ABSTRACT
Binary mixtures of hard spheres with different diameters and square-well attraction between different particles are studied by theory and Monte Carlo simulations. In our mesoscopic theory, local fluctuations of the volume fraction of the two components are taken into account. Semi-quantitative agreement between the simulation and theoretical results is obtained, except from very small distances. The correlation functions exhibit exponentially damped oscillations, with the period determined by the interaction potential, and both the amplitude and the correlation length increasing significantly with increasing diameter ratio. Increasing size asymmetry leads also to decreasing fluctuations of the number of the smaller particles in the attractive shell of the bigger ones. For small size asymmetry, the strongest correlations occur for comparable volume fraction of the two components. When the size ratio increases, the maximum of the structure factor moves to a larger volume fraction of the bigger particles, and for the size ratio as large as 4, the maximum goes beyond the accessible range of volume fractions. Our results show that when the neighbourhood of different particles is energetically favoured, the particles are much more uniformly distributed than in the random distribution even at relatively high temperature, especially for large size asymmetry.

1. Introduction
Local structure in simple liquids is determined by packing of hard spheres representing particle cores. Even in the case of spherical shapes, however, the distribution of the particles or molecules can be significantly different when the interactions between them exhibit some competing tendencies. In binary mixtures, gas–liquid separation or demixing transitions occur in the fluid part of the phase diagram. In some cases, however, microsegregation or self-assembly into various aggregates can take place [1–4]. Moreover, for sufficiently asymmetric binary hard-sphere mixtures, the competition between two length scales, associated with the two diameters, leads to structural crossover upon changing the composition [5–9]. In this case, the ordering of the mixture can be either on the length scale set by the small or the large particles with a crossover line, that separates these regions.

In the case of electrostatic interactions, repulsion between like charges competes with attraction of opposite

charges. At sufficiently low temperature, this competition leads to various ionic crystals in simple salts, as well as to a rich variety of ordered structures in mixtures of oppositely charged colloid particles with different size ratios \([10–12]\). In the fluid phase, the order can still be present locally, as observed in simulations of ionic liquids (IL) and IL mixtures (ILM) \([13]\), and predicted theoretically \([14–20]\). The local order can be directly observed near a planar boundary, since the concentration or density profiles are similar to the corresponding correlation functions. Indeed, charge density oscillations in direction perpendicular to the planar boundary have been found in experiments, simulations and theory \([21–25]\). In directions parallel to the confining plane, either hexagonal or stripe pattern formed by co-ions is formed in the near-surface layer, and the order extends beyond the first two layers of ions in ILM \([24, 26]\). Local order in mixtures of colloid particles can be induced by non-coulombic interactions as well, for example by H-bonds formation between different particles \([27]\).

Determination of the local structure in the case of Coulombic interactions by traditional liquid theories is very difficult \([15, 28]\), especially in the case of large size asymmetry. It is easier to determine the structure of the fluid within the density functional theory (DFT) \([8, 29]\) that can very well predict the structure induced by the packing of hard spheres. Unfortunately, in the standard DFT the interactions are taken into account in an expression of the mean-field (MF) type. This expression is inaccurate in a disordered phase with the local structure induced by the competing interactions, and the internal energy in this phase is overestimated \([30]\). As a result, instead of a disordered phase with strong local order, an ordered phase with long-range charge oscillations with a small amplitude is predicted for a significant part of the phase diagram \([16, 31, 32]\). A continuous transition to this ordered phase occurs at a \(\lambda\)-surface, where the correlation functions in Fourier representation diverge for a particular wavenumber \([16, 19, 32]\). Neither this divergence nor the continuous transition exist in reality. This disadvantage is cured in the modified DFT for mixtures, where the variance of the local volume fraction of the components is taken into account \([33]\). In Ref. \([34]\), it was shown that the results of the modified DFT agree semiquantitatively with Monte Carlo (MC) simulations for the binary mixture with equal diameters of the particles of the two species. In this work, we consider binary mixtures with different size ratios of the components, and calculate correlation functions within the theory developed in Ref. \([33, 34]\).

