ABSTRACT: Recent poverty research based on analyses of panel data have highlighted the importance of income dynamics. In this paper we study mobility into and out of relative income poverty from one year to the next using data for twelve countries from the European Community Household Panel Survey (ECHP). The ECHP has unique potential as a harmonized data set to serve as the basis for comparisons of income and poverty dynamics across EU countries, and here we begin exploiting this potential by analysing income poverty transitions from Wave 1 to Wave 2. As well as describing the extent of these transitions, we analyse the pattern by fitting log-linear and linear by linear models commonly employed in the analysis of social mobility. Moving from general to specific models we show the relative impact of hierarchy, immobility and affinity effects. Our analysis shows that cross-national variation in short-term poverty dynamics is predominantly a consequence of ‘shift’ rather than ‘association effects’. Variation across countries in patterns of poverty persistence is extremely modest. Models that assume that the processes underlying poverty dynamics are constant across countries perform almost as well as those that allow for cross-national variability.

Key words: poverty dynamics; ECHP; welfare regimes; vicious circle processes; log-linear models; shift and association effects

Introduction

In this paper we analyse the extent and nature of entries into and escapes from income poverty from one year to the next in twelve European countries, using data from the first two waves of the European Community Household Panel Survey (ECHP). Recent international research based on the analysis of panel data has highlighted the importance of income dynamics. Such data have been used for some time in the USA but
have become available more recently in a number of other industrialized countries, notably Germany, the Netherlands and the UK. However, the ECHP has unique potential as a harmonized data set to serve as the basis for comparisons of mobility into and out of income poverty across European Union countries. In this paper we seek to begin exploiting this potential by looking at income poverty transitions from Wave 1 to Wave 2, carried out in 1994 and 1995, respectively.

Bane and Ellwood (1986), in what has become a classic article, argued that the analysis of poverty persistence was fundamental both to understanding poverty itself and to the development of anti-poverty policy. Assumptions about the long-term nature of poverty have been central to the development of debates on the 'culture of poverty' and existence or not of the 'underclass' (Gans 1990; Wilson 1987) as these focused on concerns about state dependence and vicious circle processes. More recently Leisering and Liebfried (1999) have argued that assumptions about processes of long-term poverty underlie arguments that the welfare state, by undermining people's capacity or inclination to cope, leads to dependency and entrapment. However, recent research based on panel data has argued that poverty spells are shorter than previously thought. In addition to the extensive US research based on the Panel Study of Income Dynamics (PSID), the range of studies documenting such findings now includes Jarvis and Jenkins's (1997) analysis of the British Household Panel Study, Duncan et al.'s (1993) study of eight North American and European countries, studies based on the German Socio-Economic Panel (SOEP) by Heady et al. (1994), the US/German/Netherlands comparison in Goodwin et al. (1999), and analyses of the duration of spells on social assistance such as Leisering and Liebfried (1999). Even the most cautious analysts, such as Jarvis and Jenkins (1997), conclude that from one year to the next there are significant numbers entering and escaping poverty. Leisering and Liebfried (1999: 9) have offered the somewhat bolder conclusion that 'poverty is often no more than an episode in the course of life and is actively overcome by most of those afflicted by it'.

The availability of longer runs of panel data has led to increasingly sophisticated analyses of poverty spells. Our analysis based on only two waves of the ECHP does not allow us to pursue such a course. However, it does offer a particularly valuable opportunity to analyse cross-national differences in short-term dynamics on a harmonized data set. Over and above differences in overall rates of poverty, is there any evidence that poverty is more persistent in one rather than another country? If such differences do exist, are they associated with variation in welfare regimes? To take the extreme example, Fritzell (1990: 18–19) notes that with two countries such as Sweden and the United States, which are seen as representing the two opposite poles as regards social policy, we might
expect to deduce clear-cut hypotheses regarding income or poverty dynamics from welfare regime theory. The Swedish model can be characterized in Esping-Andersen’s (1990) terms as universalist/institutional, whereas the US model can be seen as being of a selective/marginal type. In terms of ‘goals of inequality’ the former may be seen to emphasize equality of outcome and the latter equality of opportunity and, as Fritzell (1990: 19) observes, we might therefore expect differences in rates of economic mobility. Given this, Fritzell observes that while Swedish politics are seen to encourage social mobility, one might expect a focus on redistribution to lead to economic stability. In the US, on the other hand, Fritzell (1990: 20) notes, the relatively free operation of market processes might lead one to expect more ups and downs. However, Fritzell observes that the position is more complicated than this since Sweden and the US also represent opposite extremes on the distribution of income inequality and thus a move between two categorical ranks may involve a greater step, in absolute terms, in the latter rather than the former. As a consequence, ceteris paribus, one might expect greater positional movement in Sweden. This illustrates, as Dirven (1996) stresses, the importance of specifying models of mobility that take into account the income distances between different classes. Other factors that may complicate the relationship include cross-national variations in the rate of poverty and short-term variations in macroeconomic conditions. Thus Duncan et al. (1993) suggest that there is an inverse relationship between the estimated incidence of poverty and escape rates while cyclical variations in factors such as the level of unemployment might also be expected to play a role. Moreover, aspects of social policy other than cash benefits might play a role. In Sweden, for instance, active labour market policies might be expected to minimize labour market marginalization and encourage economic mobility.

As the foregoing discussion indicates, even in the case of such extremes as Sweden and the US it turns out to be a far from simple matter to specify a priori hypotheses on the basis of welfare regime theory. Instead of attempting to specify such hypotheses this paper pursues a different but necessary strategy in the analysis of poverty dynamics. In line with similar research in the field of social mobility we make use of methods of log-linear analysis to distinguish between the following kind of effects:

- **Structural effects or absolute variations in poverty mobility.** To what extent is the pattern of poverty dynamics simply a consequence of corresponding variations in the distributions across poverty categories at different points in time? If, to a large degree, we could focus our attention on explaining variations in poverty rates across countries and changes in the overall distribution, we would not need to make any reference to
processes that lead to relative differences in the likelihood of escaping from poverty.

- **The impact of differences in income distances between categories.** We expect movement between income groupings to be more likely the closer they are to each other on the income hierarchy.

- **Tendencies towards immobility within particular categories.** It may be that certain points on the income distribution are inhabited by individuals who enjoy particular advantages or have certain characteristics that allow them to maintain their current status. Thus, to anticipate one of our findings, movement from above the 60 per cent median income line to any point below may be less likely than we would expect simply by taking hierarchical distance in income into account.

- **Particular affinities or disaffinities between categories.** Thus integration of households within the welfare system may make falling below particularly low income poverty lines less likely than a perspective which sees change as simply being a question of moving up or down a uni-dimensional hierarchy.

