Key challenges facing a theory of the normal state (at zero magnetic field) of the copper oxide high temperature superconductors include 1) T-linear resistivity, 2) the pseudogap, 3) absence of quasiparticles, and 4) the mid-infrared band in the optical conductivity.

Since the parent cuprates are Mott insulators, the normal state properties should, in principle, be derivable from the corresponding low-energy theory. Proper low-energy theories are constructed by integrating out the degrees of freedom at high energy, even in the simplest model for a doped Mott insulator.

\[ H_{\text{Hubb}} = -t \sum_{i,j,\sigma} g_{ij} c_{i,\sigma}^\dagger c_{j,\sigma} + U \sum_{i,\sigma} c_{i,\uparrow}^\dagger c_{i,\downarrow}^\dagger c_{i,\downarrow} c_{i,\uparrow} \]  

(1)

Here \( i, j \) label lattice sites, \( g_{ij} \) is equal to one if \( i, j \) are nearest neighbours, \( c_{i,\sigma} \) annihilates an electron with spin \( \sigma \) on lattice site \( i \), \( t \) is the nearest-neighbour hopping matrix element and \( U \) the energy cost when two electrons doubly occupy the same site. The cuprates live in the strongly coupled regime in which the interactions dominate as \( t = 0.5eV \) and \( U = 4eV \). As \( U \) is the largest energy scale, it is appropriate to integrate over the fields that generate the physics on the \( U \) scale. We showed explicitly that the Lagrangian in the extended Hilbert space is quadratic in the high-energy field and hence all integrals can be performed exactly. Let us define

\[ \mathcal{M}_{ij} = \delta_{ij} - \frac{t}{(\omega + U)} g_{ij} \sum_{\sigma} c_{i,\sigma}^\dagger c_{i,\sigma} \]  

and \( b_j = \sum_i b_{ij} = \sum_{i\sigma} g_{ij} c_{i,\sigma} V_{\sigma} c_{i,-\sigma} \) with \( V_1 = -V_1 = 1 \). At zero frequency, the exact low-energy Hamiltonian is

\[ H^R_{\text{int}} = -t \sum_{i,j,\sigma} g_{ij} \alpha_{ij\sigma} c_{i,\sigma}^\dagger c_{j,\sigma} + H_{\text{int}} - \frac{1}{\beta} Tr \ln \mathcal{M} , \]

where

\[ H_{\text{int}} = -\frac{t^2}{U} \sum_{j,k} b_{j}^\dagger (\mathcal{M}^{-1})_{jk} b_k - \frac{t^2}{U} \sum_{i,j} \varphi_{i,j}^\dagger (\mathcal{M}^{-1})_{ij} \varphi_j \]

\[ -t \sum_j \varphi_{j,\uparrow}^\dagger c_{j,\downarrow} - \frac{t^2}{U} \sum_{i,j} \varphi_{i,j}^\dagger (\mathcal{M}^{-1})_{ij} b_j + h.c. \]  

(3)

1. OVERVIEW OF LOW-ENERGY THEORY

In a series of papers, we showed how to coarse grain the Hubbard model cleanly for \( U \gg t \). We accomplished this by extending the Hilbert space of the Hubbard model and associating with the high energy scale a new fermionic oscillator which is constrained. The coupling constant for the fermionic oscillator is \( U \).

We showed that once the constraint is solved, we obtained exactly the Hubbard model. However, since the energy scale of the new oscillator is \( U \), the low-energy theory is obtained by integrating over this field. We showed explicitly that the Lagrangian in the extended Hilbert space is quadratic in the high-energy field and hence all integrals can be performed exactly. Let us define

\[ H_{\text{int}}^R = -t \sum_{i,j,\sigma} g_{ij} \alpha_{ij\sigma} c_{i,\sigma}^\dagger c_{j,\sigma} + H_{\text{int}} - \frac{1}{\beta} Tr \ln \mathcal{M} , \]

where

\[ H_{\text{int}} = -\frac{t^2}{U} \sum_{j,k} b_{j}^\dagger (\mathcal{M}^{-1})_{jk} b_k - \frac{t^2}{U} \sum_{i,j} \varphi_{i,j}^\dagger (\mathcal{M}^{-1})_{ij} \varphi_j \]

\[ -t \sum_j \varphi_{j,\uparrow}^\dagger c_{j,\downarrow} - \frac{t^2}{U} \sum_{i,j} \varphi_{i,j}^\dagger (\mathcal{M}^{-1})_{ij} b_j + h.c. \]  

(3)
which contains a charge 2e bosonic field, $\varphi_i$.

