Measurement of prompt $D^0$, $D^+$, $D^{*+}$, and $D_s^+$ production in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV

ALICE Collaboration

Abstract

The measurement of the production of prompt $D^0$, $D^+$, $D^{*+}$, and $D_s^+$ mesons in proton–lead (p–Pb) collisions at the centre-of-mass energy per nucleon pair of $\sqrt{s_{NN}} = 5.02$ TeV, with an integrated luminosity of $292 \pm 11 \mu b^{-1}$, are reported.

Differential production cross sections are measured at mid-rapidity ($-0.96 < y_{\text{cms}} < 0.04$) as a function of transverse momentum ($p_T$) in the intervals $0 < p_T < 36$ GeV/c for $D^0$, $1 < p_T < 36$ GeV/c for $D^+$ and $D^{*+}$, and $2 < p_T < 24$ GeV/c for $D_s^+$ mesons. For each species, the nuclear modification factor $R_{\text{pPb}}$ is calculated as a function of $p_T$ using a proton-proton (pp) reference measured at the same collision energy. The results are compatible with unity in the whole $p_T$ range. The average of the non-strange D mesons $R_{\text{pPb}}$ is compared with theoretical model predictions that include initial-state effects and parton transport model predictions. The $p_T$ dependence of the $D^0$, $D^+$, and $D^{*+}$ nuclear modification factors is also reported in the interval $1 < p_T < 36$ GeV/c as a function of the collision centrality, and the central-to-peripheral ratios are computed from the D-meson yields measured in different centrality classes. The results are further compared with charged-particle measurements and a similar trend is observed in all the centrality classes. The ratios of the $p_T$-differential cross sections of $D^0$, $D^+$, $D^{*+}$, and $D_s^+$ mesons are also reported. The $D_s^+$ and $D^+$ yields are compared as a function of the charged-particle multiplicity for several $p_T$ intervals. No modification in the relative abundances of the four species is observed with respect to pp collisions within the statistical and systematic uncertainties.
1 Introduction

Measurements of heavy-flavour hadron production in proton–nucleus collisions allow for an assessment of the various effects related to the presence of nuclei in the colliding system, denoted as cold-nuclear-matter (CNM) effects. Heavy quarks (charm and beauty) are primarily produced in hard-scattering processes with large momentum transfer \( Q^2 \) due to their large masses. Their inclusive production cross sections can therefore be calculated perturbatively in Quantum Chromodynamics (QCD) utilizing the factorisation approach. In this scheme, the \( p_T \) differential production cross sections of hadrons containing charm or beauty quarks are calculated as a convolution of three terms: (i) the parton distribution functions (PDFs) of the incoming nucleons, (ii) the partonic scattering cross section, calculated as a perturbative series in powers of the strong coupling constant \( \alpha_s \), and (iii) the fragmentation function, which parametrises the non-perturbative evolution of a heavy quark into a given heavy-flavour hadron species.

Theoretical predictions based on perturbative QCD (pQCD) calculations at next-to-leading order accuracy with all-order resummation of next-to-leading logarithms, such as FONLL \([1, 2]\) and GM-VFNS \([3-6]\), can describe within uncertainties the production cross sections of D and B mesons measured in pp and pp collisions in different kinematic regions at centre-of-mass energies from 0.2 to 13 TeV (see e.g. Ref. \([7, 8]\) and references therein). In proton–nucleus collisions, various effects in the initial and final state could modify the D-meson production cross sections per nucleon–nucleon collision as compared to pp interactions. In the initial state, the production is affected by the modification of the PDFs in bound nucleons compared to those of free nucleons, depending on the parton momentum fraction \( x \), the momentum transfer \( Q^2 \) in the hard scattering process, and the nucleus mass number \( A \). At LHC energies and at mid-rapidity, the most relevant effect on the PDFs is shadowing: a reduction of the parton densities at low \( x \) (below \( 10^{-2} \)), which becomes stronger when \( Q^2 \) decreases and the nucleus mass number \( A \) increases. This effect can be described by means of phenomenological parametrisations of the PDF modifications, denoted as nuclear PDFs (nPDFs) \([11-14]\). If the parton phase-space reaches saturation, the appropriate theoretical description is the Colour Glass Condensate effective theory (CGC) \([15-19]\). The modification of the small-\( x \) parton dynamics can significantly reduce the D-meson yield at low \( p_T \). Furthermore, the multiple scattering of partons in the nucleus, before and/or after the hard scattering, can modify the kinematic distribution of the produced hadrons. Partons can lose energy in the initial stages of the collision via initial-state radiation \([20]\), or experience transverse momentum broadening due to multiple soft collisions before the heavy-quark pair is produced \([21-23]\). These effects can also induce a significant modification of D-meson production at low \( p_T \). In addition, final-state effects may also be responsible for a modification of heavy-flavour hadron yields and momentum distributions. The presence of significant final-state effects in p–Pb collisions with large multiplicities of produced particles is suggested by different observations, e.g. the presence of long-range structures in two-particle angular correlations of charged hadrons \([24, 28]\), the studies of azimuthal anisotropies in multi-particle correlations \([29, 30]\), the evolution with multiplicity of the identified-hadron transverse-momentum distributions \([31, 32]\), and the suppression of the \( \psi(2S) \) production with respect to that of J/\( \psi \) mesons \([33, 35]\).

In particular, the angular correlations in high-multiplicity p–Pb collisions were found to have similar properties (e.g. particle mass and \( p_T \) dependence \([31, 32]\)) as those observed in Pb–Pb collisions, where they are commonly interpreted as indications of a collective particle flow produced during the hydrodynamic evolution of the Quark-Gluon Plasma (QGP) \([36-39]\). The interpretation of the aforementioned results is highly debated, with the outstanding open question being whether small droplets of a fluid-like QGP are created in small collision systems (see e.g. \([40]\) for a recent review). Hydrodynamic calculations, that assume the formation of a medium with some degree of collectivity (see e.g. \([41-43]\), can describe the angular correlations measured in p–Pb collisions, which suggests a common hydrodynamic origin of the experimental observations from small to large collision systems. However, alternative explanations exist, based on gluon saturation (CGC) in the initial state \([44, 45]\), the anisotropic escape probability of partons from the collision zone \([46]\), or interactions between string-like colour fields in dense configurations of confined QCD flux tubes \([47, 48]\). If a collective expansion in the final state of
the collision occurs, the medium could also impart a flow to heavy-flavour quarks or hadrons, and modify the hadronisation dynamics of heavy quarks. Detailed calculations were performed in the framework of transport models, assuming that in p–Pb collisions at LHC energies a QGP is formed, which affects the propagation and hadronisation of heavy quarks \[49, 50\]. These models predict a significant modification of the \(p_T\) distributions of heavy-flavour hadrons in high-multiplicity p–Pb collisions as compared to pp interactions, accompanied by the presence of anisotropies in their azimuthal distributions. Recent measurements of angular correlations in p–Pb collisions involving \(J/\psi\) mesons \[51\], \(D^0\) mesons \[52\], and heavy-flavour decay electrons \[53\] provided a clear indication that long-range anisotropies are present also in the heavy-flavour sector.

In the presence of a QGP, a modification of the hadronisation is predicted: hadrons can be produced not only via the fragmentation mechanism, but also via (re)combination of charm quarks with other quarks from the medium during the deconfined phase or at the phase boundary \[54–57\]. Given the observed increase of strangeness production with increasing particle multiplicity in p–Pb and pp collisions \[31, 58, 59\], the modified hadronisation could result in an enhancement of the relative yield of \(D^+_s\) mesons with respect to non-strange charmed mesons in high-multiplicity p–Pb collisions.

In this paper, we report the measurements of the \(p_T\)-differential production cross sections and nuclear modification factors of prompt \(D^0\), \(D^+\), \(D^{*+}\), and \(D^+_s\) mesons in p–Pb collisions at \(\sqrt{s_{NN}} = 5.02\) TeV recorded with the ALICE detector in 2016. The sample used for these analyses is larger by a factor of about six with respect to the sample collected in 2013, which was used in previous publications of these observables \[60–62\]. Therefore, it is possible to obtain lower statistical and systematic uncertainties by a factor 1.5–2 and extend the \(p_T\) reach of the measurements. The ratios of the production cross sections of the different D-meson species are also reported and are compared with those measured in pp collisions at the same centre-of-mass energy. The nuclear modification factor, \(R_{pPb}\), is defined as the ratio of the cross section in p–Pb collisions to that in pp interactions scaled by the mass number of the Pb nucleus. This ratio is sensitive to cold-nuclear-matter and hot-medium effects on D-meson production in p–Pb collisions. In addition, the measurement of the nuclear modification factor for non-strange D mesons is carried out in intervals of collision centrality, called in the following as \(Q_{pPb}\). The \(Q_{pPb}\) measurements are performed in finer intervals of collision centrality, enabling in particular the measurements of D-meson production in the 10% most central collisions, in which possible final-state effects are expected to be stronger. Further insight into the centrality dependence of prompt D-meson \(p_T\) distributions is provided by the measurements of the ratios of D-meson yields in various centrality classes. Finally, the ratio of \(D^+_s\)-meson yield to that of non-strange \(D^+\) is presented as a function of the multiplicity of charged particles produced in p–Pb collisions and is compared with results measured in pp and Pb–Pb collisions at the same centre-of-mass energy.

