(Dated: June 13, 2022)

Motivated by cold atom experiments and a desire to understand far-from-equilibrium quantum transport, we analytically study the dynamics of spin helices in the 1D XX model. We use a Jordan-Wigner transformation to map the spin chain onto a non-interacting Fermi gas with simple equations of motion. The resulting dynamics are non-trivial, however, as the spin-helix initial condition corresponds to a highly non-equilibrium distribution of the fermions. We find a separation of timescales between the in-plane and out-of-plane spin dynamics. We gain insights from analyzing the case of a uniform spin chain and from a semiclassical model. One of our key findings is that the spin correlation functions decay as $t^{-1/2}$ at long time, in contrast to the experimentally-observed exponential decay.

I. INTRODUCTION

Much of our modern understanding of highly-entangled quantum matter has come from the study of spin chains. Exemplary phenomena include topological order [1, 2] and many-body localization [3]. Spin chain models were also pivotal in developing numerical techniques such as the density matrix renormalization group [4]. Cold atom experiments can now controllably implement spin chain models, allowing experimental investigation of their properties [5, 6]. While the models are old, the cold atom realizations naturally lend themselves to experimentally studying novel scenarios. For example, Jepsen et al. [5] initialized a spin chain in a helix and then observed how it evolved under the 1D XX or XXZ model Hamiltonians. Studies of such highly non-equilibrium dynamics are relatively rare, and this particular scenario has not been previously explored. Here, we model this spin helix dynamics experiment in the case of the XX model.

The XX model is an extreme limit of the anisotropic Heisenberg model, where the two in-plane components of the exchange coupling are equal and the out-of-plane coupling vanishes:

$$ H = \sum_{j} J [\sigma_{j}^{x} \sigma_{j+1}^{x} + \sigma_{j}^{y} \sigma_{j+1}^{y}]. \quad (1) $$

Here $j$ labels the site on the chain, $\sigma_{j}^{\mu}$ is the Pauli matrix for the $\mu$-th component ($\mu = x, y$), and $J$ is the strength of the coupling. The importance of this model comes from the fact that it can be mapped onto a gas of non-interacting spinless fermions. This mapping nominally reduces all static and dynamic calculations to exercises in single-particle quantum mechanics. Related transformations have become ubiquitous in condensed matter physics [7, 8]. We use this mapping to model the experiment of Jepsen et al. [5].

In that experiment, a gas of (bosonic) $^7$Li atoms are trapped in an ensemble of 1D optical lattices, nominally with one particle per site. Strong interactions suppress hopping, and the $\sigma_{j}^{z} = \pm 1$ spin states correspond to different hyperfine states of the localized atoms. Superexchange leads to nearest-neighbor spin-spin interactions, whose strength can be tuned with a Feshbach resonance. This allows the implementation of Eq. (1) or other spin models. The spin chain is initialized in a helix with $\langle \sigma_{j}^{x} \rangle = -\cos(Qj + \phi)$ and $\langle \sigma_{j}^{y} \rangle = \sin(Qj + \phi)$, where $Q = 2\pi/\lambda$ is the wavevector of the helix and $\phi$ is its phase.

In the language of fermions, the spin-helix initial state is highly unusual. We diagonalize the single-particle density matrix and show that the state is made up of several bands with fractional occupation. Starting from this initial state, we calculate the dynamics of spin correlations. Their time dependence is expressed in terms of a sum of Bessel functions, from which the long-time asymptotics are readily extracted. We compare these exact results to semiclassical and long-wavelength approximations. This leads to a physical picture in terms of spin precession and quantum spin diffusion, with the correlations decaying as $t^{-1/2}$.

The experiment instead found that this decay was exponential and used the $Q$-dependence of the time constant to distinguish between models with different transport regimes (ballistic, superdiffusive, diffusive, and sub-diffusive). Although we do not model it here, the discrepancy is likely due to the presence of empty sites in their lattice or inhomogeneities in their optical potentials or magnetic fields. The accurate quantum simulation of iconic spin models in the future will require addressing such complications.

The outline of the paper is as follows. In Sec. II, we describe the Jordan-Wigner transformation and examine the spin helix from the fermion perspective. We analyze the single-particle density matrix, describing the normal modes. In Sec. III, we detail the formalism for calculating spin correlations, and in Sec. IV, we present our results. In addition to calculating the exact dynamics, we present a long-wavelength approximation and compare to the semiclassical dynamics. Finally, we compare our results to the motivating experiment of Jepsen et al. [5] in Sec. V before giving a brief summary and outlook in Sec. VI.
II. SETUP

