ABSTRACT

We present a new time-dependent inhomogeneous jet model of non-thermal blazar emission, which reproduces the entire spectral energy distribution together with the rapid gamma-ray variability. Ultrarelativistic leptons are injected at the base of a jet and propagate along the jet structure. We assume continuous reacceleration and cooling, producing a relativistic quasi-maxwellian (or ‘pile-up’) particle energy distribution. The synchrotron and synchrotron self-Compton jet emissivity are computed at each altitude. Klein–Nishina effects as well as intrinsic gamma–gamma absorption are included in the computation. Due to the pair production optical depth, considerable particle density enhancement can occur, particularly during flaring states. Time-dependent jet emission can be computed by varying the particle injection, but due to the sensitivity of pair production process, only small variations of the injected density are required during the flares. The stratification of the jet emission, together with a pile-up distribution, allows significantly lower bulk Lorentz factors, compared to one-zone models. Applying this model to the case of PKS 2155−304 and its big TeV flare observed in 2006, we can reproduce simultaneously the average broad-band spectrum of this source as well as the TeV spectra and TeV light curve of the flare with bulk Lorentz factor lower than 15.

Key words: radiation mechanisms: non-thermal – galaxies: active – BL Lacertae objects: individual: PKS 2155−304 – galaxies: jets – gamma-rays: theory.

1 INTRODUCTION

It is widely admitted that the blazar phenomenon is due to relativistic Doppler boosting of the non-thermal jet emission taking place in radio-loud active galactic nuclei whose jet axis is closely aligned with the observer’s line of sight. Blazars exhibit very broad spectral energy distributions (SED) ranging from the radio to the gamma-ray band and dominated by two broad-band components. In the synchrotron self-Compton (SSC) scenario, the lowest energy hump is attributed to the synchrotron emission of relativistic leptonic particles, and the highest one is attributed to the inverse-Compton (IC) process of the same leptons on the synchrotron photon field. Broad-band observations of these objects are crucial to understand the jet physics and to put reliable constraints on jet parameters.

The most extreme class of blazars is the highly peaked BL lac sources (HBL), where the synchrotron/IC components peak in the ultraviolet/X-ray/gamma-ray (GeV up to TeV) range. The recent development of observational techniques in the TeV range, with Cherenkov telescopes experiments like HESS, MAGIC or VERITAS has allowed the detection of about 18 HBL above 300 GeV. These objects are well known to be highly variable in all energy bands, from radio to gamma-ray, with time-scales varying with energy. Perhaps the most extreme and remarkable example of this extraordinary variability behaviour has been caught by the HESS instrument in the recent observations of PKS 2155−304 during summer 2006 (Aharonian et al. 2007) (impressive observations have also been recently obtained for Mkn 501 i.e. Albert et al. 2007b).

The simplest models of high-energy emission assume a one-zone, homogeneous region. The SSC emission is assumed to come from a spherical zone of radius R, filled with relativistic leptons characterized by their density N and a characteristic Lorentz factor γ (e.g. most contributing to the peak emission), embedded in an isotropic magnetic field B. The blob is assume to move with a bulk Lorentz factor Γ_b yielding to a Doppler factor δ_b = [Γ_b(1 − β cos θ)]−1, where θ is the angle between the blob direction of motion and the line of sight. In this model, all physical quantities are averaged on the whole spherical region, and, more importantly, the synchrotron and IC emission are copatial. Causality constrains and a necessarily low pair creation optical depth then generally implies relatively high bulk Lorentz factor (Mastichiadis & Kirk 1997).

In the case of the 2006 big flare of PKS 2155−304 (Aharonian et al. 2007), the observed variability time-scale (∼200 s) in the TeV range implies a minimum bulk Lorentz factor of greater than 50 (Begelman, Fabian & Rees 2008) assuming a homogeneous one-zone model. However, such high values of the bulk Lorentz factor are in contradiction with constraints derived from other observational evidence (Urry & Padovani 1995; Henri & Saugé 2006, and references therein). Furthermore, one-zone models are unable
to fit the entire spectrum, the low-energy radio points being generally attributed to more distant emitting regions. More complex models have been proposed including, for example, jet stratification (Ghisellini, Maraschi & Treves 1985; Katarzyński, Sol & Kus 2003) or jet deceleration (e.g. Georganopoulos & Kazanas 2003). We present here a new approach, unifying small and large scales emission region: we consider that the radio jet is actually filled by the same particles originating from the high-energy emitting region, at the bottom of the jet, that have propagated along it. We describe thus the emitting plasma by a continuous (although variable) particle injection, submitted to continuous reacceleration and radiative cooling. This model fits well into the two-flow framework originally proposed by Pelletier (1985) and Sol, Pelletier & Asseo (1989) (see also Tsinganos & Bogovalov 2002 or the ‘spine-in-jet’ model developed by Chiaberge et al. 2000), where a non-relativistic, but powerful magnetohydrodynamics (MHD) jet launched by the accretion disk, surrounds a highly relativistic plasma of electron-positron pairs propagating along its axis. The MHD jet plays the role of a collimator and an energy reservoir for the pair plasma, which is responsible for the observed broad-band emission. The present model only concentrates on the physical parameters of the relativistic pair beam and is described in Section 2. We show its application to the case of PKS 2155–304 in Section 3 focusing on the 2006 big flare event. We then discuss our results in Section 4.

