Severe MgADP Inhibition of \textit{Bacillus subtilis} F\textsubscript{1}-ATPase Is Not Due to the Absence of Nucleotide Binding to the Noncatalytic Nucleotide Binding Sites

Abstract

\textit{F}_1-\text{ATPase from Bacillus subtilis} (BF\textsubscript{1}) is severely suppressed by the MgADP inhibition. Here, we have tested if this is due to the loss of nucleotide binding to the noncatalytic site that is required for the activation. Measurements with a tryptophan mutant of BF\textsubscript{1} indicated that the noncatalytic sites could bind ATP normally. Furthermore, the mutant BF\textsubscript{1} that cannot bind ATP to the noncatalytic sites showed much lower ATPase activity. It was concluded that the cause of strong MgADP inhibition of BF\textsubscript{1} is not the weak nucleotide binding to the noncatalytic sites but the other steps required for the activation.

Introduction

\textit{FoF}_1-\text{ATPase/synthase} (\textit{FoF}_1\textsubscript{1}) catalyzes ATP synthesis from ADP and inorganic phosphate coupled with the H\textsuperscript{+} flow driven by the electrochemical gradient of H\textsuperscript{+} across cellular membranes. \textit{FoF}_1\textsubscript{1} consists of a water-soluble \textit{F}_1 part (\textit{F}_1-\text{ATPase}) connected to a membrane-embedded H\textsuperscript{+} channel, \textit{Fo} [1–3]. \textit{F}_1-\text{ATPase} consists of \(\alpha\), \(\beta\), \(\gamma\), \(\delta\) and \(\varepsilon\) subunits and its hydrolysis of one ATP molecule at a catalytic site on the \(\beta\) subunit drives a discrete 120\(^\circ\) rotation of the \(\gamma\) subunits relative to the \(\alpha\beta\delta\varepsilon\) [4]. In \textit{FoF}_1\textsubscript{1}, rotation of the rotor subunits of \textit{F}_1 (\(\gamma\) and \(\varepsilon\)) is transferred to the \(\varepsilon\) subunit ring of \textit{Fo} to couple ATP synthesis/hydrolysis and H\textsuperscript{+} flow.

The catalytic mechanism of ATP synthase has been extensively studied by structural studies and single-molecular experiments and the mechanism of the regulation of ATP synthase becomes attracting more interests. Several regulatory mechanisms are known: the mitochondrial ATP synthase has specific regulatory protein called \textit{F}_0\textsubscript{1}, which prevent ATP hydrolysis; The chloroplast ATP synthase has a pair of cystein residues in the \(\gamma\) subunit and the formation of the disulfide between them inhibits the activity; The \(\varepsilon\) subunit of bacterial and chloroplast ATP synthase inhibits ATP hydrolysis: and so on. Among them, the most prominent is MgADP inhibition [5–7]. When the ATP hydrolysis product, MgADP, is tightly bound at a catalytic site, the \(\textit{F}_1\)-ATPase is stalled. It is a common mechanism among all ATP syntheses examined so far. Several factors are known to affect MgADP inhibition; Sodium azide stabilizes MgADP inhibition [6]: A detergent lauryldimethylamine N-oxide (LDAO) releases MgADP inhibition [8]: Incubation with Pi reduces MgADP inhibition [9]: and so on. It is also known that nucleotide binding to the noncatalytic nucleotide binding sites on the \(\alpha\) subunits facilitate escape from MgADP inhibition [10]. Thus, in the ATP hydrolysis reaction, initial high activity decreases with time due to the MgADP inhibition. Then \(\textit{F}_1\) reaches equilibrium between active and MgADP inhibited states, resulting in lower steady-state activity compared to the initial one [5,11].

