The Transition from Inspiral to Plunge for a Compact Body in a Circular Equatorial Orbit Around a Massive, Spinning Black Hole

Amos Ori\(^{(1)}\) and Kip S. Thorne\(^{(2)}\)

\(^{(1)}\)Department of Physics, Technion—Israel Institute of Technology, Haifa, 32000, Israel
\(^{(2)}\)Theoretical Astrophysics, California Institute of Technology, Pasadena, CA 91125

(Received 21 February 2000)

There are three regimes of gravitational-radiation-reaction-induced inspiral for a compact body with mass \(\mu\), in a circular, equatorial orbit around a Kerr black hole with mass \(M \gg \mu\): (i) The **adiabatic inspiral regime**, in which the body gradually descends through a sequence of circular, geodesic orbits. (ii) A **transition regime**, near the innermost stable circular orbit (isco). (iii) The **plunge regime**, in which the body travels on a geodesic from slightly below the isco into the hole’s horizon. This paper gives an analytic treatment of the transition regime and shows that, with some luck, gravitational waves from the transition might be measurable by the space-based LISA mission.

I. INTRODUCTION AND SUMMARY

The space-based Laser Interferometer Space Antenna (LISA) \(\text{(LISA)}\), if it flies, is likely to detect and study the gravitational waves from white dwarfs, neutron stars and small black holes with masses \(\mu \lesssim 1 M_\odot\), spiraling into Massive \((M \sim 10^5-10^9 M_\odot \gg \mu)\) black holes in the nuclei of distant galaxies \(\text{\cite{1,2,3}}\). In preparation for these studies, it is necessary to understand, theoretically, the radiation-reaction-induced evolution of the inspiral orbits, and the gravitational waveforms that they emit.

Regardless of an orbit’s shape and orientation, when \(\mu \ll M\) the orbital evolution can be divided into three regimes: (i) The **adiabatic inspiral regime**, in which the body gradually descends through a sequence of geodesic orbits with gradually changing “constants” of the motion \(E \equiv \text{(energy)}, \ L \equiv \text{(polar component of angular momentum)}, \) and \(Q \equiv \text{(Carter constant)}.\) (ii) A **transition regime**, in which the character of the orbit gradually changes from inspiral to plunge. (iii) A **plunge regime**, in which the body plunges into the horizon along a geodesic with (nearly) unchanging \(E, \ L, \) and \(Q\).

The plunge regime, being (essentially) ordinary geodesic motion, is well understood; and the adiabatic inspiral regime is the focus of extensive current research (see, e.g. \(\text{\cite{4,5}}\)). By contrast, so far as we are aware, there have been no publications dealing with the transition regime.

In 1990-91, we carried out an initial exploration of the transition regime for the special case of circular, equatorial orbits; but due to the press of other projects we did not publish it. Now, with prospects for LISA looking good, we have resurrected our work and present it here, in the context of LISA.

We begin, in Sec. II A, by summarizing some key, well-known details of the inspiral and plunge regimes. Then in Sec. II B we present a qualitative picture of the transition from inspiral to plunge, based on the motion of a particle in a slowly changing effective potential (Fig. 1). With the aid of this qualitative picture, in Sec. II C we derive a non-geodesic equation of motion for the transition regime, and in Sec. II D we construct the solution to that equation of motion (Figs. 2 and 3). Then in Sec. III with the aid of our solution, we estimate the gravitational-wave signal strength from the transition regime and the signal-to-noise ratio that it would produce in LISA. We conclude that, with some luck, LISA may be able to detect and study the transition waves. In Sec. IV we make concluding remarks about the need for further research.

II. ADIABATIC INSPIRAL AND PLUNGE

Throughout this paper we use Boyer-Lindquist coordinates \((t, r, \theta, \phi)\) \(\text{\cite{6}}\) for the massive hole’s Kerr metric, and we use geometrized units, with \(G = c = 1\). The hole’s mass is \(M\) and the inspiraling body’s mass is \(\mu \equiv \eta M\). We use \(M \) and \(\mu\) to construct dimensionless versions (denoted by tildes) of many dimensionfull quantities; for example, \(\tilde{r} = r/M\), and \(\tilde{t} = t/M\). The hole’s dimensionless spin parameter is \(a \equiv \text{(spin angular momentum)}/M^2\) (with \(-1 < a < +1\)). The body moves around its circular, equatorial orbit in the +\(\phi\) direction, so \(a > 0\) corresponds to an orbit that is prograde relative to the hole’s spin, and \(a < 0\) to a retrograde orbit.