2 Experimental apparatus and data sample

The ALICE apparatus \[63\] is composed of a central barrel comprising various detectors for particle reconstruction and identification at mid-rapidity (\(|\eta| < 0.9\)), a forward muon spectrometer (\(-4 < \eta < -2.5\)), and a set of forward-backward detectors for triggering and event characterisation. Typical detector performance in pp, p–Pb, and Pb–Pb collisions is presented in \[64\]. The main detector components used in this analysis are the V0 detector, the Inner Tracking System (ITS), the Time Projection Chamber (TPC), and the Time-Of-Flight (TOF) detector, which are located inside a large solenoidal magnet providing a maximum uniform magnetic field of 0.5 T parallel to the LHC beam direction (\(z\)-axis in the ALICE reference system), and the Zero-Degree Calorimeter (ZDC), located at ±112.5 m from the interaction point.

Proton–lead collisions at \(\sqrt{s_{NN}} = 5.02\) TeV were recorded with a minimum-bias (MB) interaction trigger that required coincident signals in both scintillator arrays of the V0 detector, which cover the full azimuth
The MB trigger was sensitive to about 96.4% of the p–Pb inelastic cross section [65]. Only collision events with a primary vertex reconstructed within ±10 cm from the centre of the detector along the beam axis were considered. Events with several interactions per bunch crossing, whose probability was below 0.5%, were rejected using an algorithm based on track segments, defined within the Silicon Pixel Detector (SPD, the two innermost ITS layers), to detect multiple interaction vertices.

The number of events passing these selection criteria was about 6 × 10^8. The corresponding integrated luminosity, \( L_{\text{int}} = N_{\text{MB}} / \sigma_{\text{MB}} \), is equal to 292 ± 11 \( \mu b^{-1} \), \( \sigma_{\text{MB}} = 2.09 \) b being the MB-trigger (i.e. visible) cross section measured via a van der Meer scan, with negligible statistical uncertainty and a systematic uncertainty of 3.7% [66]. During the p–Pb data-taking period, the beam energies were 4 TeV for protons and 1.58 TeV per nucleon for lead nuclei. With this beam configuration, the nucleon–nucleon centre-of-mass system moves in rapidity by \( \Delta y_{\text{cms}} = 0.465 \) in the direction of the proton beam. The D-meson analyses were performed in the laboratory-frame interval [\( y_{\text{lab}} \)] < 0.5, which leads to a shifted centre-of-mass rapidity coverage of −0.96 < \( y_{\text{cms}} \) < 0.04. Additionally, the p–Pb data sample was divided into centrality classes defined as percentiles of the visible cross section. The events were classified according to the energy deposited in the ZDC positioned in the Pb-going side (ZNA) by the neutrons produced in the interaction by nuclear de-excitation processes, or knocked out by wounded nucleons. The multiplicity of these neutrons is expected to grow monotonically with the number of nucleon–nucleon binary collisions, \( N_{\text{coll}} \). It was demonstrated in Ref. [66] that this is the least-biased centrality estimator for p–Pb interactions. The description of the average nuclear overlap function, as well as the values corresponding to the measured centrality classes, will be given in section 5.3.

### 3 Data analysis

The D-meson yields were extracted using two different analysis methods. The first method, described in Section 3.1, is based on the reconstruction of decay vertices displaced from the primary vertex. The second method, described in Section 3.2, is used only for the D^0 measurement and is based on the estimation and subtraction of the combinatorial background, without any selection criteria on the displaced decay-vertex topology. The first method allows the D-meson yield to be extracted in a \( p_T \)-interval of 1–36 GeV/c for D^0, D^+, and D^{++} and 2–24 GeV/c for D^+_s. The second method allows the D^0-meson production to be measured down to \( p_T = 0 \).

#### 3.1 Analysis with D-meson decay vertex reconstruction

The D mesons and their charge conjugates were reconstructed in the decay channels D^0 \( \rightarrow K^- \pi^+ \) (with a branching ratio, BR, of 3.89 ± 0.04%), D^+ \( \rightarrow K^- \pi^+ \pi^+ \) (BR of 8.98 ± 0.28%), D^{++} \( \rightarrow D^0 \pi^+ \) (BR of 67.7 ± 0.5%), and D^+_s \( \rightarrow \phi \pi^+ \) (with \( \phi \rightarrow K^+ K^- \)) (BR of 2.27 ± 0.08%) [67]. The analyses were based on the reconstruction of decay vertices displaced from the interaction vertex, exploiting the separation of a few hundred microns induced by the weak decays of the D^0, D^+, and D^+_s mesons. The displacement of the D^0-meson candidate decay vertex was used to select the D^{++} meson which decays strongly at the primary vertex. This is performed by combining the D^0 candidates with a soft pion in an invariant-mass analysis.

The D^0, D^+, and D^+_s candidates were defined using pairs or triplets of tracks with proper charge sign combinations with |\( \eta \)| < 0.8, \( p_T > 0.3 \) GeV/c, at least 70 associated space points in the TPC, and at least two space points in the ITS, with at least one in the SPD. The D^{++} candidates were formed by combining D^0 candidates with tracks satisfying |\( \eta \)| < 0.8, \( p_T > 0.1 \) GeV/c and at least two space
points in the ITS, including at least one in the SPD. The selection of tracks with $|\eta| < 0.8$ limits the D-meson acceptance in rapidity, which, depending on $p_T$, varies from $|y_{lab}| < 0.5$ at low $p_T$ to $|y_{lab}| < 0.8$ at $p_T > 5$ GeV/c [68]. A $p_T$-dependent fiducial acceptance region was therefore defined as $y_{fid}(p_T) > |y_{lab}|$, with $y_{fid}(p_T)$ increasing from 0.5 to 0.8 in the transverse momentum range $0 < p_T < 5$ GeV/c according to a second-order polynomial function, and $y_{fid} = 0.8$ for $p_T > 5$ GeV/c. The selection strategy is the same as in previous analyses [62]. The main variables used to select the D-meson candidates are the separation between primary and secondary vertex, the displacement of the tracks from the primary vertex, and the pointing of the reconstructed D-meson momentum to the primary vertex. For the $D^+$, a selection on the impact parameter of the candidate with respect to the primary vertex in the transverse plane was also applied. For the $D^+_s$-candidate selection, one of the two pairs of opposite-sign tracks is required to have an invariant mass compatible with the $\phi$ meson mass [67]. Further background reduction is achieved by applying particle identification to select charged pions and kaons using information of the TPC and TOF detectors. The track particle identification (PID) is obtained using a 3$\sigma$ window around the expected mean values of the specific ionisation energy loss ($dE/dx$) in the TPC gas and of the time of flight from the interaction point to the TOF detector. A 2$\sigma$ window around the expected mean values of the $dE/dx$ was applied, except for the lowest $p_T$ interval, $1.5 < p_T < 2$ GeV/c, $D^{*+}$ meson, and for the $D^+_s$ meson in those cases in which no time-of-flight information was available.

The D-meson raw yields were obtained by fitting the candidate invariant-mass distributions for each D-meson species and the mass difference $\Delta M = M_{K\pi\pi} - M_{K\pi}$ for $D^{*+}$. Examples of these distributions are shown in Fig.1 for $D^0$, $D^+$, $D^{*+}$, and $D^+_s$ mesons in different $p_T$ intervals. The $D^0$, $D^+$, and $D^+_s$ candidate invariant-mass distributions were fit with a function composed of a Gaussian for the signal shape and an exponential term to describe the background shape. The $\Delta M$ distribution of the $D^{*+}$ candidates was fit with a Gaussian function for the signal shape and a threshold function multiplied by an exponential for the background: $a \sqrt{\Delta M - m_0} \cdot e^{b(\Delta M - m_0)}$, where $a$ and $b$ are free parameters. To account for the contribution of signal candidates that are present in the invariant-mass distribution of the $D^0$ meson but were assigned the wrong decay-particle mass (reflections) an additional term was included in the fit function. It was obtained from a fit performed using a double Gaussian function of the reflection invariant-mass distributions from a Monte Carlo simulation.