Our recent study revealed that the ATPase activity of \(\textit{F}_1\)-\text{ATPase from Bacillus subtilis} (BF\textsubscript{1}) is highly suppressed by the MgADP inhibition [12]. The initial ATPase activity, which is not inhibited by the MgADP inhibition, falls down rapidly to several percent in the steady state [12]. That is very large inactivation compared to other \(\textit{F}_1\)-ATPases because they only fall into half, one third or so [5,11]. LDAO activates BF\textsubscript{1} more than a hundredfold [12] and this activation is also very large compared to those of other \(\textit{F}_1\)-ATPases (only several fold) [8]. Due in part to the strong MgADP inhibition, BF\textsubscript{1} has a strange ATP concentration dependency of steady-state ATPase activity, the ATPase activity at 20–100 \(\mu\)M ATP is lower than those at 1–10 \(\mu\)M or 200–5000 \(\mu\)M [12]. Interestingly, the \(\varepsilon\) subunit does not inhibit but activates BF\textsubscript{1} by releasing MgADP inhibition [12]. In bacterial ATP synthases, the relationship between these two inhibitions must be very important to gain proper regulation fit for the physiological demand. Thus, studying such a characteristic behavior of BF\textsubscript{1} will help us to understand how the regulation of ATP synthase varies depending on the environment where the source organisms live.

Studies with \(\textit{F}_1\)-ATPases from other species showed that the ATP binding to the noncatalytic site promotes release of inhibitory MgADP from catalytic sites and results in the substantial activation [10,13]. A mutant \(\textit{F}_1\)-ATPase from thermophilic \textit{Bacillus PS3} (TF\textsubscript{1}) that cannot bind nucleotide to the noncatalytic site showed large initial inactivation that reached to essentially no

steady-state activity [13]. In eubacterial V-type ATPases, which is thought to have the same origin as F1-ATPases, the noncatalytic B subunit does not bind nucleotide and V1-ATPase from Thermus thermophilus HB8 showed strong MgADP inhibition and no steady-state activity [14]. Inspired by these observations, we hypothesized that strong MgADP inhibition of BF1 is due to the inability of noncatalytic sites to bind nucleotide. To examine this hypothesis, we prepared a mutant of BF1.

A role for recovery from MgADP inhibition in BF1.

The noncatalytic sites showed lowered ATPase activity, indicating that the noncatalytic sites of BF1 could bind ATP. Thus, the cause of strong MgADP inhibition of BF1 is not the weak binding ability of the noncatalytic sites but other steps required for the recovery from the MgADP inhibition. However, the mutant $\delta_{\beta_1\gamma}$ complex of BF1 that cannot bind nucleotide to the noncatalytic sites showed lowered ATPase activity, indicating that the nucleotide binding to the noncatalytic sites has a substantial role for recovery from MgADP inhibition in BF1.