When the inspiraling body is not too close to the innermost stable circular orbit (isco), it moves on a circular geodesic orbit with dimensionless angular velocity \(\tilde{\Omega}\)

\[
\tilde{\Omega} \equiv M\Omega = \frac{d\phi}{dt} = \frac{1}{\tilde{r}^{3/2} + a} \tag{2.1}
\]

(where \(\phi\) is angle around the orbit) and with orbital energy \(\tilde{E}\)

\[
\tilde{E} = -\eta M \frac{1 - 2/\tilde{r} + a/\tilde{r}^{3/2}}{\sqrt{1 - 3/\tilde{r}^{2} + 2a/\tilde{r}^{3/2}}} \tag{2.2}
\]
As it moves, the body radiates energy into gravitational waves at a rate given by

\[ \dot{E}_{GW} = -\dot{E} = \frac{32}{5}\eta^2 \tilde{\Omega}^{10/3}\dot{\tilde{r}}, \tag{2.3} \]

where \( \dot{\tilde{r}} \) is a general relativistic correction to the Newtonian, quadrupole-moment formula (Table II of Ref. [4]). This energy loss causes the orbit to shrink adiabatically at a rate given by

\[ \frac{dr}{dt} = -\frac{\dot{\tilde{E}}_{GW}}{\dot{E}/dr}. \tag{2.4} \]

The inspiral continues adiabatically until the body nears the isco, which is at the dimensionless radius \( \tilde{r}_{isco} = \tilde{r}_{isco}/M \) given by

\[ \tilde{r}_{isco} = 3 + Z_2 - \text{sgn}(a)(3 - Z_1)(3 + Z_1 + 2Z_2)^{1/2}, \]

\[ Z_1 \equiv 1 + (1 - a^2)^{1/3}[1 + a]^{1/3} + (1 - a)^{1/3}, \]

\[ Z_2 \equiv (3a^2 + Z_1^2)^{1/2}; \tag{2.5} \]

cf. Table II. The circular geodesic orbit at the isco has dimensionless angular velocity (Table II), energy, and angular momentum given by

\[ \tilde{\Omega}_{isco} \equiv M\Omega = \frac{1}{\tilde{r}_{isco}^{3/2} + a}, \tag{2.6} \]

\[ \tilde{E}_{isco} \equiv \frac{E_{isco}}{\mu} = \frac{E_{isco}}{\eta M} = \frac{1 - 2/\tilde{r}_{isco} + a/\tilde{r}_{isco}^{3/2}}{\sqrt{1 - 3/\tilde{r}_{isco} + 2a/\tilde{r}_{isco}^{3/2}}}, \tag{2.7} \]

\[ \tilde{L}_{isco} \equiv \frac{L_{isco}}{\mu M} = \frac{L_{isco}}{\eta M^2} = \frac{2}{\sqrt{3\tilde{r}_{isco}}} \left( 3\sqrt{\tilde{r}_{isco}} - 2a \right). \tag{2.8} \]

As the body nears the isco, its inspiral gradually ceases to be adiabatic and it enters the transition regime (Sec. II). Radiation reaction (as controlled by \( \dot{E}_{GW} \)) continues to drive the orbital evolution throughout the transition regime, but gradually becomes unimportant as the transition ends and pure plunge takes over.

The plunge is described by high accuracy by reaction-free geodesic motion; Eqs. (3.32) of Ref. [4]. Up to fractional corrections of order \( \eta^{4/5} \), the orbital energy and angular momentum of the plunging body are equal to \( \tilde{E}_{isco} \) and \( \tilde{L}_{isco} \) throughout the plunge. [cf. Eq. (3.26) below].