A. Jordan-Wigner Transformation

The XX model in Eq. (1) is diagonalized by mapping the Pauli spin operators onto fermionic operators via the Jordan-Wigner transformation,

\[
\sigma_j^+ = 2e^{-i\pi \sum_{k=1}^{j-1} n_k a_j^\dagger}, \\
\sigma_j^- = 2e^{i\pi \sum_{k=1}^{j-1} n_k a_j}, \\
\sigma_j^z = 2n_j - 1,
\]

where \(a_j\) and \(a_j^\dagger\) are fermion annihilation and creation operators, and the fermion occupation number operator is \(n_j = a_j^\dagger a_j\). Under this transformation, Eq. (1) becomes

\[
H = 2J \sum_j \left[ a_j a_{j+1} a_j^\dagger a_{j+1}^\dagger \right] \\
= \sum_k \epsilon(k) b_k^\dagger b_k,
\]

where \(\epsilon(k) = 4J \cos(k)\) is the fermion dispersion, \(b_k = L^{-1/2} \sum_j e^{-ikj} a_j\), and \(L\) is the number of sites.

B. Initial Conditions

In Ref. [5], the spins are chosen to form a helix in the \(x-z\) plane,

\[
|\psi\rangle = \prod_j \left[ A_{j,\uparrow} |\uparrow\rangle_j + A_{j,\downarrow} |\downarrow\rangle_j \right],
\]

where

\[
A_{j,\uparrow} = \sin \left( \frac{Qj + \phi}{2} \right), \quad A_{j,\downarrow} = \cos \left( \frac{Qj + \phi}{2} \right),
\]

and where, as previously introduced, \(Q = 2\pi / \lambda\) is the helix wavevector and \(\phi\) is the initial phase of the helix. This models a helix which satisfies \(\langle \sigma_j^z \rangle = -\cos(Qj + \phi)\) and \(\langle \sigma_j^z \rangle = \sin(Qj + \phi)\). In the fermion picture, we calculate the single-particle density matrix,

\[
\rho_{lm} = \langle a_l^\dagger a_m \rangle = \langle \sigma_l^+ \sigma_m^- \prod_i \sigma_i^z \rangle \\
= \langle \sigma_l^+ \rangle \langle \sigma_m^- \rangle \prod_i \langle \sigma_i^z \rangle,
\]

where the product is over all \(i\) between \(l\) and \(m\), exclusive, and we used that the spins on different sites are uncorrelated. The diagonal elements are \(\rho_{ll} = |A_{l,\uparrow}|^2\), and the off-diagonal ones are

\[
\rho_{lm} = A_{m,\uparrow}^* A_{m,\downarrow} A_{l,\downarrow}^* A_{l,\uparrow} \left( \prod_i (|A_{i,\downarrow}|^2 - |A_{i,\uparrow}|^2) \right),
\]

where \(i\) runs from \(\min(1,m)+1\) to \(\max(1,m)-1\).

Again \(i\) runs from \(\min(1,m)+1\) to \(\max(1,m)-1\).

An example of the matrix elements of the density matrix \(\rho_{lm}\) is shown in Fig. 1 for a chain of length \(L = 100\) and a spin helix of wavelength \(\lambda = 8\) and phase \(\phi = 0\). When \(\lambda\) is an integer, the density matrix is periodic, satisfying \(\rho_{lm} = \rho_{l+m,m+l}\). It is also largely local, with the off-diagonal elements falling off rapidly. This fall-off can be understood as a consequence of the product of \(\langle \sigma_i^z \rangle\) terms in Eq. (10). Since there are sites where \(|\langle \sigma_i^z \rangle| \neq 1\), this product always has a magnitude less than 1, leading to exponentially-falling correlations. Moreover, if there is a site where \(\langle \sigma_i^z \rangle = 0\), the density matrix has no non-zero elements with \(|l - m| > \lambda\).

The structure when \(\lambda\) is not an integer is more complicated. A rational \(\lambda = p/q\) (where \(p\) and \(q\) are relatively prime) yields a density matrix with periodicity \(p\). Irrational \(\lambda\) gives a quasi-periodic behavior. Regardless, the elements \(\rho_{lm}\) are very small when \(|l - m| \gg \lambda\). We will restrict our analysis to the case of integer \(\lambda\) and leave exploration of the more general cases to the future.

The initial state also contains pair correlations, which are encoded in \(\Delta_{lm} = \langle a_l a_m \rangle\). For \(l < m\),

\[
\Delta_{lm} = A_{m,\uparrow}^* A_{m,\downarrow} A_{l,\downarrow}^* A_{l,\uparrow} \left( \prod_i (|A_{i,\downarrow}|^2 - |A_{i,\uparrow}|^2) \right),
\]

and \(\Delta_{ml} = \Delta_{lm}^*\). As before, \(i\) runs from \(\min(1,m)+1\) to \(\max(1,m)-1\). The diagonal elements vanish, \(\Delta_{ll} = 0\). For states where the spins lie in the \(x-z\) plane, \(\Delta\) is real, and the off-diagonal elements of \(\Delta\) are equal to the off-diagonal elements of \(\rho\).
C. Bloch Bands for an Integer-Wavelength Spin Helix