The low-energy theory acts only in the original Hilbert space of the Hubbard model because we integrated out all operators which acted in the extended space. Consequently, it is incorrect to interpret $\varphi_i$ as a canonical boson operator with an associated Fock space. Likewise, we should not immediately conclude that $\varphi_i$ gives rise to a propagating charge 2e bosonic mode, as it does not have canonical kinetics; at the earliest, this could be generated at order $O(t^3/U^2)$ in perturbation theory. Alternatively, we believe that $\varphi$ appears as a bound degree of freedom. The new composite charge e state is crucial to explaining the origin of dynamical spectral weight transfer across the Mott gap. As a consequence, the conserved charge is no longer just the electron number but rather,

$$Q = \sum c^\dagger_i c_i + 2 \sum \varphi_i^\dagger \varphi_i.$$  

(4)

The terms containing $\varphi_i$ are absent from projective theories and represent the fact that consistent with the Hubbard model, the corresponding low-energy theory is not diagonal in any sector containing a fixed number of doubly occupied sites. As we have shown elsewhere, the presence of double occupancy in the low-energy theory presented above is completely compatible with the standard derivation of the t-J model. One simply has to remember that the operators appearing in the t-J model are transformed into fermions which are related by a similarity transformation to the bare electrons appearing in the Hubbard model. If the rotated fermions are expressed in terms of the original electron operators in the Hubbard model, double occupancy of the bare fermions is reinstated. In fact, the t-J model expressed in terms of the original bare electron operators contains processes which mix the doubly and singly occupied sectors with a matrix element $t^2/U$.

(3)

However, it is common to interpret the $t-J$ model as a model about physically doped holes in a Mott insulator. Unless the operators in the $t-J$ model are transformed back to the original basis, it is impossible to make any connection between doped holes in the two theories.

Physical processes mediated by the boson include singlet motion (third term in Eq. (3)) and motion of double occupancy in the lower Hubbard band (second term in Eq. (3)). The latter has a bandwidth of $t$ and, as we will show, constitutes the mid-infrared band. Since Eq. (3) retains all the low-energy degrees of freedom, a $(t/U)$ expansion is warranted. To leading order in $t/U$, $\mathcal{M} = \delta_{ij}$ and the effective low-energy Hamiltonian simplifies to

$$H_{\text{eff}} = -t \sum_{i,j,\sigma} g_{ij} c_{i\sigma} c_{j\sigma}^\dagger - \frac{t^2}{U} \sum_j b_j^\dagger b_j - \frac{t^2}{U} \sum_{i,j} \varphi_i^\dagger \varphi_i.$$  

(5)

The first two terms contain the interactions in the $t-J$ model as the two-site term in $b_j^\dagger b_j$ is proportional to the unprojected spin-spin interaction. In second-order perturbation theory, the interaction term $\varphi_i^\dagger b_i$ mediates the process in Fig. (1). In this process, hole motion over three sites is possible only if a doubly occupied site and a hole are neighbours. This process is absent if one assumes that the no-double occupancy condition in the t-J model applies to the bare electrons as well. The latter is true exactly at $U = \infty$. As we will see, this process, which is present as a result of the bosonic degree of freedom, is responsible for many of the anomalous properties of the normal state of the cuprates.