### III. THE TRANSITION FROM ADIABATIC INSPIRAL TO PLUNGE

#### A. Qualitative Explanation of Transition

As the body nears its innermost stable circular orbit, \( r = \tilde{r}_{isco} \), the adiabatic approximation begins to break down. This breakdown can be understood in terms of the effective potential, which governs geodesic radial motion via the equation

\[ \left( \frac{dr}{d\tau} \right)^2 = \left( \frac{d\tilde{r}}{d\tilde{\tau}} \right)^2 = \tilde{E}^2 - V(\tilde{r}, \tilde{E}, \tilde{L}), \tag{3.1} \]

where \( \tilde{E} \equiv E/\mu = E/(\eta M), \tilde{L} \equiv L/(\mu M) = L/(\eta M^2) \), and \( \tilde{\tau} \equiv \tau/M \) are the body’s dimensionless energy, angular momentum, and proper time. The explicit form of the effective potential can be inferred from Eqs. (3.32) and (3.33) of MTW [4]:

\[ V(\tilde{r}, \tilde{E}, \tilde{L}) = \tilde{E}^2 - \frac{1}{\tilde{r}^4} \left( [\tilde{E}(\tilde{r}^2 + a^2) - \tilde{L}a]^2 - (\tilde{r}^2 - 2\tilde{r} + a^2)[\tilde{r}^2 + (\tilde{L} - \tilde{E}a)^2] \right). \tag{3.2} \]

For a Schwarzschild black hole, this reduces to

\[ V(\tilde{r}, \tilde{E}, \tilde{L}) = \left( 1 - \frac{2}{\tilde{r}} \right) \left( 1 + \frac{\tilde{L}^2}{\tilde{r}^2} \right) \quad \text{for } a = 0 \tag{3.3} \]

(cf. Eq. (25.16) of MTW [4]).

Throughout the inspiral and transition regimes, the body moves along a nearly circular orbit; its change of radius during each circuit around the hole is \( \Delta r \ll r \). (Only after the body is well into its final plunge toward the hole does \( \Delta r \) become comparable to \( r \).) This near-circular motion guarantees that the ratio of the energy radiated to angular momentum radiated is equal to the body’s orbital angular velocity [4]:

\[ \frac{d\tilde{E}}{d\tilde{\tau}} = \tilde{\Omega} \tilde{L}. \tag{3.4} \]

Correspondingly, in and near the transition regime, which occupies a narrow range of radii around \( \tilde{r}_{isco} \), the body’s energy and angular momentum are related by

\[ \tilde{E} = \tilde{E}_{isco} + \tilde{\Omega}_{isco}\xi, \quad \tilde{L} = \tilde{L}_{isco} + \xi. \tag{3.5} \]

By combining Eqs. (2.3) and (2.8), we can regard the body’s effective potential as a function of \( \tilde{r} \) and the difference \( \xi \equiv \tilde{L} - \tilde{L}_{isco} \) of its orbital angular momentum from that of the isco.

* In reality, finite-mass-ratio effects, including those discussed in the paragraph preceding Eq. (6.11) below, will alter these energy-angular-momentum relations by amounts that scale as the first and higher powers of \( \eta \). For example, in going from Eq. (6.3) to (6.4), there can be an integration constant \( \delta \tilde{E} \) (which scales as \( \eta \) or some higher power) so \( \tilde{E} = \tilde{E}_{isco} + \delta \tilde{E} + \tilde{\Omega}_{isco}\xi \). In the presence of such effects, we redefine \( \tilde{r}_{isco} \), \( \tilde{E}_{isco} \), and \( \tilde{L}_{isco} \) to be the values of these parameters at which the \( \eta \)-corrected \( V(\tilde{r}, \tilde{E}, \tilde{L}) \) has a flat inflection point, as in Fig. 3 and \( \tilde{\Omega}_{isco} \) to be the orbital angular velocity at this \( \tilde{r}_{isco} \). Then Eqs. (3.3) remain valid even for finite mass ratio \( \eta \).
B. Equation of Motion for Transition Regime

Throughout the transition regime, because the body moves on a nearly circular orbit with radius close to \( r_{\text{isco}} \), and because the body’s small mass \( \mu \equiv \eta M \ll M \) keeps its radiation reaction weak, its angular momentum remains very close to \( \Omega_{\text{isco}} \)

\[
\frac{d\tilde{\theta}}{dt} \equiv \tilde{\Omega} \simeq \tilde{\Omega}_{\text{isco}} ,
\]

and its proper time ticks at very nearly the standard isco rate

\[
\frac{d\tilde{\tau}}{dt} \simeq \left( \frac{\tilde{d}\tilde{\tau}}{d\tilde{t}} \right)_{\text{isco}} = \frac{\sqrt{1 - 3/\tilde{r}_{\text{isco}} + 2a/\tilde{r}_{\text{isco}}^{3/2}}}{1 + a/\tilde{r}_{\text{isco}}^{3/2}} ;
\]

(cf. Eq. (5.4.5a) of [10]).