For the $M_{K\pi}$ distribution, an additional Gaussian was used to describe the $D^+ \rightarrow K^+K^-\pi^+$ signal peak present on the left side of the $D^+_s$ signal. The extracted signal is denoted as $S$ and the background level under the signal peak is denoted as $B$. The statistical significance of the observed signals, here defined as $(S/\sqrt{S+B})$, varies from 3 to 62, depending on the meson species, the centrality and the $p_T$ interval.

The D-meson raw yields extracted in each $p_T$ interval were corrected to obtain the prompt D-meson cross sections according to

$$\frac{d^2\sigma^{\text{prompt}}}{d^2p_Tdy} = \frac{1}{\Delta p_T} \cdot \frac{f_{\text{prompt}}(p_T) \cdot \frac{1}{2} \cdot N^{D^{*+}\text{raw}}(p_T)}{c_{\Delta y}(p_T)} \cdot \frac{1}{BR \cdot L_{int}}.$$  \hspace{1cm} (1)

In the formula, $N^{D^{*+}\text{raw}}$ is the raw yield (sum of particles and antiparticles) in the laboratory rapidity interval $|y_{lab}| < y_{fid}(p_T)$ in a $p_T$ interval of width $\Delta p_T$. The raw yield includes contributions from prompt and non-prompt D mesons. Non-prompt D mesons originating from beauty-hadron decays are labeled as ‘feed-down’ in the following. The $f_{\text{prompt}}$ term is the fraction of prompt D mesons in the raw yield. The rapidity acceptance correction factor $c_{\Delta y}$ was computed using the PYTHIA v6.4.21 event generator [69] with the Perugia-2011 tune as the ratio between the generated D-meson yield in $\Delta y = 2y_{fid}$, and that in $|y_{lab}| < 0.5$. The $c_{\Delta y}$ correction factor has a uniform D-meson rapidity distribution in $|y_{lab}| < y_{fid}$ in the range $|y_{lab}| < 0.8$ as shown in [62]. The factor 1/2 accounts for the fact that the measured yields include particles and antiparticles while the cross sections are given for particles only. The $(\text{Acc} \times \epsilon)^{\text{prompt}}$ is the product of the acceptance of the detectors and the efficiency of prompt D mesons, where $\epsilon$ accounts for

tailed description of the apparatus geometry, the detector response, as well as the LHC beam conditions.

Proton–proton collisions requiring a c or b pair satisfying \(|y| < 1\) were generated using a PYTHIA
v6.4.21 event generator [69] with the Perugia-2011 tune. An underlying p–Pb collision, generated with
HIJING 1.36 [70], was superimposed to each PYTHIA event in order to describe the charged-particle
multiplicity and detector occupancy observed in data. To reproduce the primary vertex resolution found
in data which improves with increasing multiplicity, generated events were weighted on the basis of their
charged particle multiplicity. The shape of the generated D-meson \(p_T\) distribution is consistent with that

Figure 1: Examplary invariant-mass distributions for \(D^0\), \(D^+\), and \(D_s^+\) candidates (plus charge conjugates) and
the mass difference \(\Delta M = M_{K\pi\pi} - M_{K\pi}\) for \(D^+\) candidates (and charge conjugates) in p–Pb collisions at \(\sqrt{s_{NN}} =
5.02\text{ TeV}\). The dashed curves represent the fit applied to the background, while the solid lines represent the total
fit function. In the case of the \(D^0\) meson, the contribution of signal reflections in the invariant-mass distribution is
shown using a gray dot-dashed line. In the case of the \(D_s^+\) invariant-mass distribution, an additional Gaussian is
used in the fit function in order to describe the \(D^+\) signal peak on the left side of the \(D_s^+\) signal.

D-meson production in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV

**Figure 2:** The product of acceptance and efficiency for $D^0$, $D^+$, $D^{*+}$, and $D_s^+$ mesons as a function of transverse momentum in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV. The values for prompt (solid line) and feed-down (dashed line) D mesons are shown.

The correction factor $f_{\text{prompt}}$ was calculated per $p_T$ interval using a FONLL-based method as described in [72]. The procedure uses the B-meson production cross section in pp collisions at $\sqrt{s} = 5.02$ TeV estimated utilising FONLL calculations, the $B \to D + X$ decay kinematics from the EvtGen package [73], the efficiencies for D mesons from beauty-hadron decays and a hypothesis on the nuclear modification factor $R_{pPb}^{\text{feed-down}}$ of D mesons from B decays. The $R_{pPb}$ of prompt and feed-down D mesons were assumed to be equal on the basis of calculations including initial-state effects via the EPS09 nPDF parametrisations [11] or the Colour Glass Condensate formalism [19], as well as the measurements of the $B^0$-meson production in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV published by the CMS Collaboration [74]. Further details are given in Sec. 4. The resulting $f_{\text{prompt}}$ values vary between 0.8 to 0.96 in the $|y_{\text{lab}}| < y_{\text{fid}}(p_T)$ interval depending on the $p_T$ range and the D-meson species.
3.2 Analysis without D-meson decay-vertex reconstruction

In order to extend the cross section measurement down to \( p_T = 0 \), a different analysis method, which does not employ geometrical selections on the displaced decay-vertex topology, was utilized for the two-body decay \( D^0 \rightarrow K^+ \pi^- \) (and its charge conjugate) [62]. This analysis technique is based on particle identification and on the estimation and subtraction of the combinatorial background of \( K\pi \) pairs. Tracks with \( |\eta| < 0.8 \) and \( p_T > 0.4 \) GeV/c were selected by applying the same track-quality cuts and pion and kaon identification criteria described above for the analysis with decay-vertex reconstruction. The \( D^0 \) and \( \overline{D}^0 \) candidates were formed by combining kaon and pion tracks with opposite charge sign (UnLike Sign. ULS). The resulting candidates were selected by applying the \( p_T \)-dependent fiducial acceptance selection, \( |y_{\text{lab}}| < y_{\text{fid}}(p_T) \), adopted for the analyses with decay-vertex reconstruction. No selections based on secondary-vertex displacement were applied because at very low \( p_T \) the D-meson decay top-ology cannot be efficiently resolved due to the insufficient resolution of the track impact parameter and the small Lorentz boost. The combinatorial background was estimated with the track-rotation technique. For each \( D^0 \) (and \( \overline{D}^0 \)) candidate, up to 19 combinatorial-background-like candidates were created by rotating the kaon track by different angles in the range between \( \pi/10 \) and \( 19\pi/10 \) radians in azimuth. The invariant-mass distribution of ULS \( K\pi \) pairs in the transverse momentum interval \( 0 < p_T < 1 \) GeV/c is shown in the left panel of Fig. 3 together with the one of the background estimated with the track-rotation technique, which was normalised to match the yield of ULS pairs at one edge of the invariant-mass interval considered for the extraction of the \( D^0 \) signal.

The invariant-mass distribution of background candidates was subtracted from the one of ULS \( K\pi \) pairs and the resulting distribution, which contains the \( D^0 \) signal and the remaining background, is shown in the right panel of Fig. 3. The \( D^0 \)/meson raw signal (sum of particle and antiparticle contributions) was extracted via a fit to the background-subtracted invariant-mass distribution. The fit function is composed of a Gaussian term to describe the signal, a second-order polynomial function to model the remaining background, and a term describing the contribution of signal candidates passing the selection criteria with swapped mass hypotheses of the final-state kaon and pion (reflections), whose invariant-mass distribution was taken from simulation. The signal-to-background ratio increases from \( 6 \cdot 10^{-4} \) to \( 3 \cdot 10^{-2} \) with increasing \( p_T \) and the statistical significance is about 9 in \( 0 < p_T < 1 \) GeV/c and is greater than 15 for \( p_T > 2 \) GeV/c.

The acceptance and efficiency were determined from the same Monte Carlo simulations used for the analysis with decay-vertex reconstruction. The resulting (Acc \( \times \varepsilon \)) of prompt \( D^0 \) mesons is shown as a function of \( p_T \) in Fig. 4. Compared to the analysis with decay-vertex reconstruction, the efficiency is higher by a factor of about 20 (3) at low (high) \( p_T \) and it demonstrates a less steep \( p_T \) dependence. Note that for the analysis without decay-vertex reconstruction the efficiency \( \varepsilon \) is almost independent of \( p_T \) and the increase of the (Acc \( \times \varepsilon \)) with increasing \( p_T \) is mainly determined by the geometrical acceptance of the apparatus. Unlike in the analysis with decay-vertex reconstruction, the efficiency is the same for prompt \( D^0 \) mesons and \( \overline{D}^0 \) mesons from beauty-hadron decays.