Materials and Methods

Plasmid construction and protein preparation

The mutation ($\delta$R354W), which corresponded to the same mutant of Escherichia coli F1-ATPase (EF1) [15], was introduced by overlap extension PCR method [16] with KOD-plus DNA polymerase (Toyobo) and by using the expression plasmid for the wild type (WT) $\delta_{\beta_1\gamma}$ complex of BF1, pET21-BF1 [12] as a template. Mutagenic primers were 5'-CTCAGGGCTATGCGCCAGCATCAATGCCC-3' and 5'-TTGTATGGCCTGAGCATCGCATCACTGAGAAGAAC-3' and the franking primers were 5'-GCGGTATTGATAAACCAGGCTAGCCAGG-3' and 5'-TCTTGTGTGATGGCTGCTTGGC-3'. The resulting 2.2 kbp DNA fragment was introduced into the EcoRV site of pZero2.1 vector (Novagen). Then the 0.8 kbp DNA fragment containing mutation was excised out by cutting this plasmid with XhoI and Neol. The fragment was put back to the original site of WT pET21-BF1 by ligating with Neol/BamHI fragment (1.2 kbp) and XhoI/BamHI fragment (7.3 kbp) of WT pET21-BF1. The resulting plasmid, pET21-BF1($\delta$R354W) was used for protein expression. The mutations ($\delta$K175A/T176A), which is known to suppress nucleotide binding to the noncatalytic site [13,17], were introduced in addition to $\delta$R354W by overlap extension PCR method with following primers by using pET21-BF1($\delta$R354W) as a template. Mutagenic primers were 5'-CCGTCACAACAGGGTCAGCAGATTGTTG-3' and 5'- ATCGCAACAGATGCTGCACCTGGTTG-3' and the franking primers were 5'-GAAATATCAGACTGATATAGG-3' and 5'-GATAAAGCCTCCGTAAACCGAAGCTG-3'. The resulting 0.6 kbp DNA fragment was introduced into the EcoRV site of pZero2.1 vector (Novagen). Then the 1.6 kbp DNA fragment containing mutations was excised out by cutting this plasmid with XhoI and Neol. The fragment was put back to the original site of pET21-BF1($\delta$R354W) by ligating with Neol/BamHI fragment (1.3 kbp) and XhoI/BamHI fragment (6.4 kbp) of pET21-BF1($\delta$R354W). The resulting plasmid, pET21-BF1($\delta$K175A/T176A/R354W) was used for protein expression. Mutations were confirmed by DNA sequencing. WT ($\delta_{\beta_1\gamma}$), $\delta$R354W mutant ($\delta_{\beta_1\gamma}^{\text{R354W}}$), and $\delta$K175A/T176A/R354W mutant ($\delta_{\beta_1\gamma}^{\text{K175A/T176A/R354W}}$) $\delta_{\beta_1\gamma}$ complexes of BF1 were prepared as described previously [12].

Fluorescence measurement

The assay mixture consisted of 50 mM Tris-H$_2$SO$_4$ (pH 7.5), 50 mM K$_2$SO$_4$ and 2 mM MgSO$_4$ was transferred to a quartz cuvette (1.5 ml). The cuvette was placed in a fluorescence spectrophotometer, FP-6500 (JASCO, Tokyo) and the temperature was controlled to 25°C. The $\delta_{\beta_1\gamma}$ complex of BF1 was added to 100 nM. The concentrated ATP-Mg solution (a mixture of equal molar ATP and MgSO$_4$) was injected into the cuvette at the time indicated and the changes in the fluorescence were measured every 0.5 s or 1 s until the fluorescence reached a plateau. Excitation and emission wavelengths were set at 300 nm and 350 nm, respectively. Excitation and emission slit widths were 5 and 10 nm, respectively. The solution was stirred continuously.
during the measurement. Emission spectra were measured before and after the time-course measurement at a rate $50\text{ nm/min}$.

Fluorescence data analysis

The time course of the fluorescence was corrected for baseline with buffer. The fluorescence change at a plateau was plotted against the ATP concentration and fitted with the simple binding equation or the Hill equation by the computer software (Origin 9.0J, Microcal Co.). The sum of two simple binding equations did not improve fitting (data not shown).

ATPase assay

ATPase activity was measured by NADH-coupled ATP-regenerating system at 25°C as described previously [12]. Reaction rates were determined at 3–5 s (initial) and 12–13 min (steady state) after the start of the reaction. The reaction rate in the presence of 0.1% LDAO was determined 100–150 s after the addition of LDAO.

Other methods

Protein concentration was determined by the method of Bradford [18] using bovine serum albumin as a standard. Chemicals were of the highest grades available.

Results and Discussion

Tryptophan fluorescence of $\alpha_3\beta_3\gamma^{\text{RW}}$ was completely quenched by the addition of ATP