Simulations of systems with Coulombic interactions are very difficult too, especially in the case of large size asymmetry \([35–37]\). It is important to note, however that the periodic arrangement of the particles of the two species is determined by the excess of the energy associated with the density or concentration wave superimposed on the average density or concentration, respectively. As shown in Ref. \([33]\), two types of local order in binary mixtures can occur – either alternating dense and dilute regions are formed, or there are alternating regions rich in the first and in the second component. For the local order formation, the wavenumber corresponding to the largest decrease of the energy compared to the homogeneous state is crucial. For this reason, similar structures are expected for different interaction potentials, if in Fourier representation they assume extrema for the same wavenumbers \([38]\). We can study model systems that are expected to have similar local structure as systems composed of charged particles. To simplify the simulation studies as much as possible, in this work we consider a model of hard spheres with different diameters of the particles of the two species, and assume a square-well potential between particles of different kind. With such interactions, nearest neighbours of different species are favoured energetically over the nearest neighbours of particles of the same species, as in the case of a binary mixture of charged particles.

The objective of our study in this work is twofold. First, we want to determine how the size asymmetry influences the periodic arrangement of particles, when the neighbourhood of different particles is energetically favoured. Our second goal is to verify the accuracy of the modified DFT for different size ratios of the particles, and for different thermodynamic states. The theoretical results are compared with Monte Carlo (MC) simulations. The simulations are performed in the canonical ensemble, while in the theory, the grand-canonical ensemble is used. Even though fluctuations of the concentration in mesoscopic regions play a significant role in our system, fluctuations of the numbers of the big and small particles in the macroscopic volume are negligible far from the gas–liquid separation. For this reason, the canonical and the grand-canonical ensembles are expected to give equivalent results for the structure of the liquid phase.

In Section 2, we introduce the model and describe briefly the simulations. In Section 3, we summarise the theory developed in Ref. \([33, 34]\), and adopt it to the considered model and to the size-asymmetric hard-sphere reference system. In Section 4.1, we present theoretical and simulation results for a small size asymmetry. Moderate and large size-asymmetry cases are described in Section 4.2 and 4.3, respectively. The results are summarised in Section 5.
2. The model and the simulation method

2.1. The model

We consider the model binary mixture in which the particles of the same species (like particles) interact through hard-core interactions and the particles of different species interact through the potential $U_{12}(r)$ beyond the hard-core. In general, the particles of different species differ in their hard-sphere diameters $\sigma_1 \neq \sigma_2$.

Thus, the pair interaction potentials are as follows:

$$u_{\alpha\alpha}(r) = \begin{cases} \infty, & r < \sigma_\alpha \\ 0, & r \geq \sigma_\alpha \end{cases},$$

$$u_{12}(r) = \begin{cases} \infty, & r < \sigma_{12} \\ U_{12}(r), & r \geq \sigma_{12}, \end{cases} \tag{1}$$

where $\sigma_{12} = (\sigma_1 + \sigma_2)/2$. For $U_{12}(r)$, we choose the square well potential, which can be presented in the form

$$U_{12}(r) = -\varepsilon \theta(r-1)\theta(a-r), \tag{2}$$

where $a$ and $r$ are in $\sigma_{12}^{-1}$ units. $a>1$ is the range of the potential and $\varepsilon$ is the interaction strength at contact of the two unlike particles. The Fourier transform of the potential $\beta U_{12}$ has the form:

$$\beta U_{12}(k) = \beta \varepsilon \frac{4\pi (ak \cos(ak) - k \cos(k) + \sin(k) - \sin(ak))}{k^3}, \tag{3}$$

where $\beta = 1/(k_BT)$, $\beta$ is the Boltzmann constant, and the wave-number $k$ is in $\sigma_{12}^{-1}$ units. The function (3) is shown in Figure 1 for $a = 1.2$.

For $a = 1.2$, the first maximum is at $k = k_0 = 4.062$.

The considered mixture undergoes two types of instability in the MF approximation: the instability (at $k = 0$) connected with the gas–liquid phase separation and the instability (at $k_0 \approx 4.062$) connected with the appearance of local inhomogeneity at the length scale $2\pi/k_0$ [33, 34].

In this work, we want to compare the local structure for small, moderate and large size asymmetry, $\alpha = \sigma_1/\sigma_2$, and choose the following values of the diameter ratio: $\alpha = 0.8, 0.6, 0.25$. The corresponding ratios of the particle volumes, $\nu_\alpha = \pi \sigma_\alpha^3/6$, are $\nu_1/\nu_2 = 0.512, 0.216, 0.015625$, respectively.