The value of such an analysis is that it allows us to distinguish between a variety of different effects and to identify underlying patterns that may not be apparent simply from a descriptive consideration of mobility outcomes. Having identified such patterns, we can then assess the extent to which they are interpretable in terms of welfare regime variation or other theoretical formulations. In any event the establishment of firm evidence on cross-national similarities and differences is a prerequisite of progress in this area since in the absence of such evidence it remains unclear what kind of theory is required.

The value of having a data set of the highest quality to answer such questions is shown by the fact that previous research has produced a number of inconsistent results (Dirven 1996). In part, such confusion may be related to the fact that the analytic methods often employed have not been adequate to distinguish between different dimensions of cross-country differences. Dirven’s (1996) analysis is one of the few to apply to poverty mobility the range of analytic techniques current in the analysis of occupational or class mobility. In this paper we seek to show the value of applying such methods to a cross-national data set.
The ECHP data set\textsuperscript{1}

The ECHP is a unique source of information on poverty rates in the European Union because of the comparability of the data generated. Comparability is achieved through a standardized design and common technical and implementation procedures, with centralized support and coordination of the national surveys by Eurostat. This includes common data processing and statistical analyses, and common sampling requirements. It is an 'input harmonized' survey in that an attempt is made to achieve comparability through standardization of content methodology and procedure at the outset.

Except in Belgium and the Netherlands, where the ECHP was a continuation of existing panels, the ECHP was launched as an entirely new survey, but in all countries used the same structure and procedures. An initial probability sample of households was interviewed using identical follow-up rules, and all surveys were based on a random probability sample design.

In Wave 1, around 61,000 households were interviewed in twelve member states.\textsuperscript{2} There is significant variation in national rates of non-response and attrition with rates in the first wave varying from 48 per cent in Denmark to 90 per cent in Italy with an overall figure of 70 per cent. Better response rates were achieved in Wave 2 with an average of 87 per cent being achieved and national rates varying from 83 per cent in Ireland and Denmark to over 90 per cent in Germany. Standard procedures have been developed and implemented for the computation of sample weights. Starting from Wave 2, weights are developed and computed centrally by Eurostat on the basis of Wave 1 weights, modified to take into account unit non-response between the waves and adjustment of the achieved sample to external control distributions by basic person and household characteristics.

The attrition rate is the degree of failure in interviewing the same set of units over time and with slight approximation varied at the household level between 5 per cent in Italy and 23 per cent in the UK, although ten of the twelve countries are found in the range 5 to 12 per cent. For Waves 1 and 2 generally, attrition does not appear to be strongly selective. The highest rates are found for adults who did not complete an individual

\textsuperscript{1} The discussion in this section draws on Eurostat (1999b, Eurostat 1999c) and Watson and Healy (1999).

\textsuperscript{2} In this paper we include all twelve countries that were included in Waves 1 and 2 of the survey. Luxembourg has a substantially smaller sample than all countries and this, together with its distinctive character, frequently leads analysts to exclude it. However, since our conclusions are unaffected by its inclusion we have retained all twelve countries.
interview in Wave 1 or who had changed their address. These factors had little influence on the sample structure. In general the relative attrition rate was 12 per cent higher for individuals in poor households in Wave 1. A higher relative attrition weight holds for those in poverty in seven of the twelve countries, and is highest for Germany. In the remaining five countries (Ireland, Italy, Greece, Spain and Portugal) the attrition rate ranges from 1.01 to 1.09 for members of non-poor households. One should note when using ratios of this type that the size of the ratio depends on whether the less common event (attrition) or the more common event (completion) is used. It is possible to calculate a set of 'illustrative weights' to give an idea of the magnitude of the impact of attrition on the sample structure. This is the average weight that would have to be applied to each cell in order to restore the completed Wave 2 sample to the distribution of characteristics of individuals in Wave 1. A weight of 1 indicates that the distributions in both waves are identical. In general the weights tend to be close to unity. For poverty the highest weight of 1.12 is found for the UK.

Comparison of the quality of the ECHP Wave 2 income distribution data with the 1994 Household Budget Survey (HBS), shows overall that the mean income level is higher in the ECHP, but only marginally. The most pronounced differences are precisely in the case of those countries in which the HBS is known to be of limited quality. The ECHP data indicate on average a somewhat greater disparity than the HBS. The decile shares in the bottom half of the income distribution are smaller but mostly only by 0.2 to 0.3 per cent. Considering the percentage below 50 per cent of mean equivalized income the average according to the ECHP is around 16 per cent compared to 13 per cent in the HBS. For the Gini coefficient the ECHP values are on average 2 percentage points higher than the HBS: 31 per cent compared to 29 per cent. However, Spain, Luxembourg and Italy, where particular difficulties exist with the HBS data, account for practically all of this difference.

Measuring income mobility in the ECHP

The results presented in this paper from the ECHP are based on the User Data Base (UDB) containing data from Wave 1 and Wave 2 as released for public use by Eurostat. The income measure employed is total disposable income, including transfers and after deduction of income tax and social security contributions, with the household taken as the income recipient unit. The principal accounting period for income employed in the ECHP is the previous calendar year, so the Wave 1 and Wave 2 income measures relate to calendar year 1993 and calendar year 1994, respectively. The unit of analysis is individuals present in both waves.
Since the standard of living attainable on a given level of household income will vary with the size and composition of the household, we adjust for these differences using equivalence scales. The scale we employ at this point is often termed the 'modified OECD' scale: where the first adult in a household is given the value 1; this scale gives each additional adult a value of 0.5 and each child a value of 0.3. The number of equivalent adults in each household is derived using this scale, and equivalized income is household income divided by this number. The equivalized income of the household is then attributed to each member, assuming a common living standard within the household, and our analysis is carried out using the individual as the unit of analysis. A change in the equivalized income of a particular individual over time may thus reflect either a change in the total income coming into the household, or a change in the number of adults and children depending on it, or both. In measuring income poverty we follow the widely employed practice of using a range of relative poverty lines, calculated as proportions of median equivalized income (see, for example, Eurostat 1999a). Our aim is to assess the extent of mobility into and out of income poverty from one year to the next on the basis of the equivalized income reported for 1993 versus that reported for 1994.