2 DESCRIPTION OF THE MODEL

2.1 Geometry of the model

We consider that the relativistic plasma propagates in a stationary funnel whose geometry is parametrized as follows:

\[ r(z) = R_0 \left( \frac{z}{Z_0} + \left( \frac{R_i}{R_0} \right)^{1/\omega} \right)^{a}, \]  

(1)

where \( r(z) \) is the radius of the jet at the altitude \( z \). This shape describes a jet with a ‘shifted’ paraboloid shape, with an initial inner radius \( R_i \) at \( z = 0 \), and a radius \( R_0 \) at a distance \( Z_0 \) from the apex (see Fig. 1). The index \( a \) is lower than 1 for a collimated jet. The magnetic field inside the jet is radially averaged at each altitude, and has the following dependence:

\[ B(z) = B_0 \left( \frac{r(z)}{R_0} \right)^{-\lambda}. \]  

(2)

We take \( \lambda \) between 1 and 2, the two extreme values describing, respectively, a pure toroidal or a purely poloidal field distribution.

We consider that the jet is continuously accelerating, starting from rest (\( \Gamma_b = 1 \) at \( z = 0 \)) and reaching an asymptotic value \( \Gamma_{b,\infty} \). The acceleration is assumed to take place over a distance comparable with \( Z_0 \). A detailed model of the acceleration mechanism is beyond the scope of this Letter, so we chose a simple parametrization to describe the evolution of \( \Gamma_b(z) \):

\[ \Gamma_b(z) = \left( 1 + \frac{\Gamma_{b,\infty} - 1}{1 + \frac{\Gamma_{b,\infty}}{\xi}} \right)^{1/a}, \]  

(3)

\( a \) being a ‘stiffness’ parameter describing the width of the accelerating region.

2.2 Particle energy distribution

In our model, the energy distribution function (EDF) of the electron-positron plasma is assumed to be a relativistic maxwellian (or ‘pile-up’) distribution:

\[ n(\gamma, z, t) = n_0(z, t) \gamma^2 \exp \left[ -\frac{\gamma}{\gamma_0(z, t)} \right], \]  

(4)

where \( n_0(z, t) \) is a normalization factor and \( \gamma_0 \) is the characteristic ‘pile-up’ Lorentz factor. This distribution is a natural outcome of some acceleration processes like second-order Fermi acceleration or magnetic reconnection (Schlickeiser 1984, 1985; Henri & Pelletier 1991; Saugé & Henri 2004). It has also been shown by Saugé & Henri (2004) that a pile-up distribution is well suited to reproduce the narrow peaked high-energy component of TeV blazars.

When the plasma propagates in the structure, the particles lose energy via synchrotron and IC cooling, producing the observed emission. It turns out, however, that the cooling time is too short for the relativistic particles to fill the whole jet. It is thus necessary to assume a fast reacceleration process along the jet. The acceleration rate is parametrized by a shifted power law with an index \( \xi \) and an exponential cut-off after some altitude \( Z_0 \) to avoid energy divergence:

\[ Q_{\text{acc}}(z) = Q_0 \left[ \frac{z}{Z_0} + \left( \frac{R_i}{R_0} \right)^{1/\omega} \right]^{-\xi} \exp \left( -\frac{z}{Z_0} \right). \]  

(5)

In the two-flow framework (see Introduction), this reheating is naturally provided by the surrounding MHD structure via second-order Fermi process. Then, we only need to determine two parameters to fully describe the relativistic plasma: \( n_0(z, t) \) and \( \gamma_0(z, t) \); \( \gamma_0(z, t) \) is determined by balancing radiative losses and reacceleration, and \( n_0(z) \) by a continuity equation as explained in the next paragraph.