This nearly circular motion at \( \tilde{r} \simeq \tilde{r}_{\text{isco}} \) produces gravitational waves which carry off angular momentum and energy at very nearly the same rate as they would for circular geodesic motion at \( \tilde{r}_{\text{isco}} \). This means that \( \tilde{E} \) and \( \tilde{L} \) evolve in accord with Eqs. (3.5), where

\[
\frac{d\xi}{d\tilde{\tau}} = -k\eta ,
\]

and

\[
k = \frac{32}{5} \tilde{\Omega}_{\text{isco}}^{7/3} \frac{1 + a/\tilde{r}_{\text{isco}}^{3/2}}{\sqrt{1 - 3/\tilde{r}_{\text{isco}} + 2a/\tilde{r}_{\text{isco}}^{3/2}}} \tilde{\dot{r}}_{\text{isco}} ;
\]

(cf. Eqs. (2.3), (3.5), (3.7), and Table I). It is the smallness of \( \eta \equiv \mu/M \) (e.g., \( \eta = 10^{-5} \) for the realistic case of a 10\( M_\odot \) black hole spiraling into the 10\(^6\)\( M_\odot \) black hole) that makes the angular momentum \( \xi \) evolve very slowly and keeps the body in a nearly circular orbit throughout the transition regime (cf. the factors of \( \eta \) that appear in Eqs. (3.3) and (3.2)—which with Eqs. (3.11) and (3.22) imply \( dr/d\tilde{\tau} \propto \eta^{7/3} \)).

In the transition regime, the body’s radial motion is described by the geodesic equation of motion with a radial self force per unit mass \( \eta \tilde{F}_{\text{self}} \) inserted on the right-hand side:

\[
\frac{d^2\tilde{r}}{d\tilde{\tau}^2} = -\frac{1}{2} \frac{\partial V(\tilde{r}, \xi)}{\partial \tilde{r}} + \eta \tilde{F}_{\text{self}} .
\]

This radial self force, like the radiation reaction force that drives the inspiral, is produced by interaction of the body with its own gravitational field—field having been influenced by the black hole’s spacetime geometry; see, e.g., Ref. [10]. The contravariant radial component of the self force, with dimensionality restored using \( \tau = M\tilde{\tau} \) and \( \tau = M\tilde{\tau} \), is \((d\tilde{p}^r/d\tilde{\tau})_{\text{self}} = (\mu \tilde{\nu}^2 \tilde{r} / d\tilde{\tau}^2)_{\text{self}} = (\mu / M)(d^2\tilde{r} / d\tilde{\tau}^2)_{\text{self}} = \eta^2 \tilde{F}_{\text{self}} \).
(We write it as $\eta F_{\text{self}}$ because its magnitude is proportional to $\eta = \mu/M$.)

The radial self force $\eta F_{\text{self}}$ is nondissipative (since it has hardly any radial velocity with which to couple). This contrasts with the $\phi$-directed radiation-reaction force, which couples to the orbital angular velocity to produce a shrinkage of the body’s spacetime geometry \[11–13\]. In this paper, we shall ignore all such self force or absorb it into $\eta$ the various parameters that characterize the effective potential: the location $\tilde{r}_{\text{isco}}$ of the innermost stable circular orbit (at which the $\xi = 0$ effective potential curve has its inflection point), the values at the isco of the orbital energy and angular momentum $\tilde{E}_{\text{isco}}$ and $\tilde{L}_{\text{isco}}$, and the constant $\alpha$ defined below. There will be other $O(\eta)$ changes in $\tilde{r}_{\text{isco}}$, $\tilde{E}_{\text{isco}}$, $\tilde{L}_{\text{isco}}$, and $\alpha$ caused by the body’s own perturbation of the hole’s spacetime geometry \[11–13\]. In this paper, we shall ignore all such changes, and correspondingly we shall neglect the radial self force $\eta F_{\text{self}}$.