In the case of size asymmetry, the concentration of the larger particles can be defined in two different ways. We can either consider the mole fraction of the 2nd species, $x = \rho_2/\rho$, or the fraction of the volume occupied by the larger particles, $c = \zeta_2/\zeta$. If we choose the mole fraction, then we can present the packing fractions $\zeta_1$ and $\zeta_2$ as follows:

$$\zeta_1 = \frac{(1-x)a^3\zeta}{x+(1-x)a^3}, \quad \zeta_2 = \frac{x\zeta}{x+(1-x)a^3}. \tag{4}$$

2.2. The simulations

The binary mixture with $\alpha = 0.8, 0.6, 0.25$ and $a = 1.2\sigma_{12}$ has been simulated via Monte Carlo technique in the NVT ensemble. $N = N_1 + N_2$ particles (systems I–III in Table 1) were placed in a cubic box with periodic boundary conditions applied in the three directions. The interactions between the particles are described in Equations (1)-(2). In simulations, it is convenient to choose the diameter of the smaller particles, $\sigma_1$, and the square-well depth $\varepsilon$ as the length and energy units. A cut-off radius, which is the interaction range of the square well potential, depends on $\sigma_2$; for that reason it is indicated

$$\zeta_1 = \frac{(1-x)a^3\zeta}{x+(1-x)a^3}, \quad \zeta_2 = \frac{x\zeta}{x+(1-x)a^3}. \tag{4}$$

Table 1. Simulation details for the systems considered. For systems I–II the size of the simulation box is $20\sigma_1$, but for system III, the box size is $40\sigma_1$. $N_1, 1/1, and N_2, 1/2$ denote the number of particles and the volume fraction of the species 1 and 2, respectively. $R_{\text{cut}}$ is the cut-off length in $\sigma_1$ units, $\zeta_i = \pi \rho_i \sigma_i^3/6, \rho_i = N_i/V$, and $T^* = k_BT/|\varepsilon|$.

| Systems | $\alpha = \sigma_1/\sigma_2$ | $T^*$ | $N_1$ | $N_2$ | $\zeta_1$ | $\zeta_2$ | $R_{\text{cut}}$ |
|---------|------------------------|-------|------|------|---------|---------|-----------|
| I       | 0.8                    | 0.1   | 2597 | 1799 | 0.17    | 0.23    | 1.35      |
| II      | 0.6                    | 0.1   | 3514 | 886 | 0.23    | 0.27    | 1.6       |
| III     | 0.25                   | 0.6   | 15,890 | 516 | 0.13    | 0.27    | 3.0       |
in Table 1. For each system, $10^7$ Monte Carlo steps for equilibration, and $10^6$ steps for production have been run.

The pair distribution functions
\[ g_{\alpha\beta}(r) = \frac{\langle \hat{\rho}_\alpha(r_1) \hat{\rho}_\beta(r_1 + r) \rangle}{\langle \hat{\rho}_\alpha \rangle \langle \hat{\rho}_\beta \rangle} \]  
(5)

have been determined by standard methods for the systems listed in Table 1.