Mobility vis-à-vis relative income poverty lines

Table 1 shows cross-national variations in poverty rates across countries for poverty lines set at 40, 50 and 60 per cent of median equivalent income. Not surprisingly, there is a great deal of variation in the levels of relative income poverty across European Union countries. As many other

|              | <40% | <50% | <60% |
|--------------|------|------|------|
| Germany      | 7.5  | 11.7 | 15.9 |
| Denmark      | 1.7  | 4.1  | 8.3  |
| Netherlands  | 3.2  | 6.0  | 10.3 |
| Belgium      | 5.7  | 10.4 | 17.0 |
| Luxembourg   | 4.4  | 7.4  | 15.5 |
| France       | 4.6  | 8.5  | 15.0 |
| UK           | 5.5  | 12.8 | 20.8 |
| Ireland      | 2.3  | 6.5  | 17.0 |
| Italy        | 8.2  | 12.4 | 18.7 |
| Greece       | 11.3 | 15.8 | 22.1 |
| Spain        | 7.3  | 12.3 | 20.0 |
| Portugal     | 11.7 | 17.0 | 23.6 |
studies have shown, relative income poverty is generally much higher in the countries with lower mean income per capita (see, for example, Hagenaars et al. 1994 and Eurostat 1999a). However, the nature of the variation depends to some extent on the particular poverty line one chooses. At the 40 per cent line, Denmark and Ireland display the lowest poverty rates, with only 2 per cent falling below that line. The highest rates are observed mainly in the southern European countries, with Greece and Portugal having a rate of 11 per cent and Italy, Spain and Germany 7 or 8 per cent. With the 50 per cent line, Denmark continues to have the lowest rate at 4 per cent and Greece and Portugal the highest rates at 16 and 17 per cent, respectively. The UK and Belgium join Italy, Spain and Germany in the group of countries having the next highest rate of poverty, in a range between 10 and 13 per cent. Ireland is now found in the group of countries with relatively low poverty rates of between 6 and 9 per cent. At the 60 per cent line, much less variation is observed. While Portugal and Greece still have the highest poverty rates, at 23 and 22 per cent, respectively, the UK, Italy and Spain now have rates of 20 per cent and five other countries have poverty levels between 15 and 17 per cent. The countries with distinctively low numbers below this threshold are the Netherlands and Denmark, with rates of 8 and 10 per cent, respectively. Thus while some countries are consistently low, intermediate or high poverty countries, the status of others depends on the line on which one focuses, as does the extent of the disparities between these categories.

From a poverty perspective we wish to assess the extent to which changes in income from Wave 1 to Wave 2 bring people above or below relative income poverty lines. To see how common this is and how much it varies across countries, we categorize each individual in the ECHP in relation to the relative income lines constructed for their own country. We take median equivalized income as the reference point, and our categories are:

- below 40 per cent of the median;
- between 40 and 50 per cent of the median;
- between 50 and 60 per cent of the median; and
- at or above 60 per cent of the median.

Trends in the numbers below the relative income lines between the two waves could clearly have an impact on the extent of poverty escapes or entries. Poverty rates in Wave 2 were higher than in Wave 1 in Ireland and in Denmark with all three relative income lines, whereas there were consistent falls in relative income poverty in Italy, Greece and Spain. We would thus expect more poverty entries in Ireland and Denmark, and more escapes in Italy, Greece and Spain, than if the level of poverty had remained unchanged.
In Table 2 we show the extent of poverty persistence for all three poverty lines by country - in other words, we take those below the line in Wave 1 and see what percentage were still below that line in Wave 2. With the 40 per cent line this varies from a low of 24 per cent in the UK to a high of 59 per cent in Germany. In all but two countries, at least one in two of those in poverty in Wave 1 exits from poverty by Wave 2, and in four countries the escape rate is nearer to two-thirds. Persistence levels are consistently higher with the 50 per cent line, with the lowest persistence level of 41 per cent being found in the Netherlands and the highest of 68 per cent in Portugal. However, except for Portugal, at least one in three still escapes income poverty.

With the 60 per cent poverty line, a majority of those in poverty in Wave 1 are still in poverty in Wave 2 in all the countries, and in all but two cases the persistence rate is at 60 per cent or above. The lowest level of persistence, 52 per cent, is again found in the Netherlands while the highest level is observed in Portugal.

Given the substantial numbers escaping poverty, the other side of the coin is that the number who experience poverty in either 1993 or 1994 is significantly greater than the number poor at one point in time. We see from Table 3 that with the 40 per cent poverty line the percentage exposed to poverty at some point ranges from 4 to 16 per cent compared to a range of 2 to 12 per cent in 1993. Typically the increase is of the order of 50 per cent, but in the UK and Belgium the rate comes closer to doubling. For the 50 per cent line the percentage experiencing poverty at some point runs from 8 to 23 per cent compared to 4 to 17 per cent poor in 1993. With the 60 per cent line the difference is less dramatic, reflecting the lower exit rate. In most countries the numbers experiencing poverty

**TABLE 2.** Income poverty persistence from 1993 to 1994 in the ECHP

| Country    | <40% | <50% | <60% |
|------------|------|------|------|
| Germany    | 59.3 | 60.7 | 70.2 |
| Denmark    | 33.1 | 41.9 | 57.4 |
| Netherlands| 41.5 | 41.0 | 52.2 |
| Belgium    | 36.2 | 50.2 | 57.6 |
| Luxembourg | 50.9 | 54.6 | 62.2 |
| France     | 36.3 | 50.4 | 64.5 |
| UK         | 24.4 | 44.7 | 59.9 |
| Ireland    | 30.4 | 47.0 | 68.6 |
| Italy      | 43.3 | 50.5 | 60.3 |
| Greece     | 52.2 | 56.7 | 63.4 |
| Spain      | 45.2 | 48.7 | 61.5 |
| Portugal   | 47.7 | 67.5 | 74.1 |
are between 25 and 50 per cent higher than the numbers poor in 1993, although in Denmark the increase is significantly higher.

How far do those escaping from relative income poverty move up the distribution? We look in the first column of Table 4 at how many of those escaping from below the 40 per cent line are in fact above the 50 per cent line in Wave 2. Similarly, we look in column 2 at how many of those escaping from below the 50 per cent line are above the 60 per cent line in Wave 2. We see that in this sense, across all the countries, a very substantial proportion of those escaping above these relative income lines actually rise well above them. About 60-80 per cent of those rising above the 40 or 50 per cent line end up above the 50 and 60 per cent lines, respectively. While there is some variation across countries, this is not

### Table 3. Percentage of individuals experiencing poverty in either 1993 or 1994 in the ECHP

| Country     | <40% line | <50% line | <60% line |
|-------------|-----------|-----------|-----------|
| Germany     | 10.7      | 15.7      | 22.1      |
| Denmark     | 3.5       | 7.7       | 14.2      |
| Netherlands | 5.8       | 9.6       | 14.3      |
| Belgium     | 9.4       | 16.5      | 24.9      |
| Luxembourg  | 6.8       | 12.1      | 20.2      |
| France      | 7.4       | 13.3      | 21.1      |
| UK          | 10.0      | 19.6      | 28.7      |
| Ireland     | 5.5       | 12.1      | 24.4      |
| Italy       | 11.4      | 16.8      | 25.3      |
| Greece      | 15.1      | 21.1      | 28.9      |
| Spain       | 10.5      | 17.2      | 26.5      |
| Portugal    | 15.6      | 22.5      | 30.3      |