The prompt contribution to the \( D^0 \)-meson raw yield, \( f_{\text{prompt}} \), was estimated with the same FONLL-based method used for the analysis with decay-vertex reconstruction. The resulting \( f_{\text{prompt}} \) values decrease with increasing \( p_T \) (from about 0.96 for \( p_T < 3 \) GeV/c to about 0.9 in the interval \( 8 < p_T < 12 \) GeV/c) and are larger than in the analysis with decay-vertex reconstruction, since the feed-down component is not enhanced by the selection criteria.

3.3 Measurement of the prompt D-meson fraction based on a data-driven method

The prompt fractions of \( D^0 \), \( D^+ \), and \( D^{*+} \) mesons, calculated via the FONLL-based method, were cross-checked for the analysis with decay vertex reconstruction utilizing a data-driven method that exploits the different shapes of the transverse-plane impact parameter to the primary vertex (\( d_0 \)) of prompt and feed-down \( D \) mesons. The D-meson candidates were selected using the same criteria described in Section 3.1.
D-meson production in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV

Figure 5: Left: Exemplary fits to the impact-parameter distributions of $D^0$, $D^+$, and $D^{*+}$ candidates. The curves show the fit functions describing the prompt, feed-down, and background contributions as well as their sum, as described in the text. Right: fraction of prompt $D^0$, $D^+$, and $D^{*+}$ raw yield as a function of transverse momentum $p_T$ compared with the values obtained with the FONLL-based approach. The results from the data-driven method are shown as square markers with the error bars (boxes) representing the statistical (systematic) uncertainty. The central values of $f_{\text{prompt}}$ from the FONLL-based approach are shown as the dashed lines and the uncertainty as red boxes.
with the exception that for D$^+$ the impact-parameter selection criteria were not applied. An additional selection was based on the candidate invariant-mass fits. The D$^0$ and D$^+$ mesons candidates were selected to have an invariant mass $|M - M_{D^0}| < 1.5\sigma$, while for D$^{*+}$-meson candidates a $|\Delta M - \Delta M_{D^{*+}}| < 2.5\sigma$ selection was applied, where $\sigma$ is the standard deviation of the Gaussian function describing the D-meson invariant-mass signal. The prompt fraction was estimated via an unbinned likelihood fit of the $d_0$ distribution of the D-meson candidates using the fit function

$$F(d_0) = S \cdot [(1 - f_{prompt})F_{feed-down}(d_0) + f_{prompt}F_{prompt}(d_0)] + B \cdot F_{backgr}(d_0).$$

In this function, $F_{prompt}(d_0)$, $F_{feed-down}(d_0)$ and $F_{backgr}(d_0)$ are functions describing the impact-parameter distributions of prompt and feed-down D mesons and of background candidates. The function $F_{prompt}$ consists of a detector resolution term modeled with a Gaussian function and a symmetric exponential term, $\frac{1}{\sqrt{2\pi}} \exp \left(-\frac{|d_0|}{\lambda} \right)$ (with $\lambda$ as a free parameter), with the latter describing the tails of the impact-parameter distribution of prompt D mesons. The $F_{feed-down}$ is the convolution of the detector resolution term with a symmetric double-exponential function ($F_{true}$) that describes the intrinsic impact-parameter distribution of D mesons from B-meson decays, which is determined by the decay length and decay kinematics of B mesons. The parameters of the $F_{prompt}$ and $F_{feed-down}$ functions were fixed to the values obtained by fitting the distributions from Monte Carlo simulations, with the exception of the Gaussian width of the detector-resolution term, which was kept free when applying the fit to the data in order to compensate for a possible imperfect description of the ideal impact-parameter resolution in the simulation. The function $F_{backgr}$ was parametrised on the impact-parameter distribution of background candidates, which were selected from side bands relative to the signal peak in the invariant-mass distributions, and in the case of D$^{*+}$, the mass-difference distribution. The function consists of a double Gaussian and a symmetric exponential term, which describes the tails, as reported in Ref. [62]. In the case of the D$^+$, the function presents a double-peak structure with a depletion around zero that is induced by the selections applied.

The left panels of Fig. 5 show examples of fits to the impact-parameter distributions of D$^0$, D$^+$, and D$^{*+}$ mesons in the transverse-momentum intervals $2 < p_T < 3$ GeV/$c$, $3 < p_T < 4$ GeV/$c$, and $5 < p_T < 6$ GeV/$c$, respectively. The prompt fraction estimated using the data-driven approach has systematic uncertainties due to (i) the impact-parameter distribution assumed for prompt and feed-down D mesons and background candidates; (ii) the uncertainty on the signal and background yields extracted from the invariant-mass fits; and (iii) the consistency of the procedure, evaluated via a Monte Carlo closure test. These uncertainties were estimated using the procedures described in Ref. [62]. The total systematic uncertainty on $f_{prompt}$ based on the data-driven approach for the three D-meson species is about 2–3% in the interval $3 < p_T < 16$ GeV/$c$ and about 5% in the interval $2 < p_T < 3$ GeV/$c$ and above 16 GeV/$c$.

The prompt fraction of D$^0$, D$^+$, and D$^{*+}$ mesons measured utilizing the data-driven method is compared with the one calculated with the FONLL-based approach in the right panels of Fig. 5. For D$^0$, D$^+$, and D$^{*+}$ in $1 < p_T < 2$ GeV/$c$ and for the D$^{*+}$ in $24 < p_T < 36$ GeV/$c$, given the poor precision of the impact-parameter fit, it was not possible to determine $f_{prompt}$ with the data-driven approach. The prompt fraction measured with the impact-parameter fits is compatible with the FONLL-based estimation within 1$\sigma$ for almost all points.

### 4 Systematic uncertainties

Systematic uncertainties on the D-meson production cross sections were estimated considering the following sources:

(i) extraction of the raw yield from the invariant-mass distributions; (ii) track reconstruction efficiency; (iii) D-meson selection efficiency; (iv) PID efficiency; (v) the assumption on the shape of the D-meson $p_T$ spectrum generated in the simulation; (vi) subtraction of the feed-down from beauty-hadron decays.
Table 1: Summary of relative systematic uncertainties on $D^0$, $D^+$, $D^{*+}$, and $D^*_s$. The event centrality-dependent uncertainties are marked by the symbol ⋄.

| $p_T$ (GeV/c) | $D^0$ | $D^+$ | $D^{*+}$ | $D^*_s$ |
|--------------|-------|-------|----------|---------|
| 0–1          | 5%    | 3%    | 3%       | 3%      |
| 2–2.5        | 2%    | 3%    | 7%       | 2%      |
| 10–12        | 3%    | 2%    | 3%       | 6%      |
| 2–4          | 3%    | 2%    | 3%       | 6%      |
| 8–12         | 3%    | 2%    | 3%       | 6%      |

In addition, the $p_T$-differential cross sections have a systematic uncertainty on the overall normalisation induced by the uncertainties on the integrated luminosity of 3.7% [65] and on the branching ratios of the considered D-meson decays [67]. The estimated values of the relative systematic uncertainties are summarised in Table I.

The systematic uncertainties on the raw yield extraction were evaluated for each D-meson species by repeating the invariant-mass distribution fits, for each $p_T$ and centrality interval, varying the lower and upper limits of the fit range and the functional form of the background fit function. In addition, the same approach was used with a bin-counting method, in which the signal yield was obtained by integrating the invariant-mass distribution after subtracting the background estimated from a fit to the side bands. For $D^0$ mesons, an additional contribution due to the description of signal reflections in the invariant-mass distribution was estimated by varying the ratio of the integral of the reflections over the integral of the signal and the shape of the templates used in the invariant-mass fits. The systematic uncertainty was defined as the root mean square of the distribution of the signal yields obtained from the described variations. The uncertainty ranges between 1% and 15% depending on the D-meson species, $p_T$, event centrality and charged-particle multiplicity intervals of the measurement. An increase in the raw yield extraction uncertainties was observed in the most central collisions due to the lower centrality and charged-particle multiplicity intervals of the measurement. A systematic uncertainty on the selection efficiency originates from imperfections in the description of the D-meson kinematic and decay properties and of the detector resolution and alignment in the simulation. For the analyses based on the decay-vertex reconstruction, the uncertainty was estimated by comparing the corrected yields obtained by repeating the analysis with different sets of selection criteria, resulting in significant modification of efficiencies, raw yield, and background estimates.
The assigned uncertainty for non-strange D mesons is 2–3% in most of the \( p_T \) intervals and it increases to 7% at low \( p_T \), where the efficiencies are low and steeply fall with decreasing \( p_T \), because of the tighter geometrical selections. A larger uncertainty (ranging from 7% at high \( p_T \) to 14% at low \( p_T \)) was estimated for the \( D^+_c \) mesons, for which more stringent selection criteria were used in the analysis, as compared to non-strange D mesons. In the case of the \( D^0 \)-meson analysis without decay-vertex reconstruction, the stability of the corrected yield was tested against variations of the single-track \( p_T \) selection and no systematic effect was observed.