We shall describe the body’s location in the transition regime by

$$R \equiv \tilde{r} - \tilde{r}_{\text{isco}}. \quad (3.11)$$

Throughout the transition regime both $R$ and $\xi$ are small, and correspondingly the effective potential can be expanded in powers of $R$ and $\xi$. Up through cubic terms in $R$ and linear terms in $\xi$ (the order needed for our analysis), the effective potential takes the form

$$V(R, \xi) = \frac{2\alpha}{3} R^3 - 2\beta R\xi + \text{constant}, \quad (3.12)$$

where $\alpha$ and $\beta$ are positive constants that we shall evaluate below. Note that for $\xi = 0$, this is a simple cubic potential with inflection point at $R = 0$, i.e. at $\tilde{r} = \tilde{r}_{\text{isco}}$; and note that for $\xi > 0$, it acquires a maximum and a minimum, while for $\xi < 0$ it is monotonic; cf. Fig. \[\text{a}\]. By inserting Eq. \[\text{12}\] into Eq. \[\text{10}\], setting $\tilde{r} = \tilde{r}_{\text{isco}} + R$, and neglecting the radial self force or absorbing it into $\tilde{r}_{\text{isco}}$, $\alpha$ and $\beta$ as described above, we obtain the following radial equation of motion:

$$\frac{d^2 R}{d\tilde{t}^2} = -\alpha R^2 + \beta \xi. \quad (3.13)$$

By then setting $\tilde{\tau} \equiv 0$ at the moment when $\xi = 0$ and using Eq. \[\text{3.8}\] for the rate of change of $\xi$, so

$$\xi = -\eta \kappa \tilde{\tau}, \quad (3.14)$$

we bring our equation of motion into the form

$$\frac{d^2 R}{d\tilde{\tau}^2} = -\alpha R^2 - \eta \beta \kappa \tilde{\tau}. \quad (3.15)$$

We shall explore the consequences of this equation of motion in the next subsection, but first we shall deduce the values of $\alpha$ and $\beta$.

The constants $\alpha$ and $\beta$ can be evaluated from the following relations, which follow directly from \[\text{3.12}, \text{3.11}\] and \[\text{3.5}\]:

$$\alpha = \frac{1}{4} \left( \frac{\partial^2 V(\tilde{r}, \tilde{E}, \tilde{L})}{\partial \tilde{r}^2} \right)_{\text{isco}}, \quad (3.16)$$

$$\beta = -\frac{1}{2} \left( \frac{\partial^2 V(\tilde{r}, \tilde{E}, \tilde{L})}{\partial \tilde{L} \partial \tilde{r}} + \Omega \frac{\partial^2 V(\tilde{r}, \tilde{E}, \tilde{L})}{\partial \tilde{E} \partial \tilde{r}} \right)_{\text{isco}}. \quad (3.17)$$

By inserting expression \[\text{3.2}\] into these relations, we obtain $\alpha$ and $\beta$ in the limit $\eta \equiv \mu/M \to 0$:

$$\alpha = \frac{3}{\tilde{r}_{\text{isco}}^3} \left( \tilde{r}^2 + 2a^2(\tilde{E}^2 - 1) - \tilde{L}^2 \tilde{r} + 10(\tilde{L} - a \tilde{E})^2 \right)_{\text{isco}}$$

$$\beta = \frac{1}{1296} \quad \text{for } a = 0, \quad (3.18)$$

$$\beta = \frac{2}{\tilde{r}_{\text{ISCO}}^3} \left( (\tilde{L} - a^2 \tilde{E}) \tilde{t} - 3(\tilde{L} - a \tilde{E})(1 - a \tilde{\Omega}) \right)_{\text{isco}}$$

$$= \frac{1}{36\sqrt{3}} \quad \text{for } a = 0. \quad (3.19)$$

Here $\tilde{r}_{\text{isco}}$ and $\tilde{\Omega}_{\text{isco}}$ are given by Eqs. \[\text{2.5} \text{ and } \text{2.6}\] and $\tilde{L}_{\text{isco}}$ and $\tilde{E}_{\text{isco}}$ are expressed in terms of $\tilde{r}_{\text{isco}}$ by Eqs. \[\text{2.7}\] and \[\text{2.8}\]. Numerical values of $\alpha$ and $\beta$, computed from these equations, are tabulated in Table \[\text{III}\].