### Table 4. Extent of income increase for those escaping from poverty between Wave 1 and Wave 2

| Country     | % of all those escaping above 40% line who are above 50% line in Wave 2 | % of all those escaping above 50% line who are above 60% line in Wave 2 |
|-------------|------------------------------------------------------------------------|---------------------------------------------------------------------|
| Germany     | 75.9                                                                  | 65.5                                                                |
| Denmark     | 60.5                                                                  | 81.0                                                                |
| Netherlands | 82.9                                                                  | 72.7                                                                |
| Belgium     | 71.3                                                                  | 78.6                                                                |
| Luxembourg  | 63.2                                                                  | 74.2                                                                |
| France      | 77.5                                                                  | 67.3                                                                |
| UK          | 76.6                                                                  | 64.1                                                                |
| Ireland     | 70.6                                                                  | 52.3                                                                |
| Italy       | 82.4                                                                  | 77.4                                                                |
| Greece      | 77.4                                                                  | 73.3                                                                |
| Spain       | 77.0                                                                  | 65.7                                                                |
| Portugal    | 60.2                                                                  | 64.4                                                                |
consistent across the two poverty lines - the percentage escaping to 'well above the line' is low with the 40 per cent line but not the 50 per cent line, in Portugal and Denmark, for example.

With minor exceptions, the clear pattern across all twelve countries is that the higher the relative income line on which one focuses, the lower the exit rate from Wave 1 to Wave 2. However, there is no consistent association between the level of poverty in Wave 1 and poverty persistence.

Taking the 50 per cent line as an illustration, some countries with relatively high poverty rates in Wave 1 have relatively high persistence rates (Germany, Portugal), while others have relatively low persistence rates (UK). Some of the countries with relatively low poverty rates in Wave 1 with this line have low persistence/high escape rates (Denmark, the Netherlands) while others occupy an intermediate position (Ireland). Nor is there a consistent association between trends in the overall poverty rate between the two waves, and poverty persistence. Of the countries where poverty rates went up between the two waves, only in Ireland for the 60 per cent line is an above-average persistence level observed. Despite the fact that poverty rates fell between the two waves, Greece still shows relatively high persistence. Furthermore, the proportion escaping to well above the poverty line does not appear to bear a consistent relationship with either the poverty rate or the percentage escaping from poverty with the line in question. These results present a different pattern to that described by Duncan et al. (1993: 221) on the basis of their analysis of eight countries. They found a marked inverse relationship between the poverty rate and the escape rate:

Countries with large fractions of their populations below the poverty line have lower escape rates. In other words, the higher in the distribution of poverty line cuts, the fewer the transitions out of poverty. This is only logical since, everything else the same, the higher the poverty threshold, the farther away the average poor family is from the line and the higher the income increase required to escape.

The fact that the pattern we observe is by no means so straightforward suggests that a variety of other factors are operating. Disentangling the possible impact on mobility of the level of poverty, changes in that level between the two waves, and cross-national differences in underlying patterns of fluidity will require that we move beyond a description of poverty dynamics to a formal modelling of the underlying processes. It is to this analysis that we proceed in the next section.
Modelling cross-national poverty dynamics

As Dirven (1996) notes, early attempts to model cross-national income dynamics have attempted to draw on Esping-Andersen’s work on welfare regimes as a source of hypothesis formulation. Thus Fritzell’s (1990) comparison of Sweden and the US hypothesized that the extent of decommodification in Sweden, with the welfare system constructed in a fashion that reduces the impact of market events for people’s economic well-being, would reduce mobility compared with the USA. However, there is a complex set of factors at work here that need to be taken into account in the analytic approach one adopts. Since income inequality is less in Sweden, the distance one is required to move between poor and non-poor categories is less and that would actually be expected to promote mobility. Furthermore, when we have controlled for other factors we might expect that exit from poverty would be easier in countries with low poverty rates. In order to develop our understanding of cross-national differences in poverty dynamics it will be necessary to distinguish between different factors contributing to the process. Such an analysis can be undertaken using log-linear models, commonly employed in the study of social class mobility. Log-linear analysis models cell counts in contingency tables in terms of association among the variables. For our 192-cell table of four destinations by four origins by twelve countries we start by defining the conditional independence or perfect mobility model which allows for association between country and origin and destination but hypothesizes no association between origin and destination. This serves as a reference point against which we can evaluate more plausible models. With \( I \pm J \pm K \) table for origin (O), destination (D) by country (C), the independence model has the additive form\(^3\)

\[
\log F_{ijk} = \lambda + \lambda^{OC} + \lambda^{DC} \tag{1}
\]

At the other extreme is the saturated model shown in equation (2) which exhausts the degrees of freedom and provides a perfect fit to the data by allowing for all two-way associations and the three-way association between origin, destination and country:

\[
F_{ijk} = \lambda + \lambda^{OC} + \lambda^{DC} + \lambda^{OD} + \lambda^{ODC} \tag{2}
\]

3. In presenting our models we follow the standard formulation whereby a model that contains a higher-order interaction term also contains all of the lower-order terms involving those factors. Thus the full specification of equation (1) would include \( \lambda^O + \lambda^C + \lambda^D \).
In considering the application of log-linear models to poverty dynamics, it is useful to make the distinction between absolute and relative mobility. Absolute mobility rates refer to the percentage of individuals in some base category who are mobile. Such rates are easily expressed in the sort of percentage terms we have employed thus far. By contrast, relative rates are produced by comparison of such rates across country, time or socio-demographic group. The distinction between absolute and relative mobility rates originates in attempts to understand what were considered to be rather different sorts of mobility, which have frequently been described in the social class context as structural and exchange mobility (Hout 1989). Structural mobility relates to the share of mobility over time that arises from differences in the origin and destination distributions. The basic idea is that a shift in the distribution across categories leads to people being 'pushed' out of certain origin categories and 'pulled' into certain destination categories. Exchange mobility, on the other hand, is considered to arise as a consequence of the differential advantages associated with different class origins that may be used to avoid access to undesirable destinations or to enter or remain in desirable ones. Exchange mobility thus reflects the extent of equality of opportunity. In the absence of an overall shift in the extent of poverty, changes in the pattern of exchange mobility would necessarily require both winners and losers, with mobility out of poverty being compensated for by corresponding mobility into poverty.

There are some difficulties with attempting to disaggregate mobility in this fashion since it involves assumptions about what the extent and pattern of mobility might have been in the absence of structural change. In practice, it is implausible to assume that factors, which may alter the shape of the poverty distribution, such as the rate of economic growth, are unrelated to influences shaping the pattern of exchange mobility. However, as Erikson and Goldthorpe (1992: 204-5) point out, a model developed by Sobel et al. (1985) allows us to develop an approach to measuring effects of marginals that avoids such difficulties. Thus instead of thinking in terms of origin effects plus destination effects we would think in terms of the size effect of the two classes involved ($\lambda_i^O + \lambda_j^O$) plus the marginal shift effect ($\lambda_j^D - \lambda_j^O$). Such effects, Erikson and Goldthorpe (1992) note, can be understood as the effects of changes between origin and destination distributions which raise the odds of mobility to a given destination by the same factor across all origins alike. 