A. Electron Spectral Function

We analyze the nature of the electronic excitations at low energy by focusing on the electron spectral function. Since this calculation cannot be done exactly, we establish at the outset the basic physics that a correct calculation should preserve. We have shown previously that the electron creation operator at low energy,$$c_{i,\sigma}^\dagger \to (1 - n_{i,\sigma}) c_{i,\sigma}^\dagger + V_{\sigma} \frac{t}{U} b_i^\dagger M_{ij}^{-1} c_{j,\sigma} - V_{\sigma} \frac{s}{U} \varphi_i^\dagger M_{ij}^{-1} c_{j,\sigma}.$$  

(6)

contains the standard term for motion in the lower Hubbard band (LHB), $(1 - n_{i,\sigma}) c_{i,\sigma}^\dagger$ for electron doping) with a renormalization from spin fluctuations (second term) and a new charge $e$ excitation, $c_{i,\sigma} M_{ij}^{-1} \varphi_j^\dagger$. In the lowest order in $t/U$, our theory predicts that the new excitation corresponds to $c_{i,\sigma} \varphi_i^\dagger$, that is, a hole bound to the charge 2e boson. This extra charge $e$ state mediates dynamical (hopping-dependent) spectral weight transfer across the Mott gap.

Consequently, we predict that an electron at low energies is in a superposition of the standard LHB state (modified with spin fluctuations) and a new charge $e$ state which is a composite excitation. It is the presence of these
two distinct excitations that gives rise to the static (state counting giving rise to 2x) and dynamical parts of the spectral weight transfer. A saddle-point analysis will select a particular solution in which $\varphi_i$ is non-zero. This will not be consistent with the general structure of Eq. (6) in which part of the electronic states are not fixed by $\varphi_i$. Similarly, mean field theory in which $\varphi_i$ is assumed to condense, thereby thwarting the possibility that new excitations form, is also inadequate.

The procedure we adopt is the simplest that preserves the potential strong interactions between the Bose and Fermi degrees of freedom. We treat $\varphi_i$ to be spatially independent with no dynamics of its own. This interpretation is consistent with the fact that $\varphi_i$ acquires dynamics only through electron motion. Under this assumption, the single-particle electron Green function

$$G(k, \omega) = -iFT \int [D\varphi^*][D\varphi] \int [Dc^*_i][Dc_i(t)c_j^*(0)] \exp^{-\int L[c,\varphi]dt},$$

where $FT$ refers to the Fourier transform and $T$ is the time-ordering operation. Further, since our focus is on the new physics mediated by the interaction between the Bose and Fermi degrees of freedom and Eq. (6) suggests that the spin-spin interaction simply renormalizes the electronic states in the LHB, we will neglect the spin-spin term. To see what purely fermionic model underlies the neglect of the spin-spin term in Eq. (5), we integrate over $\varphi_i$. The full details of how to carry out such an integration are detailed elsewhere. The resultant Hamiltonian is not the Hubbard model but rather,

$$H' = H_{Hubb} - \frac{t^2}{U} \sum_i b^\dagger_i b_i,$$

a $t - J - U$ model in which the spin-exchange interaction is not a free parameter but fixed to $J = -t^2/U$. That the $t - J - U$ model with $J = -t^2/U$ is equivalent to a tractable IR model, namely Eq. (6) without the spin-spin term, is an unexpected simplification. As Mott physics still pervades the $t - J - U$ model in the vicinity of half-filling, our analysis should reveal the non-trivial charge dynamics of this model. That is, the physics we uncloak here is independent of the spin degrees of freedom. In fact, what we show is that the spin-spin interaction (as in the hard-projected $t - J$ model) is at best ancillary to many of the normal state properties of the cuprates.

To proceed, we will organize the calculation of $G(k, \omega)$ by first integrating out the fermions (holding $\varphi$ fixed)

$$G(k, \omega) = \int [D\varphi^*][D\varphi] FT \left( \int [Dc^*_i][Dc_i(t)c_j^*(0)] \exp^{-\int L[c,\varphi]dt} \right)$$

where now

$$L = \sum_{k\sigma} (1 - n_{i\sigma})c_{k\sigma}^\dagger c_{k\sigma} - \left(2\mu + \frac{s^2}{U} \right) \varphi^\dagger \varphi - \sum_{k\sigma} (g_{t \alpha k} + \mu) c_{k\sigma}^\dagger c_{k\sigma} + s\varphi^\dagger \sum_k (1 - \frac{2s}{U}) c_{-k\uparrow} c_k \uparrow + c.c.$$