### C. Solution for Motion in the Transition Regime

The equation of motion in the transition regime, Eq. \[\text{3.15}\], can be converted into dimensionless form by setting

$$R = \eta^{2/5} R_o X, \quad \tilde{\tau} = \eta^{-1/5} \tau_o T, \quad (3.20)$$

where

$$R_o = (\beta \kappa)^{2/5} \alpha^{-3/5}, \quad \tau_o = (\alpha \beta \kappa)^{-1/5}; \quad (3.21)$$

cf. Table \[\text{III}\]. The resulting dimensionless equation of motion is

$$\frac{d^2 X}{dT^2} = -X^2 - T. \quad (3.22)$$

We seek the unique solution of this differential equation which, at early times $T \ll -1$, joins smoothly onto the adiabatic inspiral solution of Sec. \[\text{II}\]. In that adiabatic inspiral, the orbit is the circle at the minimum of the effective potential of Fig. \[\text{a}\] and Eq. \[\text{12}\], i.e., the circle at $R = \sqrt{\beta \kappa} / \alpha = \sqrt{-\beta \kappa \tilde{\tau} / \alpha}$, which translates into

$$X = \sqrt{-T} \quad \text{for adiabatic inspiral near the isco. \quad (3.23)}$$
Adiabatic Inspiral: The analytic solution \( (3.23) \) for adiabatic inspiral outside the isco. Transition: The numerical solution to the dimensionless equation of motion \( (3.22) \) for the transition regime in the vicinity of the isco. Plunge: The analytic solution \( (3.25) \) for the orbital plunge inside the isco.

\[
\begin{align*}
\text{Adiabatic Inspiral} & \quad \text{Transition} & \quad \text{Plunge} \\
\text{FIG. 2. Dimensionless orbital radius } & \quad \text{FIG. 3. Same as Fig. 2, but drawn on a different scale.}
\end{align*}
\]

We have not been able to find an analytic formula for the solution to the equation of motion \( (3.22) \) that joins smoothly onto this adiabatic solution, but it is easy to construct the unique solution numerically. It is plotted in Figures 2 and 3, along with the adiabatic inspiral solution \( (3.23) \) and the plunge solution \[Eq. (3.25) \text{ below}]\.

The transition solution is well approximated by adiabatic inspiral at times \( T < -1 \), but at \( T > -1 \) it deviates from adiabatic inspiral and evolves smoothly into a plunge. The solution diverges \( (X \to -\infty) \) at a finite time \( T = T_{\text{plunge}} \sim 3.412 \).

In the plunge regime, radiation reaction is unimpor-

\[1\]The divergence of \( X \) at \( T = T_{\text{plunge}} \) does not imply a divergence of \( r \) or any other physical quantity. Rather, it marks the breakdown of the transition approximation at very large values of \(|X|, |X| \gtrsim X_{\text{break}} \sim \eta^{-2/5} \); \[cf. Eq. (3.23)\]. More specifically, when \( -X \gtrsim X_{\text{break}} \), higher-order terms tant; i.e., the orbit evolves inward with (very nearly) constant orbital angular momentum \( \tilde{L} \sim \tilde{L}_{\text{final}} \) and energy \( \tilde{E} \sim \tilde{E}_{\text{final}} \) (which we evaluate below); i.e., the orbit is well approximated by geodesic free fall. In the dimensionless equation of motion \( (3.22) \), the free-fall approximation translates into neglecting the last term, \( T \), so \( d^2X/dT^2 = -X^2 \), which has the analytic first integral

\[
dX/dT = -\sqrt{\text{constant} - \frac{2}{3}X^3}. \quad (3.24)
\]

For large \(|X|\), the constant can be neglected and we obtain the analytic solution

\[
X = \frac{-6}{(T_{\text{plunge}} - T)^2} \quad \text{for plunge near the isco,} \quad (3.25)
\]

which is plotted in Figs. 2 and 3.

Combining Eqs. \( (3.5), (3.14), \) and \( (3.20) \), one finds that throughout the transition regime, the energy and angular-momentum deficits (i.e., the deviations of \( \tilde{E} \) and \( \tilde{L} \) from their isco values) scale as \( \eta^{4/5} \). In particular, the final deficits in the plunge stage are given by

\[
\begin{align*}
\tilde{L}_{\text{final}} - \tilde{L}_{\text{isco}} &= - (\kappa \tilde{\eta} T_{\text{plunge}}) \eta^{4/5}, \\
\tilde{E}_{\text{final}} - \tilde{E}_{\text{isco}} &= - \tilde{\Omega}_{\text{isco}} (\kappa \tilde{\eta} T_{\text{plunge}}) \eta^{4/5},
\end{align*} \quad (3.26)
\]

where, as was noted above,

\[
T_{\text{plunge}} = 3.412. \quad (3.27)
\]

\[\quad\]