2.3 Pair production

We compute at each altitude and frequency the pair production optical depth in the comoving frame. Absorption of gamma-ray photons induces the formation of new pairs that are supposed to be continuously reaccelerated as explained above. It results then in an increase in the particle flux \( \Phi(z, t) = \int n(\gamma, z, t)S(\gamma)\Gamma_b\beta_c d\gamma \), which is conserved in the absence of pair creation. \( \Phi(z) \) is computed through a continuity equation: the importance of pair creation is measured by the variation of this flux. The pair production optical depth is smaller than that expected in one-zone models, where soft photons are produced cosmatically with higher energy ones. Indeed a relativistic Maxwellian particle distribution results in a much lower local soft photon density, compared to a power-law spectrum: soft photons are produced farther away in the jet and do not contribute to opacity. Consequently, it allows significantly lower bulk Lorentz factor compared to the ones obtained with simple one-zone models.

In the case of PKS 2155–304, our results are compatible with an asymptotic bulk Lorentz factor of about 15, much below the value of 50 inferred by some authors (e.g. Begelman et al. 2008). It turns out that pair production plays a fundamental role in explaining the flares in gamma-rays, because when the optical depth is close to one, a very small variation of the initial particle density can trigger a considerable enhancement in the pair production region.

2.4 The jet spectrum

Knowing \( n_0(z, t) \), \( \gamma_0(z, t) \), \( r(z, t) \) and \( B(z, t) \), we compute the emissivity at each altitude in the jet by assuming a SSC process for the radiative mechanism. The total intensity of the jet is then determined by integrating the emissivity all along the jet. The emissivity is enhanced in the observer frame by the Doppler boosting.
take also into account the attenuation of the gamma-ray signal by the cosmic diffuse infrared background, chosen as the ‘modified’ Primack model P45 (Aharonian et al. 2006).

Once injected at the base of the jet, the particles contribute first to the high-energy part of the jet SED. As they propagate, their emissivity peaks progressively at lower energy, producing the low-energy part of the spectrum. Hence, the jet can be seen as a continuous succession of time-dependent one-zone SSC models that propagate inside a stationary geometry, each of them contributing with its particular spectrum to the whole observed SED. The spectral shape of the whole SED is not controlled by the local particle energy distribution (which is always locally a narrow pile-up), but rather by the $z$-dependencies of the jet radius, the magnetic field and the acceleration rate. A constant injection rate would lead to a stationary emission pattern, which would be rather easy to fit. In reality, however, the observed instantaneous spectra are a complicated convolution of the whole history of the jet, keeping the memory of the whole past (and unknown) injection pattern. We describe below a simple procedure to extract the physical parameters of the jet from the observed spectra, despite the fact that they do not correspond to a simple steady state of the jet.

2.5 Time-dependent simulations

Real observations result from a complex combination of the whole injection pattern at the basis of the jet. Due to the propagation of particles, the high-energy part of the synchrotron and TeV components will be dominated by a single flare, occurring at the basis, whereas the low-energy part of the spectrum is a convolution over a large scale of the past jet history: it is thus rather a time-averaged spectral state mixing quiescent and flaring states. The instantaneous spectrum is thus a mix of different ideal ‘steady states’.

To constrain the geometrical parameters, we first build a virtual set of data called the fake flaring spectrum, that would be observed if the jet was constantly flaring. The high-energy part of this spectrum is the really observed emission during a flare. On the other side, its low-energy part corresponds to the observed data corrected by an enhancement factor to take into account that the actual jet is flaring only a fraction $f$ (called duty cycle) of the time. This enhancement factor is then $f^{-1}$ since the real jet is filled only partially with the high particle density associated to a flare, whereas the fake spectrum corresponds to a fully filled jet. For the intermediate (X-rays) energy bands, the procedure is not so accurate because a small (but statistically variable) number of flares can contribute to the flux.