The mutant $\alpha_3\beta_3\gamma^{\text{RW}}$ showed large fluorescence compared to the WT (Fig. 1). Addition of ATP resulted in the quenching of fluorescence to the same level as the WT background, indicating that the fluorescence from tryptophan introduced near the noncatalytic sites was completely quenched by the addition of ATP. Thus, as reported on EF1 [13], tryptophan fluorescence could be used as the indicator of nucleotide binding to the noncatalytic sites of the $\alpha_3\beta_3\gamma^{\text{RW}}$ complex. The time course of fluorescence showed the ATP-concentration dependent rate and magnitude of fluorescence quenching (Fig. 2). There was a small jump in the fluorescence upon addition of ATP but this was not considered in the calculation of the degree of quenching. The titration with ATP showed an apparent $K_d = 34.4\pm1.2\text{ mM}$ with simple binding equation and an apparent $K_d = 36.5\pm0.7\text{ mM}$ and $n = 1.47\pm0.1$ with Hill equation (Fig. 3). These values were in the same range as that reported on EF1 ($K_d = 36.5\text{ mM}$ and $n = 1.47$ with Hill equation) [15]. It should be noted that part of ATP will be hydrolyzed into ADP and Pi and the noncatalytic sites will be filled with some combination of ATP and ADP depending on initial ATP concentration since the fluorescence measurement did not include pyruvate kinase, an ATP-regenerating enzyme. Nevertheless, according to the results of ATPase measurement (Fig. 4), only a few percent of ATP was hydrolyzed before fluorescence reached the plateau ($\sim100\text{ s}$) at high concentrations of ATP such as 1 mM.

$\alpha_3\beta_3\gamma^{\text{RW}}$ was inhibited severely even the noncatalytic sites were filled

Except for the lower steady-state activity, the mutant $\alpha_3\beta_3\gamma^{\text{RW}}$ showed similar ATPase properties to the $\alpha_3\beta_3\gamma^{\text{WT}}$ (Fig. 4); very
high initial activity and strong inactivation to approximately 1% of the initial activity, and activation by LDAO more than 300-fold at 2 mM ATP for example. The lower steady-state activity may be due to the altered affinity or specificity of noncatalytic site by the mutation, although the fluorescence measurements (Fig. 3) indicate that ATP should fill noncatalytic sites in the steady-state (12–13 min after the start of the reaction) ATPase measurement at >200 μM ATP. Thus, BF1 was strongly inhibited by the MgADP inhibition even when the noncatalytic sites were filled with ATP. Although ATP and ADP could affect differently on releasing MgADP inhibition, even when the noncatalytic sites were filled with ATP. Although MgADP inhibition is common to all ATP synthases, the degree of that varied considerably. There have been no report about such strong MgADP inhibition on other F1-ATPases. To study what determines the degree of the MgADP inhibition may help us to understand the whole picture of the physiological regulation of ATP synthases from various species living in the various environment.

**Conclusions**

The noncatalytic nucleotide binding sites of BF1 can bind nucleotides by the affinity similar to other F1-ATPases. From the result, there rose the possibility that the nucleotide binding to noncatalytic site of BF1 does not affect release of MgADP inhibition. However, this was not the case because the \( \alpha_3\beta_3\gamma^{\text{ANC}} \) mutant had even lower steady-state activity than the WT or the RW mutant. Thus, the most part of strong MgADP inhibition of BF1 is due to the different factors. Inefficient transmission of the conformational changes from the noncatalytic sites to the catalytic sites induced by the binding of ATP to the noncatalytic sites [22] or the intrinsic propensity of catalytic \( \beta \) subunit, for example, are the candidates. Following results presented here, we are carrying out the experiments that may determine the part responsible for the strong MgADP inhibition of BF1 from the different point of view. Although the MgADP inhibition is common to all ATP synthases, the degree of that varied considerably. There have been no report about such strong MgADP inhibition on other F1-ATPases. To study what determines the degree of the MgADP inhibition may help us to understand the whole picture of the physiological regulation of ATP synthases from various species living in the various environment.

**Supporting Information**

**Figure S1** Emission spectra of \( \alpha_3\beta_3\gamma^{\text{ANC}} \) of BF1. Fluorescence emission spectra of \( \alpha_3\beta_3\gamma^{\text{ANC}} \) in the absence and presence of 1 mM ATP were measured as Fig. 1. Solid line and dotted line represent in the absence and presence of ATP, respectively. The fluorescence values are normalized to peak in the absence of ATP as 100%.