**IV. GRAVITATIONAL WAVES FROM TRANSITION REGIME, AND THEIR OBSERVABILITY**

The gravitational waves emitted in the transition regime are all near the orbital frequency \( 2\pi \Omega_{\text{isco}} \) and its harmonics. The strongest waves are at the second harmonic (twice the orbital frequency):

\[
f \sim 2 \frac{\Omega_{\text{isco}}}{2\pi} = \frac{\tilde{\Omega}_{\text{isco}}}{\pi M}. \quad (4.1)
\]

in the Taylor expansion \( (3.12) \) become important and stop the divergence. Well before this (in fact, throughout the range \( 1 \ll -X \ll X_{\text{break}} \)) both the transition approximation and the free-fall approximation \( (\tilde{E} = \tilde{E}_{\text{final}} = \text{constant}, \tilde{L} = \tilde{L}_{\text{final}} = \text{constant}) \) are valid, so these two approximations can be matched in this regime to obtain a solution valid all the way down to the horizon. The same type of breakdown also occurs at the other asymptotic limit \( +X \gtrsim X_{\text{break}} \): The transition regime’s adiabatic-inspiral equation \( (3.23) \) breaks down and must be replaced, via matching at \( 1 \ll X \ll X_{\text{break}} \), by the exact Kerr metric’s adiabatic inspiral formulae \[4\].
We shall compute their properties.

The transition waves last for a proper time \( \Delta t = M \Delta \tau_{\text{source}} \), during which the body spirals inward through a radial distance \( \Delta r = M \Delta \tilde{r}_{\text{source}} \), where \( \Delta \tilde{r} \) covers the range \( \tau \approx -1 \) to \( \approx 2.3 \) and \( \Delta X \) covers the range \( X \approx 1 \) to \( X \approx -5 \) (Fig. 3); i.e.,

\[
\Delta T = 3.3, \quad \Delta X = 6. \tag{4.2}
\]

Correspondingly, neglecting any cosmological redshift, the duration of the transition waves as seen at Earth is

\[
\Delta t = \frac{M}{(d\tilde{r}/dt)_{\text{source}}} \eta^{-1/5} \tilde{r}_{\text{source}} \Delta T, \tag{4.3}
\]

and their frequency band is \( \Delta f = (1/\pi M)(d\tilde{r}/dt)_{\text{source}} \Delta \tilde{r} \), which, using the above expression for \( \Delta \tilde{r} \) and Eq. (2.1) for \( \tilde{r} \), gives

\[
\Delta f = \frac{3}{2\pi M} \tilde{r}_{\text{source}} \sqrt{(\tilde{r}_{\text{source}}^2/5) \tilde{r}_{\text{source}} \Delta X}. \tag{4.4}
\]

The total number of cycles of these transition waves is

\[
N_{\text{cyc}} = f \Delta t = \frac{\tilde{r}_{\text{source}} \eta^{-1/5} \Delta T}{\pi (d\tilde{r}/dt)_{\text{source}}}. \tag{4.5}
\]

These second-harmonic waves arriving at Earth have the form

\[
\begin{align*}
\eta_+ &= h_{\text{amp}} \cos(2\pi f dt + \varphi_+), \\
\eta_\times &= h_{\text{amp}} \cos(2\pi f dt + \varphi_\times),
\end{align*}
\]

where \( \varphi_+ \) and \( \varphi_\times \) are constant phases. The amplitudes \( h_{\text{amp}} \) depend on the source’s orientation. When one squares and adds these amplitudes and then averages over the sky (“...”), one obtains an rms amplitude

\[
h_{\text{amp}}^{\text{rms}} = (h_{\eta_+ \text{amp}}^2 + h_{\eta_\times \text{amp}}^2)^{1/2}, \tag{4.6}
\]

which is related to the power being radiated into the second harmonic by \( \dot{E}_2 = 4\pi D^2 (h_{\text{amp}}^{\text{rms}})^2 (2\pi f)^2/32\pi \); cf. Eq. (35.27) of MTW. Here \( D \) is the distance to the source. Equating this to the radiated power

\[
\dot{E}_2 = (32/5)\eta^2 \tilde{r}_{\text{source}}^{10/3} \tilde{\epsilon}_{\infty,2}, \tag{4.7}
\]

where \( \tilde{\epsilon}_{\infty,2} \) is a relativistic correction factor listed on the first line of Table IV of [3], we obtain the following expression for the waves’ rms amplitude

\[
h_{\text{amp}}^{\text{rms}} = \frac{8}{\sqrt{5}} \frac{M \eta}{D} \tilde{r}_{\text{source}}^{2/3} \sqrt{\tilde{\epsilon}_{\infty,2}}. \tag{4.7}
\]