4. The Sobel et al. model suggests an alternative parametrization in the context of a model that offers a new way of effecting the distinction between structural and exchange mobility that requires symmetrical models. However, as Erikson and Goldthorpe (1992: 205) note, the method of presenting structural shifts is detachable from the model.
In measuring relative mobility we require a measure of association that depends only on the joint distribution of the variables and not on the marginals (Rudas 1998: 9). The ‘effects’ or degrees of association of log-linear models are interpreted in terms of odds or odds ratios $\theta_{ij}$, which provide a measure of association whose possible range of values is not influenced by the marginal distribution of the variables involved. In all log-linear models the $\theta_{ij}$ can be expressed as a function of the model’s parameters. In comparing tables the odds ratios are unaffected by variations in the marginals of the tables. In studies of mobility the odds ratio can be viewed as the chance of an individual of origin category $i$ being found in destination class $j$ rather than any other single class or set of classes, relative to the chances of an individual of origin category $i'$ being found in $j$ rather than in any other single class or set of classes; that is $(F_{ij}/F_{i'})/(F_{ij'}/F_{ij'})$. In mobility terms, equality of access to a more desirable rather than a less desirable destination from different origin classes would give rise to an odds ratio of unity. The greater the deviation from this value the less equal is the competition between individuals of different origins. Although the set of possible odds ratios in an $I \times J$ table is $(I^2 - 1)(J^2 - 1)$, a smaller set of odds ratios formed from adjacent rows and columns is sufficient to generate the full complement of all possible odds ratios. Goodman terms this set of $(I-1)(J-1)$ odds ratios the ‘basic set’. In the analysis that follows we seek to develop models whose implied odds ratios provide a satisfactory account of the observed patterns of poverty mobility.

Assessment of the fit of a model involves estimating the expected cell frequencies $F_{ij}$ using the likelihood-ratio statistic ($G^2$). Nested models can be compared using differences of $G^2$ values and degrees of freedom. In addition to $G^2$ we report two further statistics for each of the models. The first is the index of dissimilarity $\Delta$, which is the sum of the positive differences between the expected and observed frequencies and thus shows the percentage of cases ‘miscalculated’ in the sense that they would have to be reallocated in order to achieve perfect correspondence between the observed and expected frequencies. Finally we report the BIC statistic which can be used to compare nested and non-nested models (Raftery 1986). As Vermunt (1997: 22) notes, BIC is based on an approach to model selection based on information theory with the aim being not to detect the true model but the model that provides the most information about the real world. It is calculated as $\text{BIC} = [G^2 - (\log n)(df)]$ and favours model parsimony. The lower the value of the BIC statistic the more plausible is the model.

5. The following discussion draws on Breen (1985a).
Modelling poverty transitions from Wave 1 to Wave 2 in the ECHP

We begin our analysis by fitting Model A, the conditional independence or perfect mobility model which allows for variation in the distributions of origins and destinations across time but posits no association between origin and destinations. Table 5 shows that this model, which will serve as a reference point for more plausible models, returns a $G^2$ of 41,887 for 108 degrees of freedom and misclassifies 16 per cent of cases. Model B, the Constant Social Fluidity Model (CnSF), allows for variation across country in the impact of origins and destinations, and therefore absolute mobility, but constrains relative mobility to be constant over time. This model misclassifies only 1.85 per cent of all cases and reduces the $G^2$ value of the independence model by 97.3 per cent. However, the $G^2$ value of 1140.3 with 99 degrees of freedom is statistically significant.

As a first test for differences in relative mobility across countries we employ Model C, a log-multiplicative layer effect model - the so-called 'unidiff' model. This model posits that the pattern of association is the same across country, but it allows for the strength of this association to differ by a uniform amount, so allowing for more or less marked inequality in social fluidity across time (Erikson and Goldthorpe 1992; Xie 1992). That is, let $\alpha_{ijk}$ represent the log-linear association parameters between origins ($i = 1, \ldots, I$) and destinations ($j = 1, \ldots, J$) in each of $k = 1, \ldots, K$ tables. Then the unidiff model specifies:

$$\alpha_{ijk} = \alpha_{ij} \beta_k$$

(3)

### Table 5. Models for poverty dynamics 1993 and 1994 for ECHP countries

| Models                                      | $G^2$  | df  | $\Delta$ | $rG^2$ | BIC   |
|---------------------------------------------|--------|-----|----------|--------|-------|
| A. Conditional independence O$\times$C + D$\times$C | 41,887 | 108 | 15.99    |        |       |
| B. Constant social fluidity O$\times$C + D$\times$C + O$\times$D | 1,140.3 | 99  | 1.85     | 97.3   | $\mp$39.37 |
| C. Unidiff                                  | 887.8  | 88  | 1.45     | 97.9   | $\mp$160.8 |
| D. Homogeneous quasi-uniform association    | 1,499.3| 104 | 2.05     | 96.5   | 260.0 |
| E. Homogeneous quasi-uniform association + AF1 | 1,222.6| 103 | 1.94     | 97.1   | $\mp$4.8 |
| F. Heterogeneous quasi-uniform association + AF1 | 976.6  | 92  | 1.60     | 97.7   | $\mp$119.7 |
| G. Homogeneous linear by linear model of median income + AF1 | 1,766.0 | 103 | 2.29     | 95.8   | 127.7 |
| H. Heterogeneous linear by linear model of median income + AF1 | 999.65 | 92  | 1.57     | 97.6   | $\mp$96.65 |
where $\alpha_{ij}$ is a set of baseline origin-destination parameters common to all $k$, and $\beta$ is a parameter whose value is specific to each $k$ and whose effect is to raise or lower the association parameter compared with their baseline values. This model uses 11 degree of freedom more than the CnSF model and yields a deviance of 887.8 for 88 degrees of freedom, which is a statistically significant improvement in the CnSF model. It reduces the independence $G^2$ by 97.9 per cent and leads to a reduction in the BIC statistic compared to the CnSF model from $\mp 39.4$ to $\mp 160.8$. Thus the unidiff model suggests that significant variation in the magnitude of association between origins and destinations exists across countries but that the scale of such variation is modest.