In addition, the efficiency values could also be sensitive to the generated shapes of the D-meson transverse-momentum distributions and to the multiplicity of particles produced in the collision. The systematic uncertainty due to the generated D-meson \( p_T \) spectrum shape was estimated by considering different input distributions (PYTHIA, FONLL) and was found to be negligible. The effect of possible differences between the charged-particle multiplicity distributions in data and multiplicity-weighted simulation, used to compute the efficiencies in the different centrality classes, as explained in section 3.1, varied between 0 and 2% depending on the D-meson species, \( p_T \), event centrality, and charged-particle multiplicity intervals.

To estimate the uncertainty on the PID-selection efficiency the analysis was repeated without PID selection, or with less stringent criteria in the cases where the signal extraction was not reliable without PID, as for example for the \( D^+_c \) and the \( D^0 \)-meson analysis without decay-vertex reconstruction. In addition, the pion and kaon PID selection efficiencies were compared in the data and in simulation using high purity samples of pions from the decay of \( K^0_s \) and kaons identified with the TOF combined with the D-meson decay kinematics. The PID uncertainty was found to vary between 0 and 1.5% depending on the PID selection criteria used for each D-meson species.

The systematic uncertainty on the subtraction of feed-down from beauty-hadron decays (i.e. the calculation of the \( f_{\text{prompt}} \) fraction) was estimated by varying the FONLL parameters (b-quark mass, factorisation and renormalisation scales) as described in [2] and by varying the hypothesis on the nuclear modification factor of feed-down D mesons in the range 0.9 < \( Q_{pPb}^{\text{feed-down}} / Q_{pPb}^{\text{prompt}} \) < 1.3 for the integrated centrality interval and central collisions, and between 0.9 < \( Q_{pPb}^{\text{feed-down}} / Q_{pPb}^{\text{prompt}} \) < 1.1 for the peripheral collisions, where the possible differences of the D-meson production mechanisms in p–Pb with respect to pp collisions are expected to be reduced as observed for both charmed mesons and charged particles. The uncertainty ranges between 2% and 5% depending on the D-meson species, \( p_T \), event centrality and charged-particle multiplicity intervals.

## 5 Results

### 5.1 \( p_T \)-differential cross sections

The analysis without decay-vertex reconstruction allows for a direct measurement of the inclusive \( D^0 \)-meson cross section because no selections that alter the fraction of prompt and feed-down D mesons are applied. The inclusive \( D^0 \)-meson cross section in p–Pb collisions is shown in the left panel of Fig. 6 and is compared with the measurement in pp collisions at the same centre-of-mass energy, published in [71]. The cross section in pp collisions was scaled by the Pb mass number \( A = 208 \) and corrected for the rapidity shift in p–Pb collisions using FONLL calculations. The correction for the rapidity shift is a \( p_T \)-dependent factor of the order of 1–3%. The uncertainty assigned on this correction is evaluated varying the quark mass and the perturbative scale parameters and including the PDFs uncertainty, and is 1% at low \( p_T \) and negligible at high \( p_T \).

The total cross section for inclusive \( D^0 \)-meson production in p–Pb collisions per unit of rapidity in \(-0.96 < y_{\text{cms}} < 0.04\) was calculated integrating the \( p_T \)-differential cross section as described in Ref. [62]. The cross section is extrapolated to the whole \( p_T \) range using FONLL calculations in order to take into account the fraction of cross section not measured for \( p_T > 12 \text{ GeV}/c \). An uncertainty is estimated for
the extrapolation varying the quark mass and the perturbative scale parameters and including the PDFs uncertainty. The resulting cross section is

$$d\sigma^{\text{inclusive D}^0}_{p-Pb, 5.02 \text{ TeV}} / dy = 91.2 \pm 3.4 \text{ (stat.)} \pm 3.2 \text{ (syst.)} \pm 3.4 \text{ (lumi.)} \pm 0.9 \text{ (BR)}^{+0.4}_{-0.2} \text{ (extrap.)} \text{ mb.}$$  \hspace{1cm} (3)$$

The right panel of Fig. 6 shows the comparison of the $p_T$-differential production cross sections for prompt D$^0$ mesons with $-0.96 < y_{cms} < 0.04$ in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV obtained from the analysis with and without decay-vertex reconstruction. The results are consistent within statistical uncertainties.

Considering the statistical and systematic uncertainties obtained in the two analyses, the most precise measurement of the prompt D$^0$ production cross section is obtained using the results from the analysis without decay-vertex reconstruction in the interval $0 < p_T < 1$ GeV/$c$ and the analysis with decay-vertex reconstruction for $p_T > 1$ GeV/$c$. The resulting cross section is shown in the top-left panel of Fig. 7

The total cross section for prompt D$^0$-meson production per unit of rapidity in $-0.96 < y_{cms} < 0.04$ was also calculated, as described in Ref. [62], using the measurement obtained combining the methods with and without decay-vertex reconstruction. The resulting value is

$$d\sigma^{\text{prompt D}^0}_{p-Pb, 5.02 \text{ TeV}} / dy = 88.5 \pm 2.7 \text{ (stat.)}^{+5.3}_{-6.1} \text{ (syst.)} \pm 3.3 \text{ (lumi.)} \pm 0.9 \text{ (BR)} \text{ mb.}$$  \hspace{1cm} (4)$$

In Ref. [62], the $c\bar{c}$ production cross section in the rapidity interval $-0.96 < y_{cms} < 0.04$ was reported. This calculation used the fraction of charm quarks hadronising into D$^0$ mesons to be $f(c \rightarrow D^0) = 0.542 \pm 0.024$ which was derived in Ref. [76] by averaging the measurements in $e^+e^-$ collisions at LEP. Recent measurements of the $Λ_c$-baryon production cross section in pp collisions at $\sqrt{s} = 7$ TeV and in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV [77][78] suggest that the fragmentation fractions of charm quarks...
Figure 7: \(p_T\)-differential production cross sections of prompt \(D^0\), \(D^+\), \(D^{*+}\), and \(D_s^+\) mesons with \(-0.96 < y_{\text{cms}} < 0.04\) in p–Pb collisions at \(\sqrt{s_{\text{NN}}} = 5.02\) TeV compared with the respective pp reference cross sections \([71]\) scaled by the Pb mass number (\(A = 208\)) and corrected for the rapidity shift. For the \(D^0\) meson, the results in the range \(0 < p_T < 1\) GeV/c are obtained from the analysis that was performed without decay-vertex reconstruction, while those in the range \(1 < p_T < 36\) GeV/c are taken from the analysis with decay-vertex reconstruction. The vertical bars and the empty boxes represent the statistical and systematic uncertainties.
into charmed baryons in pp collisions at LHC energies might differ significantly from the LEP results. Therefore, more precise measurements of charmed-baryon production cross sections are needed for an accurate calculation of the charm production cross section.

The average transverse momentum $\langle p_T\rangle$ of prompt $D^0$ mesons obtained with the procedure described in Ref. [62] is

$$\langle p_T\rangle_{D^0_{pp}, 5.02\text{ TeV}}^{\text{prompt}} = 2.07 \pm 0.02 \text{ (stat.)} \pm 0.04 \text{ (syst.) GeV/c}.$$  

(5)

The result is compatible within statistical uncertainties with the one obtained in pp collisions at the same centre-of-mass energy: $\langle p_T\rangle_{pp, 5.02\text{ TeV}}^{\text{prompt}} = 2.06 \pm 0.03 \text{ (stat.)} \pm 0.03 \text{ (syst.) GeV/c}$ [71].

The $p_T$-differential cross sections for the other three D-meson species ($D^+, D^{++}$, and $D_s^+$) are shown in the other panels of Fig. 7. The cross sections measured in p–Pb collisions are compatible with the measurements published using the 2013 p–Pb data sample [60, 61], while having a factor 1.5–2 smaller in the other panels of Fig. 7. The cross sections measured in p–Pb collisions are compared with the corresponding pp reference cross sections at the same centre-of-mass energy [71] and rapidity interval.