The effective Lagrangian can be diagonalized and written as
in terms of a set of Bogoliubov quasiparticles,

\[
\begin{align*}
\gamma_{k_1}^* &= +\cos^2 \theta_k c_{k_1} + \sin^2 \theta_k c_{-k_1} \\
\gamma_{k_1} &= -\sin^2 \theta_k c_{k_1} + \cos^2 \theta_k c_{-k_1}
\end{align*}
\] (13)

\[
\begin{align*}
\gamma_{k_1}^* &= +\cos^2 \theta_k c_{k_1} + \sin^2 \theta_k c_{-k_1} \\
\gamma_{k_1} &= -\sin^2 \theta_k c_{k_1} + \cos^2 \theta_k c_{-k_1}
\end{align*}
\] (14)

where \( \cos^2 \theta_k = \frac{1}{2}(1 + \frac{\eta_k}{\lambda_k}) \). Here, \( \alpha_k = 2(\cos k_x + \cos k_y) \), \( \eta_k = 2(\cos k_x - \cos k_y) \), \( E_0 = -(2\mu + \frac{\eta_k}{\lambda_k})\varphi^* \varphi \), \( E_k = -g_t \alpha_k - \mu \), \( \lambda_k = \sqrt{E_k^2 + \Delta_k^2} \), \( \Delta_k = s\varphi^*(1 - \frac{t^2}{4}\alpha_k) \) and \( g_t = \frac{2t}{t + t^2} \) when \( \delta = 1 - n \rightarrow 1 - Q + 2\varphi^* \varphi \) is a renormalized factor which originates from the correlated hopping term \( (1 - n i\omega) c_{i\sigma}^\dagger c_{j\sigma}(1 - n j\sigma) \). Starting from Eq. (12), we integrate over the fermions in Eq. (10) to obtain,

\[
G(k, \omega) = \frac{1}{Z} \int [D\varphi^*][D\varphi] G(k, \omega, \varphi) \exp -\sum_k (E_0 + E_k - \lambda_k - \frac{2}{\beta} \ln(1 + \exp^{-\beta \lambda_k}))
\] (15)

where

\[
G(k, \omega, \varphi) = \frac{\sin^2 \theta_k[\varphi]}{\omega + \lambda_k[\varphi]} + \frac{\cos^2 \theta_k[\varphi]}{\omega - \lambda_k[\varphi]}
\] (16)

is the exact Green function corresponding to the Lagrangian, Eq. (12). The two-pole structure of \( G(k, \omega, \varphi) \) will figure prominently in the structure of the electron spectral function. To calculate \( G(k, \omega) \), we numerically evaluated the remaining \( \varphi \) integral in Eq. (15). Since Eq. (15) is averaged over all values of \( \varphi \), we have circumvented the problem inherent in mean-field or saddle-point analyses. Physically, Eq. (15) serves to mix (through the integration over \( \varphi \)) all subspaces with varying numbers of double occupancies into the low-energy theory. Hence, it should retain the full physics inherent in the bosonic degree of freedom.

The spectral function for \( U = 10t \) evaluated from Eq. (10) and displayed in Figs. (2a) and Fig. (3) exhibits four key features. First, regardless of the doping, there is a low-energy kink in the electron dispersion. The enlarged region in Fig. (4a) shows, in fact, that two kinks exist. The low-energy kink occurs at roughly \( 0.2t \approx 100meV \). By treating the mass term for the boson as a variable parameter, we verified that the low-energy kink is determined by the bare mass. In the effective low-energy theory, the bare mass is \( t^2/U \). This mass is independent of doping. Experimentally, the low-energy kink is impervious to doping. Consequently, the boson offers a natural explanation of this effect that is distinct from the phonon mechanisms which have been proposed.

Second, a high-energy kink appears at roughly \( 0.5t \approx 250meV \) which closely resembles the experimental kink at \( 300meV \). At sufficiently high doping (see Figs. (3k) and (3l)), the high-energy kink disappears.