3. Theory

3.1. Brief summary of the DFT for inhomogeneous mixtures

In the case of size asymmetry, the number density of smaller particles can be larger than the number density of the big ones, but the volume occupied by them can be significantly smaller. For this reason, the theory developed in Ref. [33] is based on the local volume fractions, $\zeta_\alpha(r) < 1$, where in the binary mixture $\alpha = 1, 2$. We are interested in the correlation functions in the disordered phase,
\[ G_{\alpha\beta}(r) = \langle \Delta \zeta_\alpha(r_0) \Delta \zeta_\beta(r + r_0) \rangle, \]  
(6)
where $\Delta \zeta_\alpha(r) = \zeta_\alpha(r) - \bar{\zeta}_\alpha$, and $\bar{\zeta}_\alpha$ is the average volume fraction of the species $\alpha$ in the disordered phase. In our theory it is more convenient to consider the above functions. Their relation with the pair distribution functions determined in simulations is simply $G_{\alpha\beta} = \zeta_\alpha \zeta_\beta (g_{\alpha\beta} - 1)$. The matrix $\mathbf{G}$ with the elements defined in (6) satisfies the analogue of the Ornstein–Zernicke equation, $\mathbf{G} = \mathbf{C}^{-1}$, where the inverse correlation functions $\tilde{C}_{\alpha\beta}(r_1, r_2)$ (related to the direct correlation functions) are the second functional derivatives with respect to $\zeta_\alpha(r_1)$ and $\zeta_\beta(r_2)$ of the functional
\[ \beta F(\zeta_1, \zeta_2) = \beta \Omega_{\text{co}}[\zeta_1, \zeta_2] - \ln \left[ \int D\phi_1 \int D\phi_2 e^{-\beta H_{\text{fluc}}} \right], \]  
(7)
where
\[ H_{\text{fluc}}[\zeta_1, \zeta_2, \phi_1, \phi_2] = \Omega_{\text{co}}[\zeta_1 + \phi_1, \zeta_2 + \phi_2] - \Omega_{\text{co}}[\zeta_1, \zeta_2], \]
and $\Omega_{\text{co}}[\zeta_1, \zeta_2]$ is the grand potential with the local volume fractions constrained to have the fixed forms. We assume
\[ \Omega_{\text{co}} = \frac{1}{2} \int dr_1 \int dr_2 V_{\alpha\beta}(|r_1 - r_2|) \zeta_\alpha(r_1) \zeta_\beta(r_2) - TS - \mu_\alpha N_\alpha, \]
where $V_{\alpha\beta}(r) = U_{\alpha\beta}(r)/(v_\alpha v_\beta)$ is the interaction potential (in appropriate units) between the species $\alpha$ and $\beta$ separated by the distance $r$, the entropy $S$ satisfies the relation $-TS = \int f_\lambda(\zeta_1(\mathbf{r}), \zeta_2(\mathbf{r}))d\mathbf{r}$, where $f_\lambda$ is the free-energy density of the hard-core reference system in the local-density approximation, and $\mu_\alpha, N_\alpha$ are the chemical potential and the number of particles of the species $\alpha$, respectively. $\phi_\alpha(\mathbf{r})$ is the local fluctuation of the volume fraction of the component $\alpha$.

In MF, the second term on the RHS of Equation (7) is neglected. In the lowest-order non-trivial approximation beyond MF [33],
\[ \tilde{C}_{\alpha\beta}(k) = \beta \tilde{V}_{\alpha\beta}(k) + A_{\alpha\beta} + \frac{A_{\alpha\beta} q_0}{2} \tilde{G}_{q_0}, \]  
(8)
where $\tilde{f}(k)$ denotes the function $f$ in Fourier representation, and the summation convention is used. In the above equation,
\[ A_{\alpha_1\cdots\alpha_j} = \frac{\partial C_{\alpha_1\cdots\alpha_j}^2(\zeta_1, \zeta_2)}{\partial \zeta_{\alpha_1} \cdots \partial \zeta_{\alpha_j}}, \]  
(9)
with $\alpha_i = 1, 2$. Note that in this approximation, the dependence of $\tilde{C}_{\alpha\beta}(k)$ on $k$ comes only from $\beta \tilde{V}_{\alpha\beta}(k)$. The last term in Equation (8) is the fluctuation contribution, and comes from the last term in (7) in the Brazovskii-type approximation [39]. Here, $\tilde{G}_{q_0}$ denotes the integral
\[ \tilde{G}_{q_0} = \int \frac{dk}{(2\pi)^3} \tilde{G}_{q_0}(k). \]  
(10)

Equations (8)–(10) have to be solved self-consistently. In general, it is a non-trivial task.