To better understand the initial conditions, we diagonalize the density matrix, extracting the normal modes and their occupation numbers:

\[ \rho_{tm} = \sum_\alpha f_\alpha v_{l}^{(\alpha)} v_{m}^{(\alpha)}. \]  

(13)

Here \( f_\alpha \) is the number of fermions in mode \( \alpha \), with wavefunction \( v_{m}^{(\alpha)} \). These solve the eigenvalue problem

\[ \sum_m \rho_{tm} v_{m}^{(\alpha)} = f_\alpha v_{l}^{(\alpha)}. \]  

(14)

In a thermal ensemble of non-interacting fermions, the \( v_{l}^{(\alpha)} \) are plane waves and the occupation numbers correspond to a Fermi distribution. As we show below, the helix initial condition corresponds to a very different structure.

As previously stated, we specialize to the case where the wavelength \( \lambda \) of the helix is an integer, and \( \rho_{tm} = \rho_{t, \phi + \lambda, \phi + \lambda} \). We then use Bloch’s theorem to write the eigenvectors in the form \( v_{m}^{(\alpha)} = e^{iqm}\phi_{m}^{(\alpha)} \), where \( \phi_{m}^{(\alpha)} \) satisfies \( \phi_{m+\lambda}^{(\alpha)} = \phi_{m}^{(\alpha)} \). Periodicity in \( \lambda \) implies that \( q \in \left[-\frac{\pi}{\lambda}, \frac{\pi}{\lambda}\right] \). Writing \( m = n + s\lambda \), the eigenvalue equation Eq. (14) becomes

\[ \sum_n \Gamma_{ln}(q) \phi_{n}^{(\alpha)} = f_\alpha(q) \phi_{l}^{(\alpha)} \]  

(15)

for the \( \lambda \times \lambda \) matrix

\[ \Gamma_{ln}(q) = \sum_{s} \rho_{t, n + s\lambda} e^{iq(n-l+s\lambda)} \]

\[ = \left( \rho_{tl} + \frac{\rho_{t, n + \lambda} e^{iq\lambda}}{1 - \chi e^{iq\lambda}} + \frac{\rho_{t, n - \lambda} e^{-iq\lambda}}{1 - \chi e^{-iq\lambda}} \right) e^{iq(n-l)}, \]

where \( 0 \leq l, n < \lambda \) and \( \chi = \prod_{j=1}^{\lambda} (|A_{j,\downarrow}|^2 - |A_{j,\uparrow}|^2) \). The matrix \( \Gamma_{ln}(q) \) is numerically diagonalized to obtain occupation numbers for \( \lambda \) separate “bands” as a function of wavevector \( q \).

Figure 2 shows the bands for \( \lambda = 8 \) and \( \phi = 0 \). In this particular case there is one band for which the occupation is uniformly 0 and another for which it is uniformly 1. These are a consequence of the choice of helix phase, \( \phi = 0 \); for this \( \phi \) there are sites where the spins are pointing in the +z and −z direction. The fermions on those sites are localized and give rise to the uniformly filled/empty bands. For arbitrary \( \phi \), one instead finds a single state at \( q = 0 \) for which \( f_\alpha = 1 \), and a single state for which \( f_\alpha = 0 \). This latter state is found at \( q = \pi / \lambda \) if \( \lambda \) is odd or \( q = 0 \) if \( \lambda \) is even. The presence of a fully occupied state and a fully empty state is a generic feature of any classical spin configuration, not just helices: in complete generality \( v_{m}^{(1)} = A_{m,\uparrow}/A_{m,\downarrow} \) and \( v_{m}^{(0)} = (-1)^m A_{m,\downarrow}/A_{m,\uparrow} \) are eigenvectors of Eq. (14) with eigenvalues 1 and 0, respectively. One interesting feature of the occupation spectrum shown in Fig. 2 is that there are no “gaps.” Given any value of \( f_\alpha \), there is always a state with that occupation. This is very different from a thermal distribution in a multi-band model, where the energy gaps give rise to forbidden values of \( f_\alpha \). One can also observe a number of symmetries in Fig. 2. When \( \lambda \) is even, the helix is invariant under translation by half a wavelength combined with spin reversal. In the occupation spectrum this symmetry leads to a mapping \( f_\alpha \rightarrow -f_\alpha \). Reflection of the spins through the \( x-z \) plane maps \( q \rightarrow -q \). The helix is invariant under this transformation, and hence Fig. 2 has reflection symmetry.