Third, experimentally, the high-energy kink is accompanied by a splitting of the electron dispersion into two branches. As is evident, this is precisely the behaviour we find below the chemical potential. The energy difference between the two branches achieves a maximum at \( (0, 0) \) as is seen experimentally. A computation of the spectral function at \( U = 20t \) and \( n = 0.9 \) reveals that the dispersion as well the bifurcation still persist. Further, the magnitude of the splitting does not change, indicating that the energy scale for the bifurcation and the maximum energy splitting are set by \( t \) and not \( U \). The origin of the two branches is captured in Fig. (2b). The two branches below the chemical potential corre-
The formation of the composite excitation, $c_i\sigma\phi^\dagger$, leads to a pseudogap at the chemical potential primarily because the charge $2e$ boson is a local non-propagating degree of freedom. The spectral functions for $n = 0.9$ and $n = 0.8$ both show an absence of spectral weight at the chemical potential. Non-zero spectral weight resides at the chemical potential in the heavily overdoped regime, $n = 0.4$, consistent with the vanishing of the pseudogap beyond a critical doping away from half-filling. Because the density of states vanishes at the chemical potential, we expect that the electrical resistivity to diverge as $T \to 0$. Such a divergence is shown in Fig. (4a) and is consistent with our previous calculations of the dc resistivity using a local dynamical cluster method\cite{19}. When the boson is absent (Fig. (4b)), localization ceases. Although this calculation does not constitute a proof, it is consistent with localisation induced by the formation of the bound composite excitation, $c_i\sigma\phi^\dagger$. This state of affairs obtains because the boson is not an inherently dynamical excitation.

Finally, the imaginary part of the self energy at different temperatures is shown in Fig. (5). At low temperature ($T \leq t^2/U$), the imaginary part of the self-energy at the non-interacting Fermi surface develops a peak at $\omega = 0$. At $T = 0$, the peak leads to a divergence. This is consistent with the opening of a pseudogap. As we have pointed out earlier\cite{20}, a pseudogap is properly identified by a zero surface (the Luttinger surface) of the single-particle Green function. This zero surface is expected to preserve the Luttinger volume if the pseudogap lacks particle-hole symmetry as shown in the second of the figures in Fig. (5).

**B. Mid-Infrared Band**

The mid-infrared band (MIB) in the cuprates is a surprise because the optical conductivity in a doped Mott insulator is expected to be non-zero either at the far-infrared or the ultra-violet or upper-Hubbard-band scale. While many mechanisms have been proposed\cite{21}, no explanation has risen to the fore. Experimentally, the intensity in the MIB increases with doping at the expense of spec-
tral weight at high energy and the energy scale for the peak in the MIB is the hopping matrix element $t$. Since the MIB arises from the high-energy scale, the current theory which accurately integrates out the high energy degrees of freedom should capture this physics. To obtain a direct link between the conductivity and the spectral function, we work in the non-crossing approximation

$$
\sigma_{xx}(\omega) = 2\pi e^2 \int d^2k \int d\omega' (2t \sin k_x)^2 \left( -\frac{f(\omega') - f(\omega + \omega')}{\omega} \right) A(\omega + \omega', k) A(\omega', k)
$$

(17)

to the Kubo formula for the conductivity where $f(\omega)$ is the Fermi distribution function and $A(\omega, k)$ is the spectral function. At the level of theory constructed here, the vertex corrections are all due to the interactions with the bosonic degrees of freedom. Since the boson acquires dynamics only through electron motion and the leading such term is $O(t^4/U^2)$, the treatment here should suffice to provide the leading behaviour of the optical conductivity.

The optical conductivity shown in Fig. (6) peaks at $\omega/t \approx 0.5t$ forming the MIB. As the inset indicates, $\omega_{\text{max}}$ is an increasing function of electron filling $(n)$ whereas the integrated weight

