the first
order derivative of blood TG concentrations with respect to
time and (2) CUSUM-analysis for patients A-D.

Patient A presented clinically with severe hypoglycemia’s in
the first days of life, when plasma TG concentrations were
0.22 mmol/L. Enzymatic studies had confirmed diagnosis of
GSD Ia, but no molecular studies had been performed at that
time. She had been referred to the UMCG at the age of 16.
Despite strict dietary management, height has remained below
target range and she underwent a partial hepatectomy at the age
of 19 years due to liver adenomas of which the largest was
5.9 cm (arrow 1 Fig. 1a). The patient was one of the very few
GSD Ia patients known in the UMCG who was not growing
within her target range. However, dietary compliance had been
questioned over the years. In an attempt to improve her metabolic
control before surgery, she was hospitalized 3 days before the
procedure. Blood lactate concentrations only decreased to
2.3 mmol/L after increasing both enteral and parenteral carbohy-
drate intakes to supra-physiological values (4.7 and 3.9 mg/kg/ min, respectively). Based on these observations, after the hospi-
talization the prescribed absolute dietary carbohydrate intake was
increased to 5 mg/kg/min glucose, 2.2 times the estimated en-
dogenous glucose production rate, according to literature
(Huidekoper et al 2014). Following this intervention, blood lac-
tate concentrations remained increased despite higher carbohy-
drate intake (ranging between 2.9 to 7.1 mmol/L). TG concentra-
tions (absolute and CUSUM) decreased subsequently,
reflecting improved metabolic control, but she gained 8 kg of
body weight, reflecting the delicate balance between under- and
over-treatment. At that time, results on molecular testing became
available and confirmed homozygosity for the c.79delC/
p.Gln27Argfs*9 mutation in exon 1 of the G6PC gene, leading
to a severely truncated protein without any of the essential do-
 mains necessary for the G6Pase activity (Angaroni et al 2004).

Patient B is the daughter of Turkish immigrants growing in/
above the target range, (not even) adjusted for her ethnicity.
She developed severe iron treatment resistant anemia due to
multiple liver adenomas, for which she underwent a liver
transplantation at the age of 19 years (arrow 1 in Fig. 1b). In
the CUSUM-analysis, this is visible as a rapid decrease of the
CUSUM, corresponding to the TG mean. This represents im-
proved metabolic control.

The family history of patient C (family III) will be summa-
rized in the following section. After the moment this patient,
first believed to have GSD IX, received the correct diagnosis
of GSD Ia (arrow 1 in Fig. 1c), dietary management and the
compliance with this dietary management improved. TG
values (absolute and CUSUM) subsequently normalized. In
the CUSUM-analysis, this is visualized since the CUSUM
decreased to 0 mmol/L, corresponding to the TG mean.

Patient D presented clinically during a gastro-enteritis at
the age of 22 months with failure to thrive and hepaticomegaly.
After introduction of dietary management, biometrical data,
liver size, and biochemical parameters of metabolic control
have been outstanding. In the CUSUM-analysis, it can be seen
that the CUSUM is relatively low compared to patients A, B,
and C, with a maximum of 146 mmol/L depicted at the right y-
axis. She is currently still on continuous nocturnal gastric drip
feeding with a daily carbohydrate intake of 3.7 mg/kg/min
(1.2 times the estimated endogenous glucose production)
(Huidekoper et al 2014).

**Differences between patients within GSD Ia families
covering identical G6PC genotypes**

Table 3 presents the clinical and biochemical parameters and
long-term complications between siblings in four GSD Ia fam-
ilies. Heterogeneity between these GSD Ia patients is illustrat-
ed by significant differences in clinical parameters (i.e., height
ranges from −2.7 to +1.9 SDS), biochemical parameters (i.e.,
TG ranges from 2.6 to 38.8 mmol/L), and development
of long-term complications in every family.

In family I, patient 1 was additionally diagnosed with lipo-
protein lipase deficiency, but his brother was not. Patient 1
additional developed liver adenomas and nephropathy, in
contrast to his brother.

Family II was reported previously (Rake et al 2000b). The
patients differ with respect to lactate, TG and uric acid con-
centrations. Both patients developed liver adenomas, but only
patient 4 developed osteoporosis.

Family III represents four affected male GSD Ia patients,
including patient C. The patients have been considered GSD

 Springer
type IX patients for most of their lives because of their family history suggesting X-linked inheritance and their relatively mild fasting intolerances. The latter was reflected by the fact that patient 6 from family III was the index patient with an older affected brother diagnosed after him. The brothers were initially prescribed relatively low doses of uncooked cornstarch (UCCS) during the day, and late evening meals. Surprisingly, after next generation sequencing analysis

Legend: Biochemical parameters are presented as median and range. Legend: ^, significantly different compared to case E, etc.; h, height outside of target range; LS, lumbar spine; NR, not recorded; PF, proximal femur; R, radius. Differences were considered statistically significant at p < 0.05.
became available, it demonstrated homozygosity for the c.467G > T/Trp156Leu G6PC mutation in exon 4, known to be associated with retained residual G6Pase activity (Shieh et al 2001; Kirk et al 2013). After revision of the diagnosis, they were prescribed late-evening doses of extended release cornstarch, aiming at normalization of laboratory parameters, although dietary compliance had been limited. There were no significant differences in clinical or biochemical parameters between the family members. However, patient 5 was the only sibling that developed three liver adenomas. These have not increased in size in the subsequent 2 years.

