Abstract

Because of its high energy density, the manganese-rich lithium layered material is a potential cathode material for power batteries. In order to effectively strengthen the comprehensive performance of lithium-rich layered material, different amounts of YPO$_4$ compounds were used to wet chemically coat the cathode materials. The LMNCO$_{0.5}$-YPO$_4$, 1.0-YPO$_4$, and 3.0-YPO$_4$ cathode materials are tested by XRD, SEM, TEM, XPS, constant current charge and discharge test, and EIS. Facts show that the positive electrode material coated with YPO$_4$ has better cycle performance and rate performance. The 1.0-YPO$_4$ sample material has the best performance. After 50 cycles of 0.5 C, its discharge capacity can still be as high as 207.4 mAhg$^{-1}$. The comprehensive performance of the cathode material is improved after being coated with YPO$_4$, which is owing to the coating of YPO$_4$. The YPO$_4$ layer weakens the electron transfer resistance, and suppress the phase transformation of the Electrode material and the formation of the SEI film.

Keywords: Mn-based Li-rich layered material, surface modification, Rare metals, electrochemical performance

I. Introduction

Nowadays, the burning of fossil energy has made the global environmental pollution crisis worse. Lithium-ion batteries have been continuously studied by many researchers due to their numerous advantages, including the characteristics of high energy density per unit mass and non-damaging to the environment. Since all these strengths mentioned above, lithium-ion secondary batteries have been praised by many researchers as one of the more potential power batteries, and will be widely used in new energy vehicles of major brands[1]. While the energy density of old generation lithium battery can hardly meet the increasing demand for energy storage[2]. In efforts to replace those conventional lithium ion cathode, many research groups have studied the complex layered oxides that combined composition of Li$_2$MnO$_3$ and LiMO$_2$ (M=Ni, Co, Mn). Lithium-rich layered oxide xLi$_2$MnO$_3$·(1-x)LiMO$_2$ has attracted wide attention because of its many excellent characteristics, including higher capacity density, wider voltage window, lower cost, and so on[3].

However, studies have found that this series of cathode materials has many technical problems that need to be solved, including significant initial irreversible capacity loss, weak large-rate discharge performance, and severe attenuation of the median voltage[4]. When the charging voltage of the lithium-rich layered oxide exceeds 4.5V, Li$_2$O will be separated from the Li$_2$MnO$_3$ composition. This precipitation is not reversible, which also causes the first cycle of the coulombic efficiency to drop. At the same time, Further delithium will cause the transition metal ions to diffuse and migrate spontaneously, thereby causing corresponding structural changes.

In order to solve these existing problems, coating and modifying the surface of the material Is a very useful ways to enhance the comprehensive performance of the battery. For example, TiO$_2$, AlPO$_4$, MoO$_3$, Al$_2$O$_3$, and ZnO are used in the study of surface modification of cathode materials, and the research results show that these compounds
can greatly strengthen the overall performance of cathode materials. As is known to all, rare earth elements are equipped with excellent thermodynamics stability and are easily have contact with electrode materials[5]. In this study, Li-rich layered oxide is surface treated with YPO₄. To research the structure and morphology of the material, this experiment used a series of characterization methods such as XRD, SEM, TEM, SEI.

II. Experimental

2.1 Synthesis of materials

The LMNCO sample material is synthesized using acetate as the basic raw material and citric acid as the chelating agent. Solving these acetic acid salts (n(Li): n(Mn): n(Co): n(Ni)= 1.2:0.54:0.13:0.13) in de-ionized water to make a complex solution. Well, it is worth raising excessive 5 atom% lithium acetate (LiAc·2H₂O) into this solution to make up for the quality loss of lithium in the sintering process. Weigh a certain amount of citric acid into de-ionized water, and then titrate it with ammonia water to maintain the pH is between 8-9. Mix the two solutions and then stir at 95 °C until the rotor doesn’t move. The gel prepared above was dried in a drying oven, and the temperature is set to 120 °C, and the drying time is set to 12 h. The material prepared above is put into a calciner for two calcining treatments at different temperatures.. The temperatures of the two calcinations were 450 °C and 900 °C, and the calcination time was 5 h and 12 h. Finally, the LMNCO sample material was prepared.