Turning to Table 6, column 1 sets out the pattern of variation in the unidiff coefficient across countries. Under this model the origin-destination association parameters in each of the twelve countries are equal to a set of baseline association parameters multiplied by the unidiff coefficient. For ease of presentation we present them in multiplicative rather than additive form, i.e. in terms of the odds rather than log odds. Thus the unidiff coefficients are normalized by setting the value for German respondents to one. A unidiff coefficient less than unity serves to reduce the size of the origin-destination association, relative to the baseline value, and conversely for a coefficient greater than one. From Table 6 we see that Germany has a relatively high level of origin-destination association. Only Luxembourg, Ireland and Portugal fail to display statistically significant lower levels of association. France, Denmark and the Netherlands display the next highest level with unidiff coefficients in the range 0.90 to 0.93. The remaining southern European countries follow this group with values in the range 0.84 to 0.87. Finally,

| Country       | Unidiff | Heterogeneous uniform association | Heterogeneous linear by linear median income model |
|---------------|---------|-----------------------------------|-----------------------------------------------|
| Germany       | 1.000   | 1.219                             | 1.299                                         |
| Denmark       | 0.902   | 1.134                             | 1.451                                         |
| Netherlands   | 0.901   | 1.121                             | 1.236                                         |
| Belgium       | 0.787   | 1.034                             | 1.105                                         |
| Luxembourg    | 1.022   | 1.198                             | 1.231                                         |
| France        | 0.927   | 1.152                             | 1.326                                         |
| UK            | 0.755   | 1.015                             | 1.161                                         |
| Ireland       | 0.967   | 1.107                             | 1.184                                         |
| Italy         | 0.856   | 1.113                             | 1.155                                         |
| Greece        | 0.839   | 1.125                             | 1.164                                         |
| Spain         | 0.871   | 1.123                             | 1.221                                         |
| Portugal      | 0.971   | 1.206                             | 1.248                                         |
the weakest level of association is found in Belgium and the UK with values of 0.79 and 0.76, respectively.

Our results to this point suggest that the vast bulk of cross-national variation in poverty dynamics is a consequence of structural or shift effects but that some significant variation in social fluidity or relative mobility opportunities does exist. The clustering of countries that emerges does not appear to be interpretable either in terms of levels of poverty or welfare regimes. However, before engaging in further discussion of these results we should consider some of the limitations of the models we have employed so far.

The first of these is that the CnSF and unidiff models are of a very general nature and make no attempt to specify the processes underlying poverty dynamics and the extent to which cross-national differences might be explicable in terms of the differential operation of such processes. A related problem is that models we have employed thus far ignore the ordering of the origin and destination categories. In what follows we attempt to employ models that rectify such deficiencies. In order to do so we make use of linear-by-linear association models that use row and column scores to structure association. The model requires assigning scores \( u_i \) and \( v_j \) to the rows and columns of the mobility table. The model is shown in equation (4):

\[
F_{ij} = \mu + \lambda^O + \lambda^D + \beta(u_iv_j) \tag{4}
\]

Odds ratios can be used to interpret the size of \( \beta \). For an arbitrary pair of rows \( h < i \) and an arbitrary pair of columns \( j < k \):

\[
\log(F_{bj}F_{ik}/F_{bk}F_{ij}) = \beta(u_i \mp u_h)(v_k \mp v_j) \tag{5}
\]

The log odds ratio is larger for pairs of rows or columns that are further apart. The odds ratio equals \( e^\beta \) whenever rows are one unit apart. For equal-interval scores all such local odds ratios are equal. Goodman (1979) referred to this case as uniform association (UA). For unit-spaced scores all \( \log v_{ij} = \beta \) and all \( v_{ij} = e^\beta \). The UA model orders the rows and columns using an arbitrary but equally spaced ordering. The row-column association is given by the parameter for the effect of the interaction term formed from these two variables: Thus, \( \beta \) is equivalent to the logarithm of the value of the odds ratios in the basic set. The odds ratios formed from adjacent rows and columns are identical and those formed from non-adjacent rows and/or columns are a power function of those in the basic set (or a multiplicative function if the log odds are used).

6. The following discussion draws on Agresti (1990: 263-5) and Breen (1985b).
Generally models containing only the main effects and the association term fail to provide a satisfactory fit to the data. In most cases it is also necessary to specifically model the diagonal cells. Among the options available is the addition of a single term distinguishing movers from stayers, which is a common convention in mobility analysis (Goodman 1979). Alternatively, one can distinguish a specific immobility tendency for each of the diagonal cells in which case each origin class can display a specific persistence. Preliminary analysis led us to include three inheritance parameters in our models. INH1 relates to immobility below the 40 per cent relative income poverty line. INH2 relates to those between the 40 and 50 per cent lines and those between the 50 and 60 per cent lines. Finally, INH3 is specific to those above the 60 per cent line. These parameters can be viewed as capturing tendencies towards persistence in a particular category over and above the degree of recruitment to the same class that implied the uniform by the other parameters in the model.

The results of fitting a series of models hypothesizing uniform association but allowing for these additional immobility or persistence parameters are also set out in Table 5. Model D, labelled the homogeneous quasi-uniform association, constrains both the $\beta$ coefficient and the inheritance parameters to be constant. While this model does not fit the data it does correctly classify the almost 97 per cent of cases and reduces the $G^2$ by 96.5 per cent. These results confirm the substantial degree of uniformity in patterns of fluidity.

An examination of residuals showed one consistent deviation of observed from expected values. This involved an overestimation of the reciprocal flows between those below the 40 per cent poverty line and those between the 50–60 per cent line. The latter will tend to contain many of those being provided for by the main welfare programmes relating to unemployment and old age. It is plausible that those who have established such rights will have acquired additional protection against a drop into the lowest category. Correspondingly, inability to establish such rights may serve as an additional barrier to entry to this category for the poorest group. In order to capture this tendency in our subsequent analysis, we add what is usually referred to as an affinity term AF1, which captures the strength of the reciprocal flow. Thus movement between these categories in either direction is distinguished from all other movements. Since the term is constant across countries it does not affect our international comparisons. The addition of this term in Model E produces an improvement in fit in terms of both $G^2$ and BIC criteria. Finally, in Model F we allow the $\beta$ parameter to vary across countries but constrain the inheritance and affinity terms to be constant. The model takes the form set out in equation (6). It returns a $G^2$ of 976.6 with 92 degrees of freedom, which remains statistically significant. However, it
correctly classifies 98 per cent of cases, reduces the conditional independence $G^2$ by almost 98 per cent and returns an improved BIC statistic of $\mp 119.7$.

$$\log F_{ijk} = \mu + \lambda^{OC} + \lambda^{DC} + AF1 + \text{INH1} + \text{INH2} + \text{INH3} + \beta_k(u,v_j)$$  \hspace{1cm} (6)

In terms of grouping of countries the outcome resembles the unidiff pattern. From Table 6 we see that Germany, Portugal and Luxembourg display the highest level of association, with $\beta$ coefficients ranging between 1.219 and 1.198, and do not differ significantly from each other. The next highest level of association is found for France and Denmark with coefficients of 1.152 and 1.134, respectively. Once again the lowest degree of origin-destination association is found in Belgium and the UK with $\beta$ coefficients of 1.034 and 1.015, respectively. However, the remaining countries are found in a narrow range between 1.107 and 1.125. The only country for which the heterogeneous quasi-UA model with the additional affinity term presents a significantly different picture to the unidiff model is Ireland. Whereas the unidiff results located Ireland among the countries with the highest level of association, the UA model locates it between the southern European countries and Belgium and the UK and, indeed, closest to the latter.