We chose to adjust approximately the spectra by some intermediate factor in this band, but we have checked that our results are not very sensitive to these points. The factor can be determined observationally from the fraction of time, we see the object flaring within statistically random observation periods. Once the ‘fake flaring’ spectrum is constructed, we use it to adjust the jet model geometrical parameters, and the flaring injection rate. We take also into account the required variability time-scale which constrains basically the jet size and the Doppler factor. The variability time-scale is commonly evaluated in one-zone models by the light travel time of the zone divided by the Doppler factor $R_{\delta c}$. However, in the case of a stationary structure like a jet, the correct estimate is to take the typical length of the emission zone, corrected for the time contraction due to the difference in light travel time to the observer along different parts of the jet, like for the superluminal motion. This gives $t_{\text{var}} \simeq \frac{R_0}{c}(1 - \beta_0 \cos \theta) = \frac{R_0}{c_\text{var}}$, which is of the same order of the one-zone (transverse) variability time-scale if we assume $R_0/Z_0 \simeq \Gamma_{\delta c}^{-1}$. The model predicts also naturally an increasing variability with energy since more and more individual flares contribute to lower energy ranges. This is indeed observed in TeV blazars (Giebel, Dubus & Khélifi 2007). Once the flaring state parameters are found, we construct a quiescent state by keeping the same jet geometry, but reducing the particle injection rate and/or acceleration rate to fit low flux observations. A general light curve can then be obtained by adjusting an injection pattern oscillating around the average flaring state, for a given particular flare.

3 APPLICATION TO PKS 2155–304

We have tested our model to the big flare event observed by HESS in 2006 July in PKS 2155–304 (Aharonian et al. 2007), the strongest flaring event ever seen in the TeV range for a blazar. During this flare, the average flux above 200 GeV of the source reached about $\sim 7$ crab. Moreover, variability with time-scales as small as $\sim 200$ s has been observed. The light curve is very well sampled (see Fig. 3), as well as the spectrum, which makes this event particularly interesting to test models.

We apply the method described previously to the SED of PKS 2155–304. We have first constructed an average spectrum of PKS 2155–304 in the low-frequencies range ($\gtrsim 10^{15}$ Hz), by compiling available archival data [from the HEASARC archive website (http://heasarc.gsfc.nasa.gov/docs/archive.html)]. Based on the activity detected by HESS, we estimate that the duty-cycle is around 10 per cent. An accurate value is not necessary since it would modify only the fake spectrum and not the real one. Then to construct the ‘fake flaring’ spectrum of this source, we combine the HESS data with the radio-to-optical ones corrected by a factor of 10. To better constrain the space parameter, we also include archival X-ray data from BeppoSAX, XMM–Newton and SWIFT at different epochs (Massaro et al. 2007), as well as archival EGRET data (Vestrand, Stacy & Sreekumar 1995). We choose not to renormalize these data by any intermediate ‘duty-cycle’ factor. Then, they would correspond, respectively, to lower limits of the ‘flaring state’ X-ray and GeV flux.

An average ‘fake flaring’ spectrum is shown in Fig. 2 in dot-dashed line. The corresponding best-fitting model parameters are reported in Table 1. Interestingly, we only needs a Doppler factor $\Gamma_{\delta c} = 15$ which is significantly below the values of $\sim 50$ inferred from one-zone model (Begelman et al. 2008). For this simulation, the characteristic time-scale $R_0/(\delta c)$ is $\sim 200$ s in agreement with observations.
Once we have obtained the best-fitting parameters of the ‘flaring state’, we fit the TeV ‘quiescent state’ by fixing the fit parameters associated with the jet structure and dynamics, allowing only the density of the particles filling the jet free to vary. We choose to fit the averaged spectrum derived above 200 GeV by HESS in Aharonian et al. (2007), since it does not strongly differ from the quiescent state. The corresponding best-fitting parameters are also reported in Table 1 and the best-fitting model has been overplotted in Fig. 2 in dashed line.

### 3.1 Time-dependent simulation

After having constrained the jet and plasma characteristics of PKS 2155–304 in both quiescent and flaring states, we aim at reproducing the light curve observed by HESS during the big flare event by using a variable injection of particle. Based on the analysis of Aharonian et al. (2007), where the light curve is decomposed in five successive asymmetric bursts, we use, for the flare period, an injection function \( \Phi(z = 0, t) \) that is the sum of five ‘generalized Gaussian’ shape (Norris et al. 1996), for example:

\[
\Phi(0, t) = \sum_i \Phi_i \exp\left(-\frac{|t - t_{i\text{max}}|}{\sigma_i} \right)^{\nu_i},
\]

where \( t_{i\text{max}} \) is the time of the maximum of the burst \( i \), \( \sigma_i \) and \( \sigma_d \) the rise (\( t < t_{i\text{max}} \)) and decay (\( t > t_{i\text{max}} \)) time constant, respectively, and \( \nu \) is a measure of the sharpness of the burst. We have plotted in the middle of Fig. 3 the assumed injection function. Before the flare, \( \Phi(z = 0, t) \) is assumed to be a crenel function that oscillates between quiescent and flaring states in agreement with the source duty cycle. At the top of Fig. 3, we have reported the HESS light curve and the simulated one. The agreement is very good. We have also overplotted in Fig. 2 in solid line an instantaneous spectrum extracted from the time-dependent simulation during the flare period. It agrees nicely with the broad-band (from radio to TeV) spectrum observed during this burst.