Through the following steps, different amounts of YPO₄ can be coated on the positive electrode material. Stoichiometric amount of the pristine LMNCO needs to be dispersed in distilled water with strong stirring, followed by adding solving liquid of Y(NO)₃·6H₂O and NH₄HPO₄ dropwise, evaporating the solvent, drying at 120 °C for 6h. Finally, the obtained coating precursor was put into a heating furnace, heated to 400 °C, kept for 6 hours, and then cooled with the furnace to make a coated sample. The contents of YPO₄ coated on the pristine LMNCO are expected to be 0wt%, 0.5 wt%, 1 wt% and 3 wt%. They are named as LMNCO, 0.5-YPO₄, 1.0-YPO₄, 3.0-YPO₄, respectively.

2.2 Characterization measurements

The phase of the positive electrode material was detected by X-ray diffractometer (SMARTLAB3KW) with Cu Kα radiation measurement. A scanning electron microscope model SU8220 was applied to characterize the microscopic morphology of the cathode material. Use the energy spectrometer (EDS) carried by the scanning electron microscope to perform elemental analysis on the samples to be tested. Use the TEM model JEOL 2010 to characterize the material. An x-ray photoelectron spectrometer with model ESCALAB 250Xi+ was used when analyzing the surface chemistry.

2.3 Electrochemical measurements

Three materials including cathode material, super P and PVDF are mixed and ground in a proportion of 8:1:1, and then dissolved in N-methyl-2-pyrrolidone by mass. Coating the blended slurry evenly on the coated aluminum foil on the rough surface with a machine, and place it in a vacuum drying oven, and the temperature is set to 120°C, and the drying time is set to 12 h. Then cutting the dried aluminum foil with a microtome into round slices with a radius of 7 mm. The positive electrode material, lithium metal and disepiment are assembled in a CR2032 coin cell. Assemble CR2032 coin-type battery in a glove box of SURPER. Use the electrochemical workstation model CHI760E to test the AC impedance test and electrochemical impedance spectroscopy test of the button battery. Use NEWARE battery test system to conduct electrochemical test on button battery, test voltage is 2.0 V ~ 4.8 V, test temperature is 25 °C.
III. Result and Discussion

3.1 Crystal structure analysis

![XRD patterns of LMNCO, 0.5-YPO₄, 1.0-YO₄ and 3.0-YPO₄ cathode materials](image)

Fig. 1 XRD patterns of LMNCO, 0.5-YPO₄, 1.0-YO₄ and 3.0-YPO₄ cathode materials

Fig. 1 displays the XRD patterns of LMNCO, 0.5-YPO₄, 1.0-YO₄ and 3.0-YPO₄ cathode materials. Fig. 1 shows that the higher intensity diffraction peaks of the four samples belong to the layered α-NaFeO₂ structure. This phenomenon indicates that the cathode material has a LiMO₂ (M=Ni, Co, Mn) structure. Careful observation of the two sets of adjacent diffraction peaks (006)/(102) and (018)/(110) shows that the two sets of diffraction peaks are clearly separated, indicating that the material has an excellent crystal structure. Observing the XRD diffraction pattern carefully, we can find that there are several weak peaks in the 20°~25° diffraction angle range. These weaker protrusions are caused by the arrangement of the three elements Li, Mn and Ni in the Li₂MnO₃ composition. Observing the XRD diffraction pattern carefully, we can find that the 3.0-YPO₄ sample has a weaker, new diffraction peak, which represents the (200) crystal plane of YPO₄ compound.

The specific value of the intensities of the characteristic peaks of the positive electrode material (003) and (104), and the specific value of a and c are generally regarded as the basic feature of a positive electrode material with a layered structure. Generally, when the ratio of the intensities of the characteristic peaks of the positive electrode material (003) and (104) is less than 1.2, which means that the mixed cations in the material are serious, and when the specific value of a and c is less than 4.899, it means that the material owns a very undesirable structure. Table 1 lists the lattice parameters of the four samples and the intensities of the characteristic peaks of the positive electrode material (003) and (104), calculated by JADE 6.0 software. The higher the ratio of (003) and (104) characteristic peak intensity and the ratio of the lattice parameters c and a means that the prepared material owns a very desirable structure. It can be found that the lattice parameters of the four sample materials before and after the coating do not change significantly. This phenomenon shows that the YPO₄ coating basically has no effect on the material structure. Because the heat treatment temperature is not high enough, only 400 degrees Celsius, and it is difficult for the Y element to enter the crystals of the active substance.
Table 1 Refined lattice parameters and ratio of characteristic peak intensities of LMNCO, 0.5-YPO₄, 1.0-YPO₄, 3.0-YPO₄