In family IV, the siblings are identical twins. Their clinical and biochemical parameters do not differ significantly and patients 9 and 10 both developed liver adenomas. However, in contrast with this brother, at the age of 17, the liver adenomas in patient 10 developed so rapidly that liver transplantation was deemed necessary. At this age, this patient also developed nephropathy.

**Discussion**

This is the first report of large heterogeneity between GSD Ia patients based on retrospective study of longitudinal clinical and laboratory data. This report shows that there are differences GSD Ia patients with homozygosity for different G6PC mutations and differences between patients within GSD Ia families carrying identical G6PC genotypes.

Based on the genotype of the patients in this study, one can speculate on the cause for the heterogeneity. In this study, patients with homozygosity for either severe nonsense mutations or active site G6PC mutations appear to be more severely affected clinically (i.e., patient A, B, E, and F in Tables 1 and 2). Historically, GSD Ia diagnosis required the confirmation of impaired G6Pase enzyme activity in frozen liver tissue. Nowadays genetic testing (including G6PC gene sequencing) is the preferred method since it is less invasive. Based on in vitro studies, many G6PC mutations can be categorized according to their predicted catalytic, helical, or non-helical locations in the enzyme (Shieh et al 2001; Chou and Mansfield 2008; Bruni et al 1999). Genotype-phenotype correlations have not been studied systematically and are complex because by far most GSD Ia patients are compound heterozygous for different G6PC mutations (Bali et al n.d.; Rake et al 2002b; Wang et al 2011).

Furthermore, the differences between affected siblings with identical G6PC mutations suggest a contribution of additional (genetic and/or environmental) modifying factors that theoretically modify the GSD Ia phenotype.

Variations of residual endogenous glucose production may be a modifying factor in GSD Ia patients. In healthy subjects, endogenous glucose production rate is age dependent and decreases relatively with body weight and age (Huidekoper et al 2014; Bier et al 1977). Interestingly, in GSD Ia patients, whole body in vivo endogenous glucose production may reach ~60% of normal, despite severely reduced or absent in vitro hepatic G6Pase activity (Huidekoper et al 2014; Kalhan et al 1982; Tsalikian et al 1984; Schwenk and Haymond 1986; Roden et al 2007). The origin of this glucose production is still a matter of debate. The metabolic block may be compensated for by (combinations of) residual G6Pase activity, (muscle) glucose-6-phosphatase-β, and/or alternative glycogenolysis (by the α-glucosidase or debranching pathway). Besides the product (i.e., glucose) deficiency, there is substrate...

Biochemical parameters are presented as median and range. *, significantly different compared to sibling; 5, significantly different compared to case 5, etc.; ^, height outside of target range; NR, not recorded; LS, lumbar spine; PF, proximal femur; R, radius; TB, total body. Differences were considered statistically significant at p < 0.05.
(i.e., G6P) accumulation in the endoplasmic reticulum of GSD Ia patients (Bali et al n.d.; Froissart et al 2011). G6P accumulation affects transcription and enzyme activity (including carbohydrate response element binding protein and 11β-hydroxysteroid dehydrogenase) of several metabolic pathways such as glycolysis, de novo lipogenesis, and the pentose phosphate pathway, which together create the complex clinical and biochemical GSD Ia phenotype (Oosterveer and Schoonjans 2014; Melis et al 2015).

This study introduces CUSUM-analysis to visualize subtle time-dependent variations of retrospectively collected TG-concentrations in cases A-D. However, it needs to be mentioned that CUSUM-analysis of retrospectively collected TG concentrations has been complex, because time intervals between measurements were not constant. Moreover, the variations in plasma TG concentrations in GSD Ia patients are not as fast as changes in glucose concentrations in these patients. Therefore, we hypothesize that prospective application of CUSUM-analysis may be a powerful tool to identify early and critical biochemical variations in patients with inherited metabolic diseases. The correlation between CUSUM-analysis of relevant biomarkers and clinically relevant outcome parameters deserves future prospective study.

There is no clear definition of ‘good metabolic control’ for GSD Ia patients, although several biomedical targets (including growth, liver size, and standard laboratory parameters such lactate, TG, cholesterol, and uric acid levels) are mentioned in GSD I management guidelines (Rake et al 2002a; Kishnani et al 2014). TG concentrations are considered as an important biometrical parameter of metabolic control. ESGSDI has recommended to aim at TG < 6.0 mmol/L (Rake et al 2002a, b). Significant differences in adenoma development/progression have been reported between GSD Ia patients with 5-year mean TG concentrations <500 mg/dL (i.e., 5.7 mmol/L) and >500 mg/dL (Wang et al 2011). In the above mentioned reports, GSD Ia patients were considered a homogenous group (Rake et al 2002a; Kishnani et al 2014). This study emphasizes that dietary management of GSD Ia patients requires individualized approaches.

Conclusion

We report large heterogeneity of (long-term) clinical and biochemical parameters between GSD Ia patients. Differences between patients carrying homozygous G6PC mutations indicate that the G6PC genotype is an important determinant of the phenotype. Differences between affected siblings with identical G6PC mutations suggest a contribution of additional (genetic and/or environmental) modifying factors to GSD Ia symptoms and signs. CUSUM analysis can be helpful to identify early changes in metabolic control for individual patients, which opens up possibilities to move toward precision medicine for metabolic patients.

BMI, body mass index; CGM, continuous glucose monitoring; CUSUM, cumulative sum; ESGSDI, European Study on Glycogen Storage Disease Type I; G6P, glucose-6-phosphate; G6Pase, glucose-6-phosphatase; G6PC, glucose-6-phosphatase, catalytic subunit; LS, lumbar spine; PF, proximal femur; R, radius; TG, triglycerides; UCCS, uncooked cornstarch.