III. FORMALISM

A. Dynamics within the Fermionic Picture

Within the Heisenberg picture, the dynamics of the fermion field operators are trivial:

\[ b_k(t) = e^{-i\epsilon(k)t}b_k, \]

(17)

\[ a_j(t) = \sum_m i^{j-m} J_{j-m}(4Jt) a_m, \]

(18)

where \( b_k = b_k(0) \) and \( a_j = a_j(0) \) are the zero-time operators and \( J_{\nu}(x) \) is the Bessel function of the first kind of order \( \nu \). Thus we can calculate any fermion correlation functions at time \( t \) in terms of the correlations at time 0, which were described in Sec. II B. For example, the occupation of site \( j \) is

\[ \langle n_j(t) \rangle = \sum_{lm} \rho_{tl} i^{j-m} J_{l-j}(4Jt) J_{m-j}(4Jt). \]

(19)

Due to the structure of the density matrix, this sum is dominated by terms where \( l \) and \( m \) are close together.
Consequently, the dynamics at a given site \( j \) are mainly influenced by the interference of fermions that propagate from closely-spaced sites on the chain.

### B. Spin Observables

Some spin correlations can be simply expressed in terms of the fermion degrees of freedom and are readily calculated. For example,

\[
\langle \sigma_z^j(t) \rangle = 2 \langle n_j(t) \rangle - 1
\]

(20)
can directly be calculated from Eq. (19). Others, such as \( \langle \sigma_x(t) \rangle \), are highly non-local in the fermions. A correlation function which is both easy to calculate and informative about the transverse spin degrees of freedom is

\[
E_j^{+-}(t) = \langle \sigma_j^-(t) \sigma_{j+1}^+(t) \rangle = 4 \langle a_j^+ \rangle (t) a_j(t).
\]

(21)
The real and imaginary parts of \( E_j^{+-} \) tell us about the relative alignment of the in-plane components of the spins on neighboring sites. \( \text{Re}\{E_j^{+-}\} = \langle \sigma_j^x \sigma_{j+1}^x + \sigma_j^y \sigma_{j+1}^y \rangle \) is the dot-product of the in-plane component of neighboring spins and is proportional to the local energy density. When the spins are nearly aligned, it effectively measures the magnitude of the in-plane spin components. The other quadrature, \( \text{Im}\{E_j^{+-}\} = \langle \sigma_j^x \sigma_{j+1}^y - \sigma_j^y \sigma_{j+1}^x \rangle \), measures the twisting (misalignment) of the in-plane spin components. In terms of the fermion density matrix,

\[
E_j^{+-}(t) = 4 \sum_{lm} \rho_{lm} - \delta_{lm} \langle \hat{d}_l \rangle \langle \hat{d}_{l+m-1} \rangle J_{l-j-1}(4Jt) j_{l-j-1}(4Jt).
\]

(22)

Similar expressions hold for the correlator

\[
E_j^{--}(t) = \langle \sigma_j^-(t) \sigma_{j+1}^-(t) \rangle = 4 \langle a_j(t) \rangle a_j(t)
\]

(23)

\[
= 4 \sum_{lm} \Delta_{lm} \langle \hat{d}_l \rangle \langle \hat{d}_{l+m-1} \rangle J_{l-j-1}(4Jt) j_{l-j-1}(4Jt).
\]

(24)

The real and imaginary parts of \( E_j^{--} \) are related to the in-plane quadrupolar alignment of neighboring spins:

\[
\text{Re}\{E_j^{--}\} = \langle \sigma_j^x \sigma_{j+1}^x + \sigma_j^y \sigma_{j+1}^y \rangle \quad \text{and} \quad \text{Im}\{E_j^{--}\} = -\langle \sigma_j^x \sigma_{j+1}^y + \sigma_j^y \sigma_{j+1}^x \rangle.
\]

### IV. RESULTS

#### A. Numerical Evaluation of Dynamics

Figures 3 and 4 show typical time-series for the correlation functions introduced in Sec. III B. Figure 3 shows the case where the helix wavelength is large, \( \lambda = 64 \), while Fig. 4 shows \( \lambda = 8 \), which is comparable to the experimental values in Ref. [5].

One sees that \( \langle \sigma_j^Z \rangle \) and \( E_j^{+-} \) (panels a,b,c of both figures) evolve on a slower timescale than \( E_j^{--} \) (panels d,e of both figures), and that this separation of timescales grows with \( \lambda \). In Sec. IV C we give a semiclassical argument which explains this behavior.

At \( t = 0 \), the spins lie in the \( x-z \) plane and \( \langle \sigma_j^z \rangle \) oscillates in space. The contrast of this oscillation drops with time, nearly vanishing at \( t \sim \frac{8h}{J} \) in Fig. 3 and at \( t \sim 0.8h/J \) in Fig. 4. At these times one sees large spatial oscillations in \( \text{Im}\{E_j^{+-}\} \), corresponding to patches where the in-plane components of the spins are twisting in different directions. Over time this pattern repeats, with the spatial contrast of \( \langle \sigma_j^z \rangle \) and \( \text{Im}\{E_j^{+-}\} \) oscillating out of phase. This is further examined in Sec. IV D.