| Samples          | a(Å)  | c(Å)  | c/a  | I(003)/I(104) |
|------------------|-------|-------|------|--------------|
| LMNCO            | 2.848 | 14.1826 | 4.9784 | 1.4841       |
| 0.5-YPO₄         | 2.8498 | 14.1714 | 4.9728 | 1.4686       |
| 1.0-YPO₄         | 2.8505 | 14.1885 | 4.9775 | 1.4865       |
| 3.0-YPO₄         | 2.8505 | 14.2155 | 4.9864 | 1.4611       |

3.2 Micro-morphology

Fig. 2 Superficial morphologies of LMNCO (a), 0.5-YPO₄(b), 1.0-YPO₄ (c) and 3.0-YPO₄ (d) cathode materials

Fig. 2 is the microscopic morphology of the four sample materials prepared in the experiment. The particles of all samples are distributed in blocks. The surface of the LMNCO is neat and full, and the particle contour can be seen clearly. However, 0.5-YPO₄ sample is covered with a little deposit; the particle contour of the sample coated with 1.0 wt% YPO₄ becomes nebulous, and there are more precipitated particles attached to the outer layer of the particles; When the concentration of YPO₄ compound is 3.0 wt%, many of sedimentary deposits appear on the surface of the particles, which are connected in a local area to cover part of the particles, which means that the YPO₄ package coverage may be too large.
Fig. 3 Elemental mapping of the Mn (b), Co (c), Ni (d), Y (e), P (f) elements of the 1.0-YPO₄ cathode material

For the purpose of getting a further study of the YPO₄ coating efficiency on the material structure. SEM mapping and TEM are put to good use. Fig. 3(b-f) shows the distribution of each element in the material. The five chemical elements Ni, Co, Mn, Y and P are evenly dispersed in the area where the particles are located, and no element enrichment is found, indicating that the YPO₄ compound is evenly scattered on the cathode material.
Fig. 4 TEM images of LMNCO (a, b) and 1.0-YPO₄ (c, d) cathode materials

Fig. 4 is TEM pictures of the LMNCO and 1.0-YPO₄. TEM pictures of the LMNCO shows that a continuous interference fringe is found from superficial regions to the grain edge, and the measured value of the interval between the interference fringes and fringes is 0.47 nm, which can be index to (003) plane[7]. Comparing the LMNCO, a protective layer is coated on the 1.0-YPO₄ sample material. Lattice spacing of the bulk material and surface of the 1.0-YPO₄ are 0.47nm and 0.345nm respectively, which corresponds to (003) plane of the layered structure (R-3m) and (200) plane of YPO₄. Observing picture Fig. 4(a), there is a thin film attached to the surface of the cathode material. It is reported that the thin film about 2-3 nm may be a Li₂CO₃ heterophase, which is commonly seen in lithium battery cathode materials. Light lithium salts are easily volatilized during the calculation stage and form Li₂CO₃ with CO₂ in the air, and this miscellaneous is not a crystal structure, so it can not be shown in the XRD diffraction pattern. Substances with low conductivity will be very unfavorable to the migration and diffusion of Li-ions.

3.3 Surface composition analysis
The XPS analysis data of the LMNCO and 1.0-YPO$_4$ is a method for testing chemical states of the transition metals. Fig. 5(a) shows that 0.5-YPO$_4$, 1.0-YPO$_4$ and 3.0-YPO$_4$ have characteristic peaks of P 2p, Y 3d, Y 3p, and Y 3s, except for the LMNCO, and these peaks increase hand in hand with the coating amount, thus it can be confirmed that the existence of the modifier YPO$_4$. The binding energies of the three elements Ni (2p3/2), Co (2p3/2) and Mn (2p3/2) are consistent with the binding energies of Ni$^{2+}$ (854.5 eV), Co$^{3+}$ (779.8 eV) and Mn$^{4+}$ (642.6 eV)[8]. The same chemical states of Ni, Co, and Mn before and after coating indicate that YPO$_4$ coating does not affect the chemical composition of the surface layer of the material. The binding energy strength of Co 2p, Ni 2p, Mn 2p drops while the coating amount goes higher. This is because the more coating amount of YPO$_4$, the thicker of the YPO$_4$ layer, and the active substance content in the XPS detection depth falls accordingly.