5.2 The $p_T$-differential nuclear modification factor

The nuclear modification factor is computed as:

$$R_{ppb} = \frac{1}{A} \frac{d^2\sigma_{D^0_{ppb}, y}^{\text{prompt}}}{d^2\sigma_{pp, y}^{\text{prompt}}},$$  

(6)

where $d^2\sigma_{D^0_{ppb}, y}^{\text{prompt}}/d^2\sigma_{pp, y}^{\text{prompt}}$ is the D-meson $p_T$-differential cross section in $-0.96 < y_{\text{cms}} < 0.04$ in p–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV, $A$ is the mass number of the Pb nucleus and $d^2\sigma_{pp, y}^{\text{prompt}}/d^2\sigma_{pp, y}^{\text{prompt}}$ is the cross section in pp collisions at the same centre-of-mass energy from [71] corrected for the rapidity shift in p–Pb collisions. The systematic uncertainties of the p–Pb and pp measurements were considered to be independent and were propagated quadratically, with the exception for the uncertainty on the feed-down correction, which was recalculated for the ratio of cross sections by consistently varying the FONLL calculation parameters in the numerator and the denominator.

Figure 8 shows the nuclear modification factors $R_{ppb}$ of prompt $D^0$, $D^+$, and $D^{++}$ mesons in the left panel and their average, along with the $R_{ppb}$ of $D_s^+$ mesons, in the right panel.

With the current uncertainties it is not possible to disentangle a possible mass dependent effect originating from a collective expansion of the system that would modify the $D^{++}$ spectrum differently with respect to the $D^0$ and $D^+$ spectra. Therefore, the average of the nuclear modification factors of the three non-strange D-meson species is considered and it was calculated using the inverse of the relative statistical uncertainties as weights. The systematic uncertainty of the average was calculated by propagating the uncertainties through the weighted average, while considering the contributions from tracking efficiency and beauty feed-down correction as fully correlated among the three species. The D-meson $R_{ppb}$ is compatible with unity over the entire measured $p_T$ interval within 2 standard deviations. The $R_{ppb}$ of strange and non-strange D mesons are compatible among each other within statistical and systematic uncertainties.

The D-meson nuclear modification factor is also compared with theoretical calculations, shown in Fig. 9. In the left panel, four theoretical calculations that include only CNM effects are displayed. A calculation based on the Colour Glass Condensate formalism [19, 29] describes the data within a 2σ uncertainty in the entire $p_T$ range, although the model underestimates systematically the measured points at low $p_T$ ($p_T < 6$ GeV/c). A FONLL calculation with CTEQ6M PDFs [80] and EPPS16 NLO nuclear modification [14] is compatible with the data within the uncertainties. The measurement lies on the upper limit of
the EPPS16 nPDF uncertainty band, while this is not the case for the D meson $R_{pPb}$ at forward rapidity measured by LHCb \cite{81}. The data are also described within the uncertainties by a LO pQCD calculation with intrinsic $k_T$ broadening, nuclear shadowing, and energy loss of the charm quarks in cold nuclear matter (Vitev et al.) \cite{82}. The calculation by Kang et al., that consists of a higher-twist calculation based on incoherent multiple scatterings, has a different trend with respect to the other models and it is excluded by the data for $p_T < 4\text{ GeV}/c$.

In the right panel of Fig. 9, the measurements are compared with the calculations of two transport models, Duke \cite{49} and POWLANG \cite{50}, both of which assume that a QGP is formed in p–Pb collisions. These models are both based on the Langevin approach for the transport of heavy quarks through an expanding deconfined medium described by relativistic viscous hydrodynamics. The Duke model includes both collisional and radiative energy loss. The POWLANG model considers only collisional processes with two choices for the transport coefficients, based on hard-thermal-loop (HTL) and lattice-QCD (lQCD) calculations. For both the Duke and the HTL based POWLANG estimates, the D-meson nuclear modification factor distribution has a peak structure, with the maximum at $p_T \approx 2.5 \text{ GeV}/c$ and $p_T \approx 3.5 \text{ GeV}/c$, respectively, possibly followed by a moderate ($< 20–30\%$) suppression at higher $p_T$, resulting from the interplay of CNM effects and interactions of charm quarks with the radially expanding medium. The trend suggested by these models is not supported by the data. The strong enhancement at $p_T \sim 3–4 \text{ GeV}/c$ observed in the model calculations is not consistent with the measured $R_{pPb}$, and a suppression larger than 10\% for $p_T > 8 \text{ GeV}/c$ is excluded by the data with a 98\% confidence level.

The $p_T$-integrated nuclear modification factor of prompt $D^0$ mesons in $-0.96 < \gamma_{\text{cms}} < 0.04$ was obtained from Eq. [6] by integrating the $p_T$-differential cross sections in pp and p–Pb collisions. The result is

$$R_{pPb}^{\text{Prompt} D^0}(p_T > 0, -0.96 < \gamma_{\text{cms}} < 0.04) = 0.96 \pm 0.05 \text{ (stat.)} \pm 0.07 \text{ (syst.)}$$  \hspace{1cm} (7)$$

and it is consistent with the atomic mass number scaling of the total charm cross section.
5.3 The $p_T$ and centrality-dependent nuclear modification factor

The measurement of the nuclear modification factor was also computed in various centrality intervals, where the centrality is defined using the energy deposited in the ZNA, as described in Section 2. For each centrality class the nuclear modification factor, $Q_{p\text{--}Pb}$, is defined as

$$Q_{p\text{--}Pb} = \frac{(d^2N_{\text{promptD}}/d^2p_Tdy)_{p\text{--}Pb}}{\langle T_{p\text{--}Pb}\rangle_i \times (d^2N_{\text{promptD}}/d^2p_Tdy)_{p\text{--}Pb}} ,$$

where $(d^2N_{\text{promptD}}/d^2p_Tdy)_{p\text{--}Pb}$ is the yield of prompt $D$ mesons in $p$–$Pb$ collisions and $\langle T_{p\text{--}Pb}\rangle_i$ is the average nuclear overlap function in a given centrality class.

The $\langle T_{p\text{--}Pb}\rangle_i$ is estimated with the hybrid approach described in Ref. 66 and is based on the assumption that the charged-particle multiplicity measured at mid-rapidity ($-1 < \eta_{\text{CMS}} < 0$) scales with the number of participant nucleons, $N_{\text{part}}$. The average nuclear overlap function is defined as $\langle T_{p\text{--}Pb}\rangle_i = \langle N_{\text{coll}} \rangle_i / \sigma_{NN}$ where $\sigma_{NN} = (67.6 \pm 0.6)$ mb is the interpolated inelastic nucleon–nucleon cross section at $\sqrt{s_{NN}} = 5.02$ TeV 84 and $\langle N_{\text{coll}} \rangle_i$ is the average number of binary nucleon–nucleon collisions in a given centrality class. The latter is obtained as

$$\langle N_{\text{coll}} \rangle_i = \langle N_{\text{part}} \rangle_i - 1 = \langle N_{\text{part}}^{MB} \rangle_1 \times \left( \frac{\langle dN_{\text{ch}}/d\eta \rangle_i}{\langle dN_{\text{ch}}/d\eta \rangle^{MB}_1} \right)_{-1 < \eta < 0} - 1 ,$$

where $\langle N_{\text{part}}^{MB} \rangle = 7.7$ 85 is the average number of participants in minimum bias collisions. The values of $\langle T_{p\text{--}Pb}\rangle_i$ used for the analyses are reported in Table 2 85. It should be noted that the hybrid method used in the centrality selection is the least-biased centrality estimator for $p$–$Pb$ interactions, as demonstrated in 66. Only a small bias in peripheral events, due to the geometrical bias in the determination of the number of hard scatterings, was observed in the studies with charged particles.
D-meson production in p–Pb collisions at \( \sqrt{s_{NN}} = 5.02 \text{ TeV} \) ALICE Collaboration

Table 2: \( \langle T_{pPb} \rangle \) and relative uncertainties for each centrality class considered in the analysis.

| Centrality classes | 0–10% | 10–20% | 20–40% | 40–60% | 60–100% |
|--------------------|--------|--------|--------|--------|---------|
| \( \langle T_{pPb} \rangle \) (1/mb) | 0.172  | 0.158  | 0.137  | 0.102  | 0.046   |
| Rel. unc.          | 6.9%   | 3.7%   | 1.7%   | 4.8%   | 5.2%    |

The average of prompt D\(^0\), D\(^+\), and D\(^*+\) meson \( Q_{pPb} \) was calculated as a function of \( p_T \) in the interval \( 1 < p_T < 36 \text{ GeV}/c \) in 0–10%, 10–20%, 20–40%, 40–60%, and 60–100% centrality classes, and is shown in Fig. 10. The D-meson \( Q_{pPb} \) measurement shows a hint of suppression in the interval \( 1 < p_T < 2 \text{ GeV}/c \). The observed suppression is strongest in the most central collisions. This is qualitatively expected from a stronger shadowing at low Bjorken-\( x \) in central collisions. There is also a hint of enhancement at \( 2 < p_T < 6 \text{ GeV}/c \) in the most central classes (0–40% centrality). The results are also compared with the charged-particle \( Q_{pPb} \) \(^1\) in each centrality class. A similar trend is observed for prompt D mesons and charged particles in each centrality class.