On a similar timescale to the oscillation of \( \langle \sigma_j^z \rangle \), \( \text{Re}\{E_j^{--}\} \), which is proportional to the local energy density, decays to a spatially uniform pattern. This can be interpreted as evidence of energy diffusion.

The real and imaginary parts of \( E_j^{+-} \) oscillate with a period which is slightly smaller than \( h/J \). Our physical interpretation of these patterns comes from comparing a uniform pattern of quantum versus classical spins, where \( E_j^{+-} \sim (\sigma^x - i \sigma^y)^2 \) tells us about the local orientation of the in-plane component of the spins. This interpretation is discussed in Sec. IV B. At short times these patterns (together with panel b) suggest that the spins are slowly twisting about the \( z \)-axis, rotating by \( \pi \) radians over half a wavelength, and reversing direction for the next half period. At longer times the pattern is slightly more complicated, with some retrograde motion. This complicated pattern is seen for both \( \lambda = 64 \) and \( \lambda = 8 \), but it is certainly clearer in Fig. 3.

In the remainder of this paper we explain the above features and compare our results to the experiment of Ref. [5] in Sec. V.

#### B. Uniform Textures & Long-Wavelength Approximation

Key insights into the behavior in Sec. IV A come from considering the uniform case, where each spin is initially tilted the same angle \( \theta \) from the negative-\( \hat{z} \) direction: \( A_{j+1} = \cos(\theta/2) \), \( A_{j+2} = \sin(\theta/2) \). This can be thought of as a helix with \( \lambda \rightarrow \infty \). Evaluating the sums in Eq. (22) and (24) yields (see Appendix A)

\[
E^{+-}(t) = \sin^2 \theta, \quad E^{--}(t) = \left( \sum_{i=0}^{\infty} (-i)^j \cos^j(\theta)(J_i(8Jt) - J_{i+2}(8Jt)) \right).
\]

(25)

(26)
The latter expression can also be written in terms of the derivatives of Bessel functions, using the identity \( J_{2k+2}(8Jt) = J_k(8Jt) - J_{k+2}(8Jt) \). The correlation function \( E^{+-} \) is time-independent: \( \text{Re}\{E^{+-}\} \) is proportional to the local energy density, which is conserved. The imaginary part of \( E^{+-} \) is chiral, measuring an in-plane twisting, and will vanish for all time.
local field seen by each spin is not quantized in the semiclassical model.

We next use Eqs. (25)–(26) to model the dynamics of spin helices in the long-wavelength limit. Treating the spin texture as locally homogeneous, we simply replace the $\theta$ in Eqs. (25)–(26) with $\theta_j = Qj + \phi$. While such an approximation fails to give any insight into $\langle \sigma_j^z \rangle$ or $E_j^{-+}$, it is revealing in regards to $E_j^{+-}$. In particular, since $\Omega_q$ does not depend on $\theta$, the spin dynamics are approximately periodic. Both the period and the power law decay match what is seen in Figs. 3 and 4.

C. Separation of Timescales for In-Plane and Out-of-Plane Dynamics

The separation of timescales in Sec. IV A is also present in the semiclassical results shown in Appendix B and hence can be understood semiclassically. In this picture, the spin at site $j$ precesses about an effective field $\vec{H}_j = 2J (\vec{\sigma}_{j-1} + \vec{\sigma}_{j+1})_\perp$, where $\perp$ indicates that only the in-plane component is taken. This is a feature of the XX model, where the spin-spin coupling only involves the in-plane components.

Within the long-wavelength limit of a spin helix, the first-order approximation to the effective field comes from taking $\vec{\sigma}_{j-1} + \vec{\sigma}_{j+1} \approx 2\vec{\sigma}_j$. The next-order correction comes from considering that neighboring spins are mostly aligned, but twist in the direction of the helix’s winding. Hence, $\vec{\sigma}_{j-1} + \vec{\sigma}_{j+1} \approx 2\vec{\sigma}_j + \frac{d^2}{\pi^2} \partial^2 \vec{\sigma}_j \parallel$ for spacing $d$ between spins, and

$$\partial_t \vec{\sigma}_j \approx 4J (\vec{\sigma}_j \times \vec{\sigma}_{j,\perp}) + 2J \left( \vec{\sigma}_j \times \frac{d^2}{\pi^2} \partial^2 \vec{\sigma}_j \parallel \right).$$  

The first term determines twisting in the plane and has a timescale of $\Omega \sim J$, which was seen earlier for the precessional frequency. The second term is a correction which determines twisting away from the winding direction. This gives out-of-plane dynamics with a frequency $\omega \sim \frac{J}{\pi^2}$, which is suppressed by a factor of $\lambda^2$ relative to the in-plane dynamics.