Fig. 6 Y 3d (a) and P 2p (b) XPS patterns of LMNCO, 0.5-YPO$_4$, 1.0-YO$_4$ and 3.0-YPO$_4$ cathode materials

Fig. 5 Co2p (b), Ni 2p (c) and Mn 2p (d) XPS patterns of LMNCO, 0.5-YPO$_4$, 1.0-YO$_4$, and 3.0-YPO$_4$ cathode materials
It can be found by fitting that the binding energy of Y element is 157.5 eV and 159.4 eV, corresponding to the binding energy of Y 3d5/2 and Y 3d3/2, which is in parallel with the value of Y3+[5]. The binding energy of P element on the material surface is about 133.4 eV, which is in parallel with the binding energy peak of P in PO43−[9]. Unlike peak changes of Co 2p, Ni 2p and Mn 2p, the peaks of Y 3d and P 2p gradually increased with the coating amount of YPO4 simultaneously. It can be seen from the above analysis that the YPO4 compound is completely coated on the original LMNCO.

3.4 Electrochemical performance

![Graph](image)

**Fig. 7 The initial charge/discharge profile (a) and the corresponding initial differential capacity vs. voltage curve (b) of LMNCO, 0.5-YPO4, 1.0-YO4 and 3.0-YPO4 cathode materials**

The first lap charge/discharge curves of the four sample materials are shown in Fig. 7(a). It’s clearly found that the initial charge profile shows two obvious charge areas, which is below or above 4.5 V. When it is below 4.5 V, the LiMO2 component is mainly involved in the charging process, and the Ni element and Co element undergo an oxidation reaction. When it is above 4.5 V, the charging capacity of the material is mainly produced by the activation of the Li2MnO3 component. First lap charge/discharge capacity of the LMNCO, 0.5-YPO4, 1.0-YPO4 and 3.0-YPO4 is 348.9/258.9 mAh g−1, 329.8/263.1 mAh g−1, 321.0/257.6 mAh g−1 and 299.7/246.6 mAh g−1, respectively. Fig. 7(b) shows the corresponding initial differential capacity vs. voltage curve. Two oxidation peaks can be found on the capacity differential curve. These two oxidation peaks respectively represent the recreation of Li[Ni1/3Mn1/3Co1/3] and Li2MnO3. Seen from the oxidation peak at 4.5V in Figure 3-6(b), it can be found that its intensity reduces along with the climb of the YPO4 coating amount. In the meanwhile, compared with the discharge platform of the four sample materials at 4.5 V as shown in Fig. 7(a), it can be found that the length of the discharge platform also tends to shorten with rising coating amount, suggesting that surface treatment can restrain the activation of Li2MnO3 component. Table 2 lists the first lap coulombic efficiency of LMNCO, 0.5-YPO4, 1.0-YO4 and 3.0-YPO4 cathode materials, which are 74.2%, 79.8%, 80.2% and 81.3%. The rise of the superficial YPO4 coating amount causes the enhancement of initial coulombic efficiency. It can be clearly found that the YPO4 coating can inhibit the activation process of Li2MnO3 component under high voltage state, reduce the precipitation of irreversible Li2O component, and advance the first lap coulombic efficiency.

**Table 2 The initial charge/discharge electrochemical data of LMNCO, 0.5-YPO4, 1.0-YO4 and 3.0-YPO4 cathode materials**

| Samples  | charge capacity (mAh g−1) | discharge capacity (mAh g−1) | Coulombic efficiency % |
|----------|---------------------------|------------------------------|------------------------|
| LMNCO    | 348.9                     | 258.9                        | 74.2%                  |