$$
N_{\text{eff}} = \frac{2m^*}{\pi e^2} \int_{0}^{\Omega_c} d\sigma(\omega)
$$

(18)
is a decreasing function. However, $N_{\text{eff}}$ does not vanish at half-filling indicating that the mechanism that causes the mid-IR is evident even in the Mott state. Here we set the integration cutoff to $\Omega_c = 2t = 1/m^*$. Both the magnitude of $\Omega_{\text{max}}$ and its doping dependence as well as the electron filling dependence of the integrated weight are consistent with that of the mid-infrared band in the optical conductivity in the cuprates.6,7,9,10,11. To determine what sets the scale for the MIB, we studied its evolution as a function of $U$. Figure (7) verifies that $\omega_{\text{max}}$ is set essentially by the hopping matrix element $t$ and depends only weakly on $J$. The physical processes that determine this physics are determined by the coupled boson-Fermi terms in the low-energy theory. The $\varphi_i^\dagger c_{ij}^\dagger$ term has a coupling constant of $t$ whereas the $\varphi_i^\dagger b_j$ scales as $t^2/U$. Together, both terms give rise to a MIB band that scales as $\omega_{\text{max}}/t = 0.8 - 2.21t/U$ (see inset of Fig. (7)). Since $t/U \approx O(0.1)$ for the cuprates, the first term dominates and the MIB is determined predominantly by the hopping matrix element $t$. Within the interpretation that $\varphi$ represents a bound state between a doubly occupied site and a hole, second order perturbation theory with the $\varphi_i^\dagger b_j$ term mediates the process shown in Fig. (1). It is the resonance between these two states that results in the mid-IR band. Interestingly, this resonance persists even at half-filling and hence the non-vanishing of $N_{\text{eff}}$ at half-filling is not evidence that the cuprates are not doped Mott insulators as has been recently claimed.44. In their work, Comanac and colleagues41 used a single-site dynamical mean-field approach. In such approaches, near-neighbour correlations are absent.

Since the physics in Fig. (1) is not present in projective models which prohibit double occupancy in the Hubbard basis (not simply the transformed fermion basis of the t-J model), it is instructive to see what calculations of the optical conductivity in the t – J model reveal. All existing calculations10,42,43 on the t – J model find that the MIB scales as $J$. In some of these calculations, superconductivity is needed to induce an MIB42 also at an energy scale of $J$. Experimentally6,7,11, it is clear that the MIB is set by the $t$ scale rather than $J$. In fact, since the MIB grows at the expense of spectral weight in the upper-Hubbard band, it is not surprising that the t-J model cannot describe this physics as first pointed
out by Uchida, et al.\textsuperscript{7} The physical mechanism we have identified here, Fig. (1) clearly derives from the high energy scale, has the correct energy dependence, and hence satisfies the key experimental constraints on the origin of the MIB. Since the physics in Fig. (1) is crucial to the mid-IR, it is not surprising that single-site analyses\textsuperscript{41} fail to obtain a non-zero intercept in the extreme Mott limit. The non-zero intercept of $N_{\text{eff}}$ is a consequence of Mottness and appears to be seen experimentally in a wide range of cuprates.\textsuperscript{6,44,45,46}

C. Dielectric function: Experimental Prediction

In the previous section, we have calculated the electronic spectral function which shows that there are two branches below the chemical potential. Such physics is explained by the formation of a new composite excitation, representing a bound state, consisting of a bound hole and a charge $2e$ boson, $\varphi_i^\dagger c_{i\sigma}$. We demonstrated that for the MIB in the optical conductivity such an excitation also appears. In principle, these composite charge excitations should show up in all electric response functions, for example, the energy loss function, $\Im (1/\epsilon(\omega,q))$, where $\epsilon(\omega,q)$ is the dielectric function. We show here that this is the case.

To this end, we calculate the inverse dielectric function,

\[
\frac{\Im}{\epsilon(\omega,q)} = \pi \frac{U}{t} \sum_p \int d\omega' (f(\omega') - f(\omega + \omega')) \times A(\omega + \omega',p + q)A(\omega',p),
\]

(19)

using the non-crossing approximation discussed earlier. Our results are shown in Fig. (8) for $n = 0.9$ and $n = 0.6$ for $q$ along the diagonal. Two features are distinct. First, there is a broad band (red arrow in Fig. (8)) with the width of order $t$ that disperses with $q$ for both doping levels. It is simply the particle-hole continuum which arises from the renormalized bare electron band. The band width is doping dependent as a result of the renormalization of the band with doping. More strikingly, for $n = 0.9$, a sharp peak exists at $\omega/t \approx 0.2t$. It disperses with $q$, terminating when $q \rightarrow (\pi,\pi)$. Physically, the sharp peak represents a quasiparticle excitation of the composite object, $\varphi_i^\dagger c_{i\sigma}$, the charge $2e$ boson and a hole. Therefore, we predict that if this new composite charge excitation, $\varphi_i^\dagger c_{i\sigma}$, is a real physical entity, as it seems to be, it will give rise to a sharp peak in addition to the particle-hole continuum in the inverse dielectric function. Since this function has not been measured at present, our work here represents a prediction. Electron-energy loss spectroscopy can be used to measure the inverse dielectric function. Our key prediction is that momentum-dependent scattering should reveal a sharp peak that appears at low energy in a doped Mott insulator. We have checked numerically the weight under the peaks in the inverse dielectric function and the sharp peak is important. Hence, the new charge $e$ particle we have identified here should be experimentally observable.