D. Contrasts

For all time, the spin patterns are periodic in space with period $\lambda$. The amplitude of variation falls with time. We can quantify this decay by looking at the magnitude of the Fourier component with wavevector $Q = 2\pi/\lambda$. For example,

$$C_Q^2(t) \equiv \frac{1}{L} \sum_j e^{iQj} \langle n_j(t) \rangle. \quad (29)$$

This quantity can be expressed in terms of the Fourier transform of the initial density matrix,

$$\rho_{kn} = \frac{1}{L} \sum_{l,rm} \rho_{lm} e^{ikl} e^{-iqlm}. \quad (30)$$
Periodicity of the spin configuration implies \( \rho_{\phi+\lambda,m+n} = \rho_{m,n} \), and hence \( \rho_{kq} \) vanishes unless \( k - q = 2\pi n/\lambda \) for integer \( n \). This leads to the simple result
\[
C^+_{Q}(t) = \sum_m \left( d_m + (-1)^m d^*_m \right) J_m(8J\tau) \tag{31}
\]
for time-independent coefficients
\[
d_m = \frac{1}{\sqrt{L}} \sum_j e^{iQ(m/2-j)} \rho_{j-m,j} \tag{32}
\]
and \( \tau = \sin(Q/2)t \). Similarly, the contrast corresponding to \( E_j^+(t) = \langle \sigma_j^- (t) \sigma_{j+1}^+(t) \rangle \) is
\[
C^-_{Q}(t) = \frac{1}{\sqrt{L}} \sum_j e^{iQj} \langle \sigma_j^- (t) \sigma_{j+1}^+(t) \rangle \tag{33}
\]
\[
= 4 \sum_m \left( \tilde{d}_m + (-1)^m \tilde{d}_m^* \right) J_m(8J\tau)
\]
for the coefficients
\[
\tilde{d}_m = e^{-iQ/2}d_{m+1} = \frac{1}{\sqrt{L}} \sum_j e^{iQ(m/2-j)} \rho_{j-m-1,j}. \tag{34}
\]
For a helix with reflection symmetry across the origin (i.e. \( \phi = 0 \)), \( C_Q^+ \) is real. Since \( \text{Im}\{E_j^{++}(t)\} \) evolves on the same timescale as \( \langle \sigma_j^z \rangle \), it is convenient to display their contrasts together. Thus we extract the contrast of \( \text{Im}\{E_j^{++}(t)\} \sim C^{-+}_{Q^*}(t) = \frac{1}{2} \left( C^{-+}_{Q}(t) - (C^{+-}_{Q^*}(t))^* \right) \).

This quantity is also real when the density matrix is real, since then \( C^{-+}_{Q^*}(t) = C^{+-}_{Q}(t) \).

Figure 5 shows the time dependence of the contrasts \( C_{Q}(t) \) and \( C_{Q^*}^{-+}(t) \) for the case \( \lambda = 8 \). The most prominent feature is an out-of-phase relationship between these two contrasts. This further corroborates the out-of-phase relationship between \( \langle \sigma_j^z \rangle \) and \( \text{Im}\{E_j^{++}\} \) that was noted in Sec. IV.A. This relationship corresponds to the spins moving in and out of the \( x-y \) plane. The second important feature is the relatively slow \( t^{-1/2} \) decay, which can be extracted from the asymptotic expressions for the Bessel functions.

V. COMPARISON TO EXPERIMENT

The experiment of Jepsen et al. [5] explored spin helices with wavelengths similar to that in Fig. 4. They solely looked at the space and time dependence of \( \langle \sigma_j^z \rangle \). Other spin correlations, however, are accessible: they could apply \( \pi/2 \) pulses to image the \( x \)- and \( y \)-components of the spins. Such data could be binned and averaged to measure \( E_j^{++} \) or \( E_j^{--} \).

The experimentalists calculated the contrast of \( \langle \sigma_j^z \rangle \), to be compared with our results depicted in Fig. 5. They also used numerical techniques to model the spin dynamics. Their numerical results for the contrast appear to be identical to ours.

As already highlighted, the contrast oscillates within a decaying envelope. The experimental oscillation period is very similar to what is expected from theory, both from our calculation and their numerics. The decay, however, is very different. Our theory predicts a \( t^{-1/2} \) fall-off, while the experiment observes an exponential decay. Possible sources of this discrepancy include the presence of empty sites in the optical lattice or inhomogeneities in the magnetic fields which tune interactions in the chain.

The nature of the decay is important: the experimentalists used the \( Q \) dependence of the decay time to conclude that the dynamics in the XX model are ballistic. Given that the exact solution does not yield an exponential decay, this interpretation may be problematic.

In order to clarify the issue, we propose future experiments study the dynamics of uniformly-tilted spins, as discussed in Sec. IV.B. Many of the dynamical features of spin helices are already present in that simpler setting, but the homogeneity of the initial state will simplify the modeling of various imperfections.