www.converter-magazine.info
The cyclic performance test of samples which contains different YPO₄ coating amount on the surface are conducted at 0.1 C for the first two cycles aiming for activating materials and at 0.5 C for the next 50 cycles. The pristine LMNCO and YPO₄ coated LMNCO show good cyclic performance in the first 20 cycles. However, except the 1.0-YPO₄ sample, a significant capacity decline can be observed from the other samples after the first 20 cycles. For the unmodified material, the discharge capacity loss is greater after 50 cycles, from 219.3 mAh g⁻¹ to 145.6 mAh g⁻¹, and the discharge capacity loss is 66.4%. After the process of YPO₄ coating, the specific discharge capacities of 0.5-YPO₄, 1.0-YPO₄ and 3.0-YPO₄ after 50 cycles are 167.7, 207 and 133.3 mAh g⁻¹, accompanied by capacities loss of 74.7%, 92.3%, 65% respectively. Compared with the pristine LMNCO, 0.5-YPO₄ and 1.0-YPO₄ gain the upper hand in displaying better cyclic performance, especially the 1.0-YPO₄ sample. This result supports the opinions that YPO₄ coated cathode material can protect the electrode material and improve the cyclic performance. On the contrary, excess amount of YPO₄ can lead to thick surface coating, eliminate the reaction of lithium de-intercalation, and lower the cyclic performance.
The charge/discharge curves are drawn in the 1st, 10th, 30th and 50th cycles at 0.5C in Fig. 9. Four sample materials experience the specific capacity loss with the electrochemical cycling. For the pristine, the discharge capacity mainly delivered between 4.8 V~3.2 V at the first cycle, when it comes to the 50th cycle, most of it is concentrated below 3.2 V. As we are well-known, in the process of charge and discharge cycles, the instability of the material structure will transform the layered structure of the material, and at the same time, its redox potential will drop from 3.2 V to 2.8 V. Specific discharge capacity of four samples during prolonged cycling below 3.2 V tends to increase, which means that the material structure will undergo irreversible changes. After the long loop is over, the proportion of the discharge capacity of the LMNCO, 0.5-YPO4, 1.0-YPO4, and 3.0-YPO4 between 2.0 V-3.2 V can reach 67.8%, 52.2%, 54.8%, and 61.1%, respectively (Table 2). This result proves that the superficial modification by YPO4 has the ability to suppress the phase transformation effectively.

![Fig. 9 Charge/discharge curves in different cycles for the LMNCO (a), 0.5-YPO4 (b), 1.0-YPO4 (c) and 3.0-YPO4 (d) cathode materials](image)
Fig. 10 shows the dQ/dV curves of four samples during cycling. There are two pairs of redox peaks on the dQ/dV curves, which are related to the reduction reaction inside the material. The reduction peak at 3.76 V in the capacity differential curve represents the reduction process of high-valent Ni and Co ions, while another reduction peak at 3.35 V on the capacity differential curve represents the reduction process of Mn$^{4+}$ in the MnO$_2$ structure. For the pristine LMNCO, the reduction peak at 3.75 V gradually weakened, and the reduction peak gradually shifted to a low potential as the cycle continued. The shift of the reduction peak at 3.35 V and the weakening of the peak after the shift means that the layered structure transforms into spinel phase gradually. The shift of the redox peak at 3.35 V is far more lighten when it comes to YPO$_4$ coating samples compared with the LMNCO. Compared with uncoated cathode material the reduction peak at 3.35 V of the LMNCO coated with YPO$_4$ has undergone huge reduction, though shift still exists. In general, the LMNCO coated with YPO$_4$ during cycling is much more stabilise than LMNCO.
Fig. 11 Rate performance of the LMNCO, 0.5-YPO₄, 1.0-YPO₄ and 3.0-YPO₄ cathode materials.

Fig. 11 shows the rate performance of all samples. The first two loops were experimented at 0.1 C for activation, and then 5 cycles were performed at different magnifications. The discharge capacity of the LMNCO sample at 0.2 C, 0.5 C, 1 C and 2 C is 217.7, 190.6, 161.3 and 106.9 mAh/g respectively. Whereas the rate performance of samples with superficial modification is doing better than the pristine, especially the 1.0-YPO₄ LMNCO. The 1.0-YPO₄ LMNCO releases 235.6 mAh/g specific capacity at 0.2 C, which is higher than 217.7 mAh/g of the pristine LMNCO. As the current density increases, the advantage of 1.0-YPO₄ LMNCO at the aspect of specific capacity stands out.