The two dispersing particle-hole features found here are distinct from a similar feature in stripe models.\textsuperscript{47} In such models the second branch\textsuperscript{47} has vanishing weight and whereas in the current theory both features are of unit weight.
Density of states for \( U \) calculated via the relationship $\bar{E}(\omega) = \int d\omega D(\omega)\omega f(\omega)$, where the internal energy, $\bar{E}$, is

\[
\bar{E} = \int d\omega D(\omega)\omega f(\omega)
\]

and $D(\omega) = \sum_k A(\omega, k)$ is the density of states displays a perfectly quadratic temperature dependence in the doping regime where the pseudogap is present as is seen experimentally. As it is the boson that underlies the pseudogap, it is the efficient cause of the $T^2$ dependence of the heat capacity. In our theory, the steeper slope occurs at smaller doping which gives rise to the largest heat capacity at half filling. This doping dependence of the heat capacity seems to contradict the experimental observations. A key in determining the magnitude of the heat capacity is the spin degrees of freedom. As we have focused entirely on the bosonic degree of freedom and not on the contribution from the spin-spin interaction terms, we have over-estimated the kinetic energy. Such terms, though they do not affect the pseudogap found here (from Eq. (6)) it is clear that the spin-spin terms renormalize the standard fermionic branch in the lower-Hubbard band leaving the new state mediated by $\tilde{\varphi}$ untouched, do alter the doping dependence.

Additionally, the thermal conductivity, $\tau(T)$, can be calculated using the Kubo formula in non-crossing approximation,

\[
\tau(T) = \frac{e}{4k_BT} \sum_k \int \frac{d\omega}{2\pi} (v_k^2)^2 \omega^2 \left( -\frac{\partial f(\omega)}{\partial \omega} \right) A(k, \omega)^2.
\]

The thermal conductivity shown in Fig. 9 scales as $T^2$ which is identical to that of the heat capacity. However, the system exhibits a larger thermal conductivity as the doping increases in contrast to the heat capacity which is decreasing as the doping increases. Physically, this signifies that the carriers are more mobile as the doping increases.

D. Heat conductivity and heat capacity

As shown by Loram and collaborators, the heat capacity in the cuprates in the normal state scales as $T^2$. Quite generally, a density of states that vanishes linearly with energy, that is, a V-shaped gap, yields a heat capacity that scales quadratically with temperature. The coefficient of the $T^2$ term is determined by the slope of the density of states in the vicinity of the chemical potential. The magnitude of the $T^2$ term should diminish as the doping increases because the slope of the density of states decreases as the pseudogap closes. As we showed in the previous section, the boson creates a pseudogap. The energy dependence of the gap is shown in the inset of Fig. 9. Quite evident is the linear dependence on energy. The resultant heat capacity shown in Fig. 9, calculated via the relationship $C_v = \frac{d\bar{E}}{dT}$, where the internal energy, $\bar{E}$, is

\[
C_v = \frac{\bar{E}}{T} \sum_{\omega} A(\omega, k) \omega f(\omega)
\]

and $\bar{E}(\omega) = \sum_{\omega} A(\omega, k)$ is the density of states displays a perfectly quadratic temperature dependence in the doping regime where the pseudogap is present as is seen experimentally. As it is the boson that underlies the pseudogap, it is the efficient cause of the $T^2$ dependence of the heat capacity. In our theory, the steeper slope occurs at smaller doping which gives rise to the largest heat capacity at half filling. This doping dependence of the heat capacity seems to contradict the experimental observations. A key in determining the magnitude of the heat capacity is the spin degrees of freedom. As we have focused entirely on the bosonic degree of freedom and not on the contribution from the spin-spin interaction terms, we have over-estimated the kinetic energy. Such terms, though they do not affect the pseudogap found here (from Eq. (6)) it is clear that the spin-spin terms renormalize the standard fermionic branch in the lower-Hubbard band leaving the new state mediated by $\tilde{\varphi}$ untouched, do alter the doping dependence.