Agresti (1990: 265) recommends that unless an uneven spacing of scores is natural then the uniform association model, which allows for the $\beta$ scores to be interpreted simply as the common local odds ratio is to be preferred. However, in the case of poverty dynamics we do have a reasonable case for attempting to approximate distances between midpoints of categories for an underlying interval scale. In Table 7 we show the median income ratios by poverty category by country. The CnSF and

| Poverty category | Median income ratio for origins by country for 1993 |
|------------------|-----------------------------------------------|
| Germany          | 1.00 1.64 1.96 3.93 |
| Denmark          | 1.00 1.40 1.68 3.21 |
| Netherlands      | 1.00 1.77 2.16 4.07 |
| Belgium          | 1.00 1.85 2.25 4.45 |
| Luxembourg       | 1.00 1.80 2.10 4.23 |
| France           | 1.00 1.57 1.88 3.85 |
| UK               | 1.00 1.46 1.77 3.75 |
| Ireland          | 1.00 1.77 2.08 4.60 |
| Italy            | 1.00 1.73 2.05 4.31 |
| Greece           | 1.00 1.65 2.00 4.32 |
| Spain            | 1.00 1.61 1.94 4.11 |
| Portugal         | 1.00 1.57 1.94 4.11 |
unidiff models made no use of information on distance between categories, and the UA model assumed that categories were equally spaced and such spacing was uniform across countries. By using the information contained in Table 7 we can estimate distances between categories and allow for cross-national variation in such distances. This allows us to begin to distinguish between cross-national differences in inequality and dynamics.

Our final model then differs from equation (6) in that the $u_i$ and $v_j$ are not assumed to be equally spaced. Instead for both origins and destinations we take those below the 40 per cent poverty line as a reference category and score them as 1. We then assign each of the other categories a score equal to the ratio of the median income of that category to the median income of the category containing those below the 40 per cent line. The relevant set of scores for origins is set out in Table 7 and the corresponding one for destinations is provided in Appendix Table A1. From Table 7 we can see that Denmark is quite distinctive in that the differentials between the categories of our poverty classification are significantly narrower. For example, the value of the ratio between those above the 60 per cent line and those below the 40 per cent line is, at a value of 3.21, lower than for any of the other countries. The countries closest to Denmark are the UK and France, which display ratio values for the comparison of the extreme categories of 3.75 and 3.85, respectively. Germany and Spain, the Netherlands and Portugal follow these with corresponding values of 3.93 and 4.11. The remaining countries all display consistently higher ratios. These include Italy, Greece, Luxembourg, Belgium and Ireland with values for the extreme categories in the range 4.23 to 4.60. The highest values are observed in Belgium and Ireland. A very similar pattern is observed for destination scores.

All other things being equal, we would expect that mobility would be easier in those countries where the distance between categories is less. The linear association model can capture this effect. The first variant of this model - Model G in Table 5 - constrains all of the association parameters including $\beta$ to be constant across countries. This model provides a poorer fit to the data than a number of earlier models returning a BIC statistic of 127.7. However, it misclassifies only 2.3 per cent of cases and reduces the conditional independence $G^2$ by 95.8 per cent. Model H in Table 5 allows $\beta$ to vary and provides a significantly better fit while not quite providing a satisfactory fit in strict statistical terms. It misclassifies only 1.57 per cent of cases and reduces the conditional independence $G^2$ by 97.6 per cent. The BIC statistic value of $\approx 96.65$ is slightly larger than in the case of the UA model. However, we would argue that the model employing the median income ratios should be preferred because it is
substantively more plausible and allows us to make important conceptual distinctions.

The \( \beta \) parameters for this model are shown in column 3 of Table 6 to facilitate comparison with the unidiff and UA models. The coefficients are reported in multiplicative form and in terms of actual country values rather than as deviations from the German case. For the median income model the highest level of association is shown by Denmark with a \( \beta \) of 1.451, followed by France with a coefficient of 1.33 and Germany 1.30. The intermediate group of countries with values in the range of 1.22 to 1.25 includes Spain, Portugal, the Netherlands and Luxembourg. While the countries with the weakest level of association encompassing a set of scores running from 1.18 to 1.11 include Italy, Greece, Belgium, Ireland and the UK. Thus the somewhat weaker association between origins and destinations shown by earlier models for Denmark and France appears to be a consequence of the lesser distance between the categories of our poverty classification in these countries. The association for the UK remains relatively weak even when we take the distance factor into account. The relative position of the other countries remains relatively unchanged.

We now turn our attention to the parameters of our preferred model. As we have shown earlier, it is variation in the shift effects that accounts for the bulk of the cross-national variation in patterns of poverty dynamics. In Table 8 we show the distribution of such effects across countries. The reference category is below the 40 per cent income line and this has a shift effect value of unity. The shift effects of the remaining three categories are then expressed relative to this category. The shift effect for the categories other than below the 40 per cent line relative to each other

| Poverty categories | <40% v. 40-50% | <40% v. 50-60% | 40% v. 60%+ |
|-------------------|----------------|----------------|-------------|
| Germany           | 0.791          | 0.668          | 0.830       |
| Denmark           | 0.881          | 0.840          | 0.529       |
| Netherlands       | 0.582          | 0.513          | 0.782       |
| Belgium           | 1.184          | 0.953          | 0.955       |
| Luxembourg        | 1.162          | 0.554          | 0.915       |
| France            | 1.279          | 1.106          | 1.048       |
| UK                | 0.848          | 0.988          | 1.001       |
| Ireland           | 0.630          | 0.513          | 0.462       |
| Italy             | 1.183          | 1.619          | 1.462       |
| Greece            | 1.391          | 1.236          | 1.431       |
| Spain             | 1.071          | 1.324          | 1.400       |
| Portugal          | 2.001          | 1.556          | 1.292       |
can be deduced from the values contained in Table 8. Portugal, Greece, Italy and, to a lesser extent, Spain and France show a shift away from the reference category towards all other categories. In Portugal and France the shift is strongest towards the 40-50 per cent category, in Italy it is towards the 50-60 per cent category, while in Spain it is towards those above the 60 per cent line. In Greece both these categories benefit almost equally. Belgium and the UK show relatively little change. Although in the former the 40-50 per cent category gains slightly at the expense of the reference category while for the latter the opposite is the case. For all other countries there is a consistent shift towards the below 40 per cent category and away from all others. This is most pronounced in Ireland and the Netherlands. In the Irish case the size of the shift is positively related to the distance between categories. For the Netherlands the shift is also greatest for the two lowest categories. For Denmark and Germany the shift towards below the 40 per cent line is somewhat weaker and takes its most extreme value for the 50-60 per cent category in the former and for those above the 60 per cent line in the latter. It is these effects which explain most of our cross-national variation.