3.5 Electrochemical Impedance Spectroscopic (EIS) Studies

Fig. 12 EIS spectrums of samples LMNCO and 1.0-YPO₄.
Table 3 Fitting value of $R_{sf}$ and $R_{ct}$ of samples LMNCO and 1.0-YPO₄

| Samples    | $R_{sf}/Ω$ | $R_{ct}/Ω$ |
|------------|------------|------------|
| LMNCO      | 2.012      | 151.1      |
| 1.0-YPO₄   | 1.883      | 79.45      |

AC Impedance Tester was carried out at charged potential of 4.0V. Fig. 12 is the EIS spectrums and the fitted equivalent circuits of the pristine and 1.0-YPO₄. The impedance spectra of LMNCO and 1.0-YPO₄ samples both contain two parts with different shapes. The first part is a semicircle pattern in the high-frequency region, and the second part is a ray in the low-frequency region. There is a small distance between the real axis of impedance and the high-frequency semicircle. This intercept represents the migration resistance of ions in the electrolyte, which is represented by the symbol $R_s$. The intercept of the semicircle in the high-frequency region on the horizontal axis corresponds to the charge transfer impedance on the surface of the material, which is represented by the symbol $R_{ct}$. The rays in the low-frequency region represent the Warburg resistance caused by the solid phase diffusion of ions in the electrode material, represented by the symbol $Z_w$.

Table 3 is the EIS data of LMNCO and 1.0-YPO₄ after fitting. From the data, the table data shows that the $R_{sf}$ and $R_{ct}$ impedance values of the 1.0-YPO₄ sample material show a significant shrinking trend, indicating that the charge transfer resistance ($R_{ct}$) that hinders the diffusion and migration of Li⁺ is effectively reduced, so that the cathode material coated by YPO₄ show better electrochemical performance.

![Fig. 13 Z’ vs $ω^{-1/2}$ plots in the low-frequency region of 1st cycle for LMNCO and 1.0-YPO₄](image)

$\text{Li}^+$ diffusion coefficient of cathode materials has been calculated by the following equations, eqs 1 and 2:[11].

$$D_{Li} = \frac{0.5R^2T^2}{F^4A^2C^2\sigma^2}$$

$$Z' = \sigma \omega^{0.5} + R'$$

Fig. 13 shows $Z'$ vs $ω^{-1/2}$ plots of 1st cycle for LMNCO and 1.0-YPO₄. $\sigma$ represents the slope of the linear fitting graph. According to Equation (1), the larger the $\sigma$ value, the smaller the diffusion coefficient of Li⁺ ($D_{Li}$). It can be clearly seen by comparing the $\sigma$ value that the Li⁺ diffusion coefficient of the LMNCO sample material is less than 1.0-YPO₄. It can be seen from the above calculation results that the surface YPO₄ coating can increase the Li⁺
diffusion coefficient of the positive electrode material, and accelerate the rate of insertion and extraction of lithium ions inside the body material.

![Fig. 14 TEM images of the LMNCO (a) and 1.0-YPO₄ (b) samples after cycling for 50 cycles](image)

Fig. 14 is a TEM characterization diagram of two sample materials LMNCO and 1.0-YPO₄ after a long cycle test. It is quite clear shown that the structure of the LMNCO was seriously damaged, and the layered lattice structure was collapsed regionally. Different from the original sample, the 1.0-YPO₄ sample as a whole shows a clear layered structure, while the surface coating layer can also be clearly seen. This suggests that surface YPO₄ coating can effectively inhibit the phase transformation, so that the material can still maintain a better layered structure after long cycle. The results are consistent with previous analysis, which indicates that surface YPO₄ coating can maintain the structural stability.

IV. Conclusion

In summary, the method of wet chemical deposition was used to successfully coat the YPO₄ composite material on the lithium-rich layered oxide. TEM confirmed that after the coating treatment, a dense YPO₄ film was formed on the sample. YPO₄-coated samples are confirmed to have improved cycling performance and rate performance at high-rate. Comparatively, the optimal performance was observed in the 1.0 wt.% YPO₄ modified sample. The 1.0 wt.% YPO₄ modified sample delivered 207.4 mAhg⁻¹ after 50 cycles. The 1.0 wt.% YPO₄ modified sample also exhibited the highest rate performance of 190.1 mAhg⁻¹ at 1 C and 163 mAhg⁻¹ at 2 C. The excellent electrochemical performance owns to the dense YPO₄ protective layer, which can promote the diffusion of lithium, and protect the cathode material from damage.