Figure 10: Nuclear modification factors of prompt D mesons as a function of \( p_T \) in 0–10%, 10–20%, 20–40%, 40–60%, and 60–100% centrality classes compared with those of charged particles \(^1\). The vertical bars represent the statistical uncertainties while the empty boxes and the shaded boxes represent the systematic uncertainties for the prompt D mesons and for the charged particles. The colour-filled boxes at \( Q_{pPb} = 1 \) represent the normalisation uncertainties on the \( \langle T_{pPb} \rangle \) \(^1\).

The D-meson \( Q_{pPb} \) in the 0–10% centrality class is compared with the predictions of the Duke \(^49\) and POWLANG \(^50\) transport models in Fig. 11. The POWLANG model describes the data for \( p_T < 3 \text{ GeV}/c \) but the data do not support the strong enhancement at \( p_T \sim 4 \text{ GeV}/c \) predicted by the model. The Duke model describes the data for \( p_T < 4 \text{ GeV}/c \). At higher \( p_T \), POWLANG simulations with the HTL transport coefficients and the Duke model predict a suppression of the D-meson yield which is not observed in the data.

\(^1\)The \( \langle T_{pPb} \rangle \) values used to compute the charged-particles \( Q_{pPb} \) were updated with respect to \(^66\) according to the values in \(^85\).
D-meson production in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV

ALICE Collaboration

Figure 11: D-meson $Q_{pPb}$ measured in the 0–10% centrality class compared with the predictions of the Duke [49] and POWLANG [50] transport models. The vertical bars and the empty boxes represent the statistical and systematic uncertainties. The colour-filled boxes at $Q_{pPb} = 1$ represent the normalisation uncertainties.

The ratio of the D-meson yield in a given centrality class with respect to yield in the most peripheral centrality class (60–100%), defined as

$$Q_{CP} = \frac{\langle d^2N^{\text{promptD}}/dp_Tdy \rangle_{p-Pb}}{\langle d^2N^{\text{promptD}}/dp_Tdy \rangle_{60-100\%}/\langle T_{pPb} \rangle_{60-100\%}}$$

was also calculated. The $Q_{CP}$ observable is independent of the pp cross section and uses the yields in peripheral p–Pb collisions as a reference. Since the contributions from the track reconstruction, selection and PID efficiency cancel out in the ratio, the $Q_{CP}$ has reduced systematic uncertainties with respect to the $Q_{pPb}$ ratio. The systematic uncertainties on the yield extraction were estimated by applying the fit variation procedure described in Section 4 directly on the signal yield ratio obtained from the invariant-mass distributions of the two centrality classes. To estimate the feed-down correction uncertainty, the contributions from the hypothesis on the nuclear modification factor of D mesons from B-hadron decays were considered as uncorrelated in each centrality class and were added in quadrature.

In Fig. [2], the average D-meson $Q_{CP}$ is shown for different centrality classes: 0–10%, 10–20%, 20–40% and 40–60%. The results are superimposed to those obtained for charged particles in the same centrality classes [66]. A similar trend is observed for both measurements: when the results from the most central classes are used as the numerator, the $Q_{CP}$ increases in the interval 1–5 GeV/$c$, reaching values of about 1.3 and then shows a decreasing trend with increasing $p_T$. A $Q_{CP} > 1$ with a significance of 3σ is observed in the range $3 < p_T < 7$ GeV/$c$ when the 20–40% centrality class is used as numerator. In this case, the normalisation uncertainty is smaller than the one of more central collisions due to the smaller separation between the centrality classes used in the calculation of $Q_{CP}$. When the 0–10% and 10–20% centrality classes are used as numerators, a $Q_{CP} > 1$ is observed in the same $p_T$ interval, with a significance of 1.5σ and 2σ due to the larger $\langle T_{pPb} \rangle$ uncertainties. A milder $p_T$ dependence is observed when the yields from more peripheral collisions are used as the numerator. A possible radial flow arising from a hydrodynamic evolution could modify the hadronisation dynamics of heavy quarks and potentially be the cause of the enhancement at intermediate $p_T$.

D-meson production in p–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV

ALICE Collaboration

Figure 12: Average D-meson and charged-particles $Q_{\text{CP}}$ using the yields measured in 0–10%, 10–20%, 20–40%, and 40–60% as numerators and the yield in 60–100% as the denominator. The vertical bars and the empty boxes represent the statistical and systematic uncertainties. The colour-filled boxes at $Q_{\text{CP}} = 1$ represent the normalisation uncertainties on the $\langle T_{pPb} \rangle$.

5.4 D-meson ratios

The ratios of the $p_T$-differential cross sections of $D^0$, $D^+$, $D^{*+}$, and $D_s^+$ mesons in the minimum bias sample are reported in Fig. 13. In the evaluation of the systematic uncertainties of the ratios, the contributions of the yield extraction and selection efficiency were considered as uncorrelated, while those of the feed-down from beauty-hadron decays and the tracking efficiency were treated as fully correlated among the different D-meson species. The measurements are compared to the ratios of D-meson cross sections in pp collisions at $\sqrt{s} = 5$ TeV [71]. The relative abundances of the four species are unmodified in p–Pb with respect to pp collisions within statistical and systematic uncertainties.

The ratios of the $D^+/D^+$-meson yields were also studied in different $p_T$ intervals as a function the multiplicity of charged particles produced in the collision. The charged-particle multiplicity, $N_{\text{ch}}$, was estimated at mid-rapidity by measuring the number of tracklets, $N_{\text{tracklets}}$, as in Refs. [68, 86]. The $D^+/D^+$ ratios were extracted in three multiplicity classes defined as 1–40, 40–70, 70–200 tracklets. A tracklet is defined as a track segment that joins the reconstructed primary vertex with a pair of space points on the two SPD layers within the pseudorapidity range $|\eta| < 1.0$. The measured $N_{\text{tracklets}}$ distribution is affected by the position of the interaction vertex along the beam axis and by the evolution of the detector conditions. The former is due to the collision system asymmetry and the limited SPD rapidity coverage, while the latter is a consequence of a variation in active SPD channels over time. To account for these effects, the $N_{\text{tracklets}}$ distributions were corrected offline on an event-by-event basis. The correlation between the measured $N_{\text{tracklets}}$ and $N_{\text{ch}}$, equivalent to the number of generated “physical primaries”, was obtained from a Monte Carlo simulation and parametrised with a linear function. Here, physical primaries are defined as prompt particles produced in the collision, along with their decay products, but excluding those from weak decays of strange particles [75]. The systematic uncertainty on the conversion from $N_{\text{tracklets}}$
D-meson production in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV

The production cross sections of the prompt charmed mesons ($D^0$, $D^+$, $D^{*+}$, and $D_s^+$) in p–Pb collisions at a centre-of-mass energy per nucleon pair of $\sqrt{s_{NN}} = 5.02$ TeV were measured as a function of $p_T$ in the rapidity interval $-0.96 < y_{\text{cms}} < 0.04$ with luminosity of $L_{\text{int}} = 292 \pm 11 \, \mu b^{-1}$. The $p_T$-differential production cross sections were reported in the transverse momentum range $0 < p_T < 36$ GeV/$c$ for $D^0$ mesons, $1 < p_T < 36$ GeV/$c$ for $D^+$ mesons, $1.5 < p_T < 36$ GeV/$c$ for $D^{*+}$ mesons, and $2 < p_T < 22$ GeV/$c$. The ratios of the $D_s^+/D^+$-meson yields are shown in Fig. 14 as a function of the number of primary charged particles per unity of pseudorapidity $(dN_{\text{ch}}/d\eta|_{|\eta|<0.3})$ in five $p_T$ intervals ranging from 2 to 16 GeV/$c$. As a comparison, the measured ratios in pp collisions [71] and in Pb–Pb collisions [87] at $\sqrt{s_{NN}} = 5.02$ TeV are also shown in the figure. Within uncertainties, there is no indication of a modification of the $D_s^+/D^+$-yield ratios in pp and p–Pb collisions, up to the highest multiplicities that could be studied with the current p–Pb sample, which are similar to those of peripheral Pb–Pb collisions (60–80% centrality class). A hint of an enhancement of the $D_s^+/D^+$-yield ratios in Pb–Pb collisions in $4 < p_T < 8$ GeV/$c$ is observed, as already shown in [87]. The larger data sample of Pb–Pb collisions collected by ALICE in 2018 will provide a more precise measurement.