Additionally, the thermal conductivity, $\tau(T)$, can be calculated using the Kubo formula in non-crossing approximation,

\[
\tau(T) = \frac{e}{4k_BT} \sum_k \int \frac{d\omega}{2\pi} (v_k^2)^2 \omega^2 \left( -\frac{\partial f(\omega)}{\partial \omega} \right) A(k, \omega)^2.
\]

The thermal conductivity shown in Fig. 9 scales as $T^2$ which is identical to that of the heat capacity. However, the system exhibits a larger thermal conductivity as the doping increases in contrast to the heat capacity which is decreasing as the doping increases. Physically, this signifies that the carriers are more mobile as the doping increases.

E. T-linear Resistivity

Over a funnel-shaped region in the $T - x$ plane, the resistivity displays the anomalous linear-T dependence. The standard explanation attributes $T-$ linear resistivity to quantum criticality. However, one of us has recently shown that under three general assumptions, 1) additional non-critical degrees of freedom carry the current and 3) charge is conserved, the resistivity in the quantum critical regime takes the universal form,

\[
\sigma(\omega = 0) = \frac{Q^2}{\hbar} \sum_{s} \left( \frac{k_BT}{\hbar c} \right)^{(d-2)/z}.
\]

Consequently, $T-$linear resistivity obtains (for d=3) only if the dynamical exponent satisfies the unphysical constraint $z < 0$. The inability of Eq. (21) to lead to a consistent account of $T-$linear resistivity signifies that 1) either $T-$linear resistivity is not due to quantum criticality, 2) additional non-critical degrees of freedom are necessarily the charge carriers, or 3) perhaps some new theory of quantum criticality can be constructed in which the single-correlation length hypothesis is relaxed.

We show that the low-energy theory presented here contains elements of both (2) and (3) which lead to $T-$linear resistivity. The formation of the pseudogap and the divergence of the electrical resistivity are highly suggestive that a bound state between a hole and the charge is conserved, the resistivity arising from electron-phonon scattering is linear in temperature. In the critical regime, the current
mechanism yields a $T$–linear resistivity for the same reason. Namely, in the critical region, the energy to create a boson vanishes as shown in Fig. 11 and hence the resistivity arising from electron-boson scattering should be linear in temperature. This mechanism is robust as it relies solely on the vanishing of the boson energy at criticality and not on the form of the coupling. To the right of the quantum critical point, standard electron-electron interactions dominate and Fermi liquid behaviour obtains. In this scenario, the quantum critical point coincides with the termination of the pseudogap phase, or equivalently with the unbinding of the bosonic degrees of freedom.

**F. Final Remarks**

We have shown here that 1) $T$-linear resistivity, 2) high and low-energy kinks in the electron dispersion, 3) pseudogap phenomena, 4) mid-infrared absorption, 5) $T^2$ heat capacity, and 6) the bifurcation of the electron addition spectrum all emerge from the bosonic degree of freedom which exists in the exact low-energy theory of a doped Mott insulator. All the features found here arise from the charge rather than from the spin dynamics and hence have nothing to do with the spin-spin interaction of the $t$–$J$ model. The essential feature of the charge $2e$ boson is that it gives the electron substructure, as is observed experimentally. Further, it does so entirely from a collective mode arising from the strong correlations. No lattice phenomena need be invoked. Consequently, we attribute the anomalies of the normal state of the cuprates to a purely electronic cause which is captured by the physics of the exact-low energy theory of a doped Mott insulator. The key experimental prediction which is sufficient to falsify this theory is the existence of a sharp quasiparticle excitation in the inverse dielectric function. The new quasiparticle represents the collective motion of a double occupancy and a hole as depicted in Fig. 1, which emerges naturally in the exact low-energy theory as a charge $2e$ boson bound to a hole. The existence of such a quasiparticle underscores the fact that double occupancy at low energy requires a hole in its immediate vicinity. Since this prediction is sharp, experimental falsification of this theory should be straightforward.