### 4 DISCUSSION

Our time-dependent inhomogeneous jet model succeeds in reproducing simultaneously the broad-band (from radio to TeV) spectrum of PKS 2155–304 as well as the TeV light curve during the big flare.

---

**Table 1.** Model parameters of the flaring and quiescent state. During the flaring state, the flux of injected particles varies between the indicated minimum and maximum values, following the injection pattern displayed in Fig. 3. The other parameters remain fixed. \( R_i, R_0, Z_0, Z_c \) are in unit of \( 10^{12} \) cm.

| State       | \( \Phi(Z_i) \) \( (10^{32} \text{s}^{-1}) \) | \( N(Z_i) \) \( (10^{45} \text{ cm}^{-1}) \) | \( \Phi(Z_0) \) \( (10^{42} \text{s}^{-1}) \) | \( N(Z_0) \) \( (10^{45} \text{ cm}^{-1}) \) | \( Q_0 \) \( (\text{s}^{-1}) \) | \( \Gamma_{\text{esc}} \) | \( R_i \) | \( R_0 \) | \( Z_0 \) | \( Z_c \) | \( B_0 \) \( (G) \) | \( \omega \) | \( \lambda \) | \( \zeta \) |

|             | Min                                         | 1.16                                        | 1051                                        | 1.55                                        | 40                                          | 2.5                                       |        |     |    |    |    |     |    |   |   |
event of 2006 July. The key idea of the method is to decompose the blazar spectrum in 'quiescent', low-luminosity states, and 'flaring', high-luminosity states. The high-energy part of the spectrum, coming from small-scale inner regions, is assumed to be, at any time, in one of these pure states. On the other hand, the low-energy part is a convolution over a large scale of the past history of the jet: it is thus rather a time-averaged spectral state mixing quiescent and flaring states in proportions given by the source 'duty cycle'. Moreover, we do not require two different populations of emitting particles like in other models (e.g. Chiaberge et al. 2000; Katarzyński et al. 2003) but simply a continuous (although variable) injection of particles at the base of the jet that propagate along the jet structure. Pair production plays an important role to amplify the initial variation, as can be seen with the variation of the particle flux along the jet during the flaring state (see Table 1): the pair current is amplified by a factor of 30 at the end of the jet, when the initial current varies only by a factor of 2.

The model can also predict light curves at different wavelengths. As an example, the X-ray (2–10 keV) and optical (V band) light curves expected during the TeV flare have been plotted at the bottom of Fig. 3. The X-ray luminosity exhibits almost simultaneous variations but with a lower amplitude (about five times smaller). On the other hand, the optical light curve shows a very different behaviour, increasing all along the flare. This is due to the large size of the optical emitting region that plays the role of a low pass filter. Consequently, the optical luminosity integrates the recent past history of the jet. These results are compatible with simultaneous multiwavelength observations made during the 'Chandra night' (oral communication).

This model puts also some constraints on the central black hole mass. Indeed, the radius at the base of the jet is directly linked to the bulk Doppler factor. From our best-fitting parameters, we find $M_{bh} = 8 \times 10^9 M_\odot$ where $r_j = GM_{bh}/c^2$ is the gravitational radius. This implies a black hole mass smaller than $10^9 M_\odot$ usually invoked in the case of PKS 2155–304 (Kotilainen, Falomo & Scarpa 1998). We believe, however, that it is still acceptable given the mass measurement uncertainties (Bettoni et al. 2003).

In this work, we do not specify the origin of the variability. Obviously, other plasma parameters can vary in addition to the injection density $N_0$. Most likely, variability can be triggered by a change in the acceleration rate described by $Q_0$ (equation 5). In a plausible scenario, long-term (year scale) variability implying the succession of quiescent and active states could be attributed to variations in the accretion rate, whereas the short (minute scale) flares would be attributed to the instability to pair creation that develops only when the initial particle density is close to a critical threshold.