6 Summary

The production cross sections of the prompt charmed mesons ($D^0$, $D^+$, $D^{*+}$, and $D_s^+$) in p–Pb collisions at a centre-of-mass energy per nucleon pair of $\sqrt{s_{NN}} = 5.02$ TeV were measured as a function of $p_T$ in the rapidity interval $-0.96 < y_{\text{cms}} < 0.04$ with luminosity of $L_{\text{int}} = 292 \pm 11 \, \mu b^{-1}$. The $p_T$-differential production cross sections were reported in the transverse momentum range $0 < p_T < 36$ GeV/$c$ for $D^0$ mesons, $1 < p_T < 36$ GeV/$c$ for $D^+$ mesons, $1.5 < p_T < 36$ GeV/$c$ for $D^{*+}$ mesons, and $2 < p_T < 22$ GeV/$c$.

Figure 13: Ratios of prompt D-meson production cross sections as a function of $p_T$ in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV. The results are compared with those of pp collisions at the same centre-of-mass energy [71]. The vertical bars and the empty boxes represent the statistical and systematic uncertainties.
D-meson production in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV

Figure 14: $D^+_s/D^+$-meson yield ratios, as a function of primary charged particles per unity of pseudorapidity in pp [71], p–Pb, and Pb–Pb [87] collisions at $\sqrt{s_{NN}} = 5.02$ TeV in five different $p_T$ intervals from 2 to 16 GeV/c.

24 GeV/c for $D^+_s$ mesons. The larger sample used for this analysis, with respect to that collected in 2013, allowed for a significant reduction, by a factor 1.5–2, of the statistical and systematic uncertainties, along with an extension of the $p_T$ reach.

The $p_T$-differential nuclear modification factor $R_{pPb}$ of D mesons, calculated by using the pp reference measured at the same centre-of-mass energy, was found to be compatible with unity for $0 < p_T < 36$ GeV/c. The $R_{pPb}$ results are described within uncertainties by theoretical calculations that include initial-state effects. The $R_{pPb}$ is also compared with parton-transport model based calculations that assume the formation of a deconfined QCD medium in p–Pb collisions. The trend predicted by these models is not supported by the data. The strong enhancement at $p_T \sim 3$–4 GeV/c observed in the calculations is not consistent with the measured $R_{pPb}$, and a suppression larger than 10% for $p_T > 8$ GeV/c is excluded by the data at 98% confidence level.

The centrality dependence of the D-meson yields was also studied in different centrality classes, from most central to peripheral collisions, in the interval $1 < p_T < 36$ GeV/c. The average $Q_{pPb}$ of prompt $D^0$, $D^+$, and $D^{*+}$ mesons is consistent with unity within the uncertainties for $p_T > 2$ GeV/c. The measurements show a hint of suppression in $1 < p_T < 2$ GeV/c stronger in the most central collisions with respect to the peripheral ones, as qualitatively expected from a stronger shadowing at low Bjorken-$x$ in central collisions. There is also a hint of enhancement in the intermediate $p_T$ region in the most central collision classes. The same trend is observed for the charged-particles $Q_{pPb}$. The average D-meson $Q_{CP}$ has been computed. For the most central collision classes, the $Q_{CP}$ increases in the $p_T$ interval 1–5 GeV/c, reaching values of about 1.3. Above a $p_T$ of 5 GeV/c the distribution tends to decrease with increasing
$p_T$. A milder $p_T$ dependence is observed for more peripheral collisions. A similar trend is observed for both charmed mesons and charged particles in all the centrality classes considered. A possible radial flow arising from hydrodynamic evolution could modify the hadronisation dynamics of heavy quarks and give rise to the enhancement measured in the intermediate $p_T$ interval.

The ratios of the $p_T$-differential cross sections of $D^0$, $D^+$, $D^{*+}$, and $D_s^+$ mesons were evaluated and compared to those measured in pp collisions at $\sqrt{s} = 5$ TeV. The relative abundances of the four species are unmodified in p–Pb collisions with respect to pp collisions, within the uncertainties. The ratios of $D_s^+ / D^{*+}$-meson yields, as a function of the number of primary charged particles per unit of pseudorapidity, show no evidence of modifications in pp and p–Pb collisions, within the uncertainties.

7 Appendix

Figure 15 presents the $Q_{pPb}$ results for $D^0$, $D^+$, and $D^{*+}$ as a function of $p_T$ for the 0–10% and 60–100% centrality classes. Figure 16 shows the $Q_{CP}$ for the three non-strange D mesons, obtained using 0–10% as central class and 60–100% as peripheral class. The results are compatible within uncertainties between the three D–meson species.

Figure 15: $D^0$, $D^+$, and $D^{*+}$ meson nuclear modification factors as a function of $p_T$ in the 0–10% (left) and 60–100% (right) centrality classes. The vertical bars and the empty boxes represent the statistical and systematic uncertainties. The colour-filled boxes at $Q_{pPb} = 1$ represent the normalisation uncertainties.
Figure 16: $D^0$, $D^+$, and $D^{*+}$ meson $Q_{\text{CP}}$, obtained using 0–10% as the central class and 60–100% as the peripheral class. The vertical bars and the empty boxes represent the statistical and systematic uncertainties, respectively. The colour-filled boxes at $Q_{\text{CP}} = 1$ represent the normalisation uncertainties.

108 Saha Institute of Nuclear Physics, Homi Bhabha National Institute, Kolkata, India
109 School of Physics and Astronomy, University of Birmingham, Birmingham, United Kingdom
110 Sección Física, Departamento de Ciencias, Pontificia Universidad Católica del Perú, Lima, Peru
111 Shanghai Institute of Applied Physics, Shanghai, China
112 St. Petersburg State University, St. Petersburg, Russia
113 Stefan Meyer Institut für Subatomare Physik (SMI), Vienna, Austria
114 SUBATECH, IMT Atlantique, Université de Nantes, CNRS-IN2P3, Nantes, France
115 Suranaree University of Technology, Nakhon Ratchasima, Thailand
116 Technical University of Košice, Košice, Slovakia
117 Technische Universität München, Excellence Cluster 'Universe', Munich, Germany
118 The Henryk Niewodniczanski Institute of Nuclear Physics, Polish Academy of Sciences, Cracow, Poland
119 The University of Texas at Austin, Austin, Texas, United States
120 Universidad Autónoma de Sinaloa, Culiacán, Mexico
121 Universidade de São Paulo (USP), São Paulo, Brazil
122 Universidade Estadual de Campinas (UNICAMP), Campinas, Brazil
123 Universidade Federal do ABC, Santo Andre, Brazil
124 University of Cape Town, Cape Town, South Africa
125 University of Houston, Houston, Texas, United States
126 University of Jyväskylä, Jyväskylä, Finland
127 University of Liverpool, Liverpool, United Kingdom
128 University of Science and Technology of China, Hefei, China
129 University of South-Eastern Norway, Tønsberg, Norway
130 University of Tennessee, Knoxville, Tennessee, United States
131 University of the Witwatersrand, Johannesburg, South Africa
132 University of Tokyo, Tokyo, Japan
133 University of Tsukuba, Tsukuba, Japan
134 Université Clermont Auvergne, CNRS/IN2P3, LPC, Clermont-Ferrand, France
135 Université de Lyon, Université Lyon 1, CNRS/IN2P3, IPN-Lyon, Villeurbanne, Lyon, France
136 Université de Strasbourg, CNRS, IPHC UMR 7178, F-67000 Strasbourg, France, Strasbourg, France
137 Université Paris-Saclay Centre d’Études de Saclay (CEA), IRFU, Département de Physique Nucléaire (DPhN), Saclay, France
138 Università degli Studi di Foggia, Foggia, Italy
139 Università degli Studi di Pavia, Pavia, Italy
140 Università di Brescia, Brescia, Italy
141 Variable Energy Cyclotron Centre, Homi Bhabha National Institute, Kolkata, India
142 Warsaw University of Technology, Warsaw, Poland
143 Wayne State University, Detroit, Michigan, United States
144 Westfälische Wilhelms-Universität Münster, Institut für Kernphysik, Münster, Germany
145 Wigner Research Centre for Physics, Hungarian Academy of Sciences, Budapest, Hungary
146 Yale University, New Haven, Connecticut, United States
147 Yonsei University, Seoul, Republic of Korea