VI. SUMMARY AND OUTLOOK

We studied the dynamics of far-from-equilibrium spin helices in the quantum 1D XX model. By mapping the spins onto non-interacting fermions, we were able to derive exact results for a number of spin correlators. For long-wavelength helices, we found a separation of timescales between the in-plane and out-of-plane spin dynamics. We explained these timescales by analyzing a mapping of various imperfections.

We compared our results to experiments, finding key differences which highlight an important challenge in quantum simulation: small imperfections can lead to qualitatively different physics.
The community’s newfound ability to experimentally study spin models has great potential to advance our understanding of quantum dynamics. These possibilities include studies of the dynamics of various spin configurations [9–13] and developments in generalized hydrodynamics [14–19]. The possibilities involving far-from-equilibrium physics are particularly rich, with ample opportunities to develop new organizing principles. These will have an impact on our understanding of natural phenomena, as well as the development future technology.

Appendix A: Spin Correlators for Uniform Spin Textures

When the spin texture is uniform, the spin correlator $E_j^{-}(t) = 4\langle a_{j+1}(t)a_j(t)\rangle$ is independent of site and can be replaced by its spatial average $E^{-}(t) = 1/L \sum_j E_j^{-}(t)$. This is related to the $p$-wave pairing amplitude

$$E^{-}(t) = \frac{4}{L} \sum_k e^{ik} \langle b_k(t)b_{-k}(t)\rangle.$$  

We substitute in the time dependence $b_k(t) = e^{-i\epsilon(k)t}b_k(0)$ and write $b_k(0)$ in terms of the spatial field operators $a_j = a_j(0)$. Noting that $\langle a_ia_j \rangle = \langle a_{i-j}a_0 \rangle$, we find

$$E^{-}(t) = \frac{4}{L} \sum_d \langle a_d a_0 \rangle \sum_k e^{-i(d-1)k-2i\epsilon(k)t}.$$  

(A2)

The sum over $k$ yields Bessel functions. Finally, we note that $\langle a_0 a_0 \rangle = 0$ and, for $d \neq 0$, Eq. (12) becomes

$$\langle a_d a_0 \rangle = \frac{1}{4} \sin^2(\theta) \cos^{d-1}(\theta),$$  

(A3)

which falls off exponentially. Separating out the $d > 0$ and $d < 0$ terms in Eq. (A2) yields

$$E^{-}(t) = \sin^2(\theta) \sum_{l=0}^{\infty} (-i)^l \cos^l(\theta) \left[ J_l(8Jt) - J_{l+2}(8Jt) \right],$$  

(A4)

which is Eq. (26).

Calculating $E^+(t) \equiv 1/L \sum_j E_j^+(t)$ follows a similar logic; the main difference is that the momentum space density $n_k = \langle b_k(0)b_k(t) \rangle$ appears instead of the $p$-wave pairing amplitude. Since $n_k$ is independent of time, so is $E^+$. Hence, $E^+(t) = E^+(0)$, or

$$E^+(t) = 4|A_1A_3|^2 = \sin^2(\theta).$$  

(A5)

As argued in the main text, we can use these homogeneous results to model a long-wavelength helix. We take the homogeneous expressions for the correlators, but re-
FIG. 6. Semiclassical calculation of the same observables as Fig. 3, again with wavelength $\lambda = 64$ and phase $\phi = 0$.

place $\theta \to \theta_j = Q_j + \phi$, arriving at

$$E_{j}^{-}(t) \approx \sin^2(\theta_j) \sum_{l=0}^{\infty} (-i)^l \cos^l(\theta_j) \left[ J_l(8Jt) - J_{l+2}(8Jt) \right],$$

(A6)

$$E_{j}^{+}(t) \approx \sin^2(\theta_j).$$

(A7)

Appendix B: Semiclassical Spin Dynamics

The Schrödinger equation is equivalent to extremizing the action

$$S = \int dt \left[ i \langle \psi | \partial_t | \psi \rangle - \langle \psi | \mathcal{H} | \psi \rangle \right].$$

(B1)

We take the product state ansatz, $|\psi\rangle = \prod_j |\psi_j\rangle$, where $|\psi_j\rangle = u_j(t)|\uparrow\rangle_j + v_j(t)|\downarrow\rangle_j$ with $|u_j(t)|^2 + |v_j(t)|^2 = 1$. The semiclassical equations of motion are found by extremizing Eq. (B1) with respect to $u_j(t)$ and $v_j(t)$.