The signal to noise ratio \( S/N \) that these waves produce in LISA depends on the orientations of LISA and the source relative to the line of sight between them. When one squares \( S/N \) and averages over both orientations, then takes the square root, one obtains [4]

\[
\left( \frac{S}{N} \right)_{\text{rms}} = \frac{h_{\text{amp}}^{\text{rms}}}{\sqrt{3} h_\text{amp}(f)/\Delta t}. \tag{4.8}
\]

Here \( 5S_h(f) \) is the spectral density of LISA’s strain noise inverse-averaged over the sky and \( 1/\Delta t \) is the bandwidth associated with the waves’ duration \( \Delta t \).

The noise spectral density \( S_h(f) \) for the current strawman design of LISA has been computed by the LISA Mission Definition Team [5]. An analytic fit to this \( S_h(f) \), after averaging over some small-amplitude oscillations that occur at \( f > 0.01 \) Hz, is the following:

\[
S_h(f) = \left[ \left( 4.6 \times 10^{-21} \right)^2 + \left( 3.5 \times 10^{-26} \right)^2 \left( \frac{1}{\text{Hz}} \right)^4 \right] \tag{4.9}
\]

\[
+(3.5 \times 10^{-19})^2 \left( \frac{f}{1\text{Hz}} \right)^2 \text{Hz}^{-1}.
\]

The rate for \( \mu \sim 10 M_\odot \) black holes to spiral into \( M \sim 10^6 M_\odot \) black holes in galactic nuclei has been estimated by Sigurdsson and Rees [3]: their “very conservative” result is \( \sim 1 \) event per year out to 1 Gpc. The inspiraling holes are likely to be in rather eccentric, nonequatorial orbits [3], for which our analysis needs to be generalized. If, however, the orbit is circular and equatorial and the holes are at 1 Gpc distance, then the above formulas give the numbers shown in Table 1.

As shown in the table, the signal to noise for this source is of order unity. With some luck in the orientation of LISA, the orientation of the source, the distance to the source, and/or the holes’ masses, a \( S/N \) of a few might occur. Since the signal would already have been detected from the much stronger adiabatic inspiral waves, this signal strength could be enough to begin to explore the details of the transition from inspiral to plunge.

\[\text{V. CONCLUSIONS}\]

Our analysis of the transition regime has been confined to circular, equatorial orbits. This is a serious constraint, since there is strong reason to expect that most inspiraling bodies will be in orbits that are strongly noncircular and nonequatorial [3]. Our estimated signal-to-noise ratio, \( S/N \sim 1 \), for LISA’s observations of the transition
regime from a circular, equatorial orbit at the plausible
distance $\sim 1$ Gpc suggests that for more realistic orbits
the transition regime might be observable. This prospect
makes it important to generalize our analysis to more
realistic orbits.

Full analyses for equatorial, noncircular orbits and for
nonequatorial, circular orbits can be carried out using
techniques now in hand: the Teukolsky formalism, and
computations of the orbital evolution based on the en-
ergy and angular momentum radiated down the hole and
off to infinity (see, e.g., Ref. [5] and references therein).
For nonequatorial, noncircular orbits, the analysis should
also be possible with existing techniques — up to an un-
known radiation-reaction-induced rate of evolution of the
Carter constant. That unknown quantity could be left as
a parameter in the analysis, to be determined when cur-
cent research on gravitational radiation reaction [17,18,6]
has reached fruition.

When this paper was in near final form, we became
aware of a similar analysis, by Buonanno and Damour
[19], of the transition from inspiral to plunge. Whereas
we treat the case of infinitesimal mass ratio $\eta \ll 1$ and
finite black-hole spin $-1 < a < +1$, Buonanno and
Damour treat finite $\eta$ ($0 < \eta \leq 1/4$) and vanishing spins
$a = 0$. Both analyses give the same dimensionless equa-
tion of motion (3.22) for the transition regime.

ACKNOWLEDGMENTS

We thank James Anderson for helpful discussions,
Theocharis Apostolatos and Richard O’Shaughnessy for
checking some details of our analysis, and Sam Finn for
helpful advice and for permission to use unpublished re-
sults from his numerical solutions of the Teukolsky equa-
tion; see Tables I and II. This work was supported in part
by NASA grant NAG5-6840, and in view of its potential
applications to LIGO, also by NSF grant AST-9731698.