In Table 9 we show the association coefficients for our final model. These include the inheritance parameters that capture the net tendencies towards immobility when we have taken the effects of other variables in the model into account. The net tendency towards immobility is weakest in the 40-50 per cent and 50-60 per cent cells, although it is still positive, as shown by the value of 1.76, and highly significant. The magnitude of

| Estimate | P       |
|----------|---------|
| INH1     | 1.906   |
| INH2     | 1.756   |
| INH3     | 5.057   |
| Affinity | 0.545   |
| β<(Germany) | 1.299 |
| β+Denmark | 1.451 |
| β+Netherlands | 1.236 |
| β+Belgium | 1.105 |
| β+Luxembourg | 1.231 |
| β+France | 1.326   |
| β+UK     | 1.161   |
| β+Ireland | 1.184 |
| β+Italy  | 1.155   |
| β+Greece | 1.164   |
| β+Spain  | 1.221   |
| β+Portugal | 1.248 |

***p < 0.001
the below 40 per cent line parameter is slightly higher at 1.91. However, by far the largest net tendency towards persistence or immobility is found among those above the 60 per cent line. (The significance levels shown with the parameters relate to deviation from the German value.)

Thus, over and above the effects captured by distance between categories and the other association parameters, the non-poor appear to enjoy additional resources that prevent them falling into poverty. The negative affinity parameter of 0.55 falls significantly below unity and captures this net tendency for the density of the movement between the below 40 per cent category and the 50-60 per cent categories to be rather less than we would expect, all other things being considered.

Conclusions

Research using panel data is highlighting the inadequacy of a static perspective on poverty. The need to understand poverty dynamics has become more pressing as both popular and political discourse has increasingly referred to a new class of 'losers', as reflected in labels such as the A-team and B-team and the 'new underclass'. However, as Esping-Andersen (1997) among others has stressed, the interpretation of such phenomena is dependent on the extent to which people’s marginality is only temporary, or involves a degree of permanence which may contribute to a further deterioration in life-chances. In this paper we have addressed the question of whether, over and above cross-national differences in poverty rates and short-term variations in those rates, there are differences in underlying patterns of fluidity which make barriers to exit from poverty more powerful in some rather than other European countries.

Our analysis of twelve European Union countries in the first two waves of the ECHP confirms that substantial mobility into and out of relative income poverty occurs from one year to the next. However, the extent of such mobility is strongly related to the particular income poverty line on which one chooses to focus. For all countries the level of mobility declines sharply as one moves from the 40 per cent to the 60 per cent relative-income line. However, no consistent relationship was found between the level of mobility in a country and the poverty rate. Neither was there a transparent relationship between overall movement in the poverty rate over time and degree of persistence of poverty.

In order to address these issues on a sounder analytic basis we made use of log-linear and linear by linear association models, commonly applied in the context of social mobility. We commenced with models of a very general form such as the constant social fluidity and unidiff models and proceeded to develop models that allowed us to distinguish between
different dimensions of the mobility process. Both types of models lead to almost identical conclusions regarding the role of absolute and relative mobility. However, the latter allows us to specify the particular processes underlying observed poverty dynamics. This is of particular value in that earlier attempts to develop the implications of welfare regime theory had shown the difficulties involved in specifying clear-cut hypotheses.

The models we employ allow for cross-national variation in the distribution across poverty categories in both 1993 and 1994. Having made allowance for such factors, we observe something close to a uniform pattern of association. In other words, it is shift rather than association effects that have primary explanatory power. Cross-national differences in poverty dynamics are predominantly a consequence of corresponding variations in overall poverty rates and short-term movements in such rates. Variation across countries in patterns of relative mobility is extremely modest. Models that assume that the processes underlying poverty dynamics are constant across countries perform almost as well as those that allow for cross-national variability. The scale and patterning of such differences that do exist does not suggest that there is a great deal to be gained in theoretical terms by a focus on such variation. In particular, it is difficult to think of an explanation couched in terms of welfare regime theory that could account for the observed pattern.

Movement between poverty categories is, in part, a function of the relative income differences between them. Our findings indicate that while there is substantial absolute variation across countries in the extent of income differences between poverty categories across countries, the relative differences are remarkably similar. Such near uniformity across countries is also apparent in the strength of the parameter associated with the hierarchical income dimension. Similarly, the specific immobility tendencies associated with each poverty category are constant across countries. Thus in each country there is a particularly strong tendency for those above the 60 per cent income line to remain there. Uniformity is also apparent in relation to the affinity term that captures the additional barrier to movement between being below the 40 per cent income line and being between the 50–60 per cent lines, which is likely to reflect the extent to which the two groups are integrated into the main forms of welfare provision.

The results of our analysis suggest that variations in the extent of short-term poverty persistence from one country to another in the EU can be accounted for by cross-national differences in overall poverty rates and short-term fluctuations in such rates rather than by differential relative poverty. We find no evidence of differential tendencies towards short-term poverty persistence of a kind consistent with welfare regime theory. The conclusion is no less important because of its negative nature.
Investment of theoretical effort in explaining non-existent cross-national differences is an unproductive enterprise. On the other hand, identification of social processes that are constant across nations presents its own theoretical challenges.  

Appendix

| Poverty category median income ratios for destinations, by country, for 1993 |
|---|---|---|---|---|
| <40% | 40-50% | 50-60% | 60%+ |
| Germany | 1.00 | 1.68 | 2.07 | 4.12 |
| Denmark | 1.00 | 1.41 | 1.73 | 3.24 |
| Netherlands | 1.00 | 1.77 | 2.20 | 4.13 |
| Belgium | 1.00 | 1.82 | 2.20 | 4.40 |
| Luxembourg | 1.00 | 1.95 | 2.33 | 4.65 |
| France | 1.00 | 1.48 | 1.78 | 3.54 |
| UK | 1.00 | 1.48 | 1.79 | 3.77 |
| Ireland | 1.00 | 1.63 | 1.94 | 4.18 |
| Italy | 1.00 | 1.77 | 2.13 | 4.47 |
| Greece | 1.00 | 1.63 | 2.02 | 4.29 |
| Spain | 1.00 | 1.54 | 1.84 | 3.84 |
| Portugal | 1.00 | 1.65 | 2.04 | 4.34 |

Acknowledgements

This paper is based on analyses of the European Community Household Panel Survey, for 1994 and 1995. The data are used with the permission of Eurostat, who bear no responsibility for the analysis or interpretations presented here. The research was carried out as a part of the work of the European Panel Analysis Group (EPAG) on a Targeted Socio-Economic Research project (CT96-3023) under the Training and Mobility of Researchers Programme of the EC’s Fourth Framework. The authors are grateful to James Williams and Dorothy Watson for their help with data issues and the participants of an ESRI seminar who helped to clarify many of the arguments in this paper. We would like to thank two anonymous referees for comments on an earlier version of this paper.