In particular, we take

$$\mathcal{H} = \sum_j \sum_{\mu\nu} J_{\mu\nu} \sigma_j^\mu \sigma_j^{\nu+1}.$$ 

(B2)

The equations of motion for the spin degrees of freedom are then found to be

$$\partial_t \langle \sigma_j^\mu \rangle = \partial_t u_j \frac{\partial \langle \sigma_j^\mu \rangle}{\partial u_j} + \partial_t v_j \frac{\partial \langle \sigma_j^\mu \rangle}{\partial v_j} + \text{h.c.}$$

(B3)

$$= \sum_{\mu\nu} C_{\mu\nu} \mu H_{j}^{\mu} \langle \sigma_j^\nu \rangle,$$

(B4)

where the mean field $H_{j}^{\mu}$ is

$$H_{j}^{\mu} = 2 \sum_{\nu} J_{\mu\nu} \left( \langle \sigma_{j+1}^\nu \rangle + \langle \sigma_{j-1}^\nu \rangle \right).$$

(B5)

These equations of motion can also be written as $\partial_t \langle \sigma_j \rangle = \langle \sigma_j \rangle \times \vec{H}_j$. As one intuitively expects, each spin simply precesses about an effective field $\vec{H}_j$, which depends on the direction of its neighbors and the anisotropy of the interaction coupling. In the case of the XX model, the mean field $H_{j}^{\mu}$ has $H_{j} = 0$ and in-plane components

$$H_{j}^{\pm} = 2 J \langle \sigma_{j-1}^\pm + \sigma_{j+1}^\pm \rangle,$$

(B6)

$$H_{j}^{x} = 2 J \langle \sigma_{j-1}^{x} + \sigma_{j+1}^{x} \rangle.$$ 

(B7)

To understand the role of quantum mechanics, it is necessary to compare the exact quantum dynamics in Fig. 3 with the semiclassical results shown in Fig. 6. The semiclassical theory captures many features of the quantum spin evolution. In particular, the time dynamics for $\langle \sigma_j^\pm \rangle$, $\text{Im} \{ E_j^{-} \}$, and $\text{Re} \{ E_j^{+} \}$ are nearly indistinguishable from the quantum dynamics shown in Fig. 3(a)–(c) until $t \approx 5\hbar/J$. Hence, the same interpretation can be used for both the quantum and semiclassical cases for these three correlators (e.g. the decay of $\text{Re} \{ E_j^{-} \}$ representing energy diffusion). Beyond $t \approx 5\hbar/J$, the semiclassical simulations possess a numerical instability.

The semiclassical theory does not capture the behavior of $E_{j}^{\pm}$. To understand the discrepancy, it is useful to again consider a uniform chain as in Sec. IVB, except with semiclassical spins. Each site is identical, so $\partial_t \bar{\sigma} = \bar{\sigma} \times \vec{H}$. With $\vec{H} = 4 J (\sigma_x, \sigma_y, 0)$, we can use that $\bar{\sigma} \times \bar{\sigma} = 0$ to write $\vec{H} = \bar{\sigma} \times (\vec{H} - 4 J \bar{\sigma}) = -4 J \sigma^2 \bar{\sigma} \times \hat{z}$. This means that the semiclassical spins simply precess about the $z$-axis with frequency $\Omega_{sc} = 4 J \cos(\theta_j)$. Consequently, $\sigma^z = \sin(\theta) \cos(\Omega_{sc} t)$ and

$$E_{sc}^{\pm}(t) = \sin^2(\theta_j),$$

(B8)

$$E_{sc}^{\pm}(t) = \sin^2(\theta_j) e^{-2i\Omega_{sc} t}.$$ 

(B9)

Importantly, the precession frequency is a continuous function of the angle $\theta$. This behavior should be contrasted with the quantum behavior in Eq. (27), where regardless of $\theta$ the spins precess with frequency $\pm 4 J$. The natural interpretation is that the effective field is quantized in the full quantum theory. The semiclassical theory also fails to account for the power-law decay seen in Eq. (27).

The semiclassical result for $E_{j}^{\pm}$ can be further understood through a long-wavelength approximation. As previously argued, we can approximate the behavior of a long-wavelength helix by taking $\theta \to \theta_j = Q_j + \phi$. In this approximation, the semiclassical correlation functions become

$$E_{j,sc}^{\pm}(t) = \sin^2(\theta_j),$$

(B10)

$$E_{j,sc}^{\pm}(t) = \sin^2(\theta_j) e^{-2i\Omega_{j,sc} t},$$ 

(B11)

for $\Omega_{j,sc} = 4 J \cos(\theta_j)$. The phase factor $E_{j,sc}^{\pm}(t) \propto e^{-2i\Omega_{j,sc} t}$ corresponds to a variable helical pattern in the $x$-$y$ plane: the pitch increases linearly in time, and the spins can rotate many times about the equator. By contrast, in the quantum dynamics the $x$-$y$ components of the spins never perform a full rotation.
The full semiclassical behavior of $E_j$ in Fig. 6(d)–(e) is similar to this long-wavelength approximation, Eqs. (B10)–(B11). The aforementioned planar twisting is clear in panels (d) and (e), with the pitch becoming greatest near $t = 2\hbar/J$. Due to aliasing, the pitch then decreases. There are some quantitative differences between the long-wavelength and exact semiclassical dynamics, but the most significant difference is the numerical instability which appears at longer times. Given that the instability is not present in the quantum calculation, we do not explore it further.