We focus on the disordered inhomogeneous phase and assume that the inhomogeneities occur on a well-defined length scale. In such a case, the peak of $\tilde{G}_{q_0}(k)$ is high and narrow. For functions with a high, narrow peak, the main contribution to the integral comes from the vicinity of the maximum. We assume that the maximum of all the integrands in (10) is very close to the minimum at $k = k_0$ of $\det \tilde{C}(k)$, and we make the approximation
\[ \tilde{G}_{\alpha\beta} = [\tilde{C}_{\alpha\beta}(k_0)] \tilde{G}, \]  
(11)
where $[\tilde{C}_{\alpha\beta}(k)] = \tilde{C}_{\beta\beta}(k)$ and $[\tilde{C}_{\alpha\beta}(k)] = -\tilde{C}_{\alpha\beta}(k)$ for $\alpha \neq \beta$, and
\[ \tilde{G} = \int \frac{dk}{(2\pi)^3} \frac{1}{\det \tilde{C}(k)}. \]  
(12)
Near the minimum at $k_0$, we have the approximation
\[ \det \tilde{C}(k) = D_0 + \frac{\beta \tilde{W}''(k_0)}{2} (k - k_0)^2 + \cdots \]  
(13)
where $\tilde{W}''(k_0)$ depends on the interaction potentials, and
\[ D_0 = \det \tilde{C}(k_0). \]  
(14)
From the approximation (13) and (12), we obtain [33, 40]
\[ G \approx \frac{k^2}{\pi \sqrt{2\beta W''(k_0)D_0}}. \]  
(15)

With all the above assumptions, the problem reduces to determination of the minimum of \(\det \tilde{C}(k)\), and to a solution of three algebraic equations for \(\tilde{C}_{\alpha\beta}(k_0)\) (see Equation (8) for \(k = k_0\)), because
\[ \tilde{C}_{\alpha\beta}(k) = \tilde{C}_{\alpha\beta}(k_0) + \beta \tilde{V}_{\alpha\beta}(k) - \tilde{V}_{\alpha\beta}(k_0). \]  
(16)

We cannot expect that \(G_{\alpha\beta}/(\zeta_\alpha \zeta_\beta) + 1\) will agree with the simulation results for \(g_{\alpha\beta}\), because in the above mesoscopic theory, the packing of hard spheres is not properly predicted. In order to separate this effect, we will calculate the concentration–concentration distribution function [41]
\[ g_{cc}(r) = x^2(1-x)^2 \left[ g_{11}(r) + g_{22}(r) - 2g_{12}(r) \right]. \]  
(17)

This function is expected to be determined mainly by the interaction between the particles, therefore it will be compared with the results of simulations.

### 3.2. Correlation functions in the considered model

For the model (1)–(2), the closed set of four equations for the unknowns \(k_0\) and \(\tilde{C}_{\alpha\beta}(k_0)\) takes the form
\[ \tilde{V}_{12}(k_0) = 0, \]  
(18)
\[ \tilde{C}_{11}(k_0) = A_{11} + \frac{k^2}{2\pi \sqrt{2\beta \tilde{W}''(k_0)D_0}} \times \left[ A_{1111} \tilde{C}_{22}(k_0) - 2A_{1112} \tilde{C}_{12}(k_0) \right. \]  
\[ \left. + A_{1122} \tilde{C}_{11}(k_0) \right], \]  
(19)
\[ \tilde{C}_{22}(k_0) = A_{22} + \frac{k^2}{2\pi \sqrt{2\beta \tilde{W}''(k_0)D_0}} \times \left[ A_{1122} \tilde{C}_{22}(k_0) - 2A_{1222} \tilde{C}_{12}(k_0) \right. \]  
\[ \left. + A_{2222} \tilde{C}_{11}(k_0) \right], \]  
(20)
\[ \tilde{C}_{12}(k_0) = \beta \tilde{V}_{12}(k_0) + A_{12} + \frac{k^2}{2\pi \sqrt{2\beta \tilde{W}''(k_0)D_0}} \times \left[ A_{1112} \tilde{C}_{22}(k_0) - 2A_{1122} \tilde{C}_{12}(k_0) \right. \]  
\[ \left. + A_{1222} \tilde{C}_{11}(k_0) \right], \]  
(21)
and we denote by \(V''\) the first (second)-order derivative of \(\tilde{V}_{12}(k)\) with respect to the wave number \(k\). Note that the minimum of \(\det \tilde{C}(k)\) corresponds to the maximum of \(\tilde{V}_{12}(k)\).

Once Equations (18)–(21) are solved, the correlation functions \(\tilde{C}_{\alpha\beta}(k)\) can be obtained from Equation (16). Finally, the interaction potential \(\tilde{V}_{12}(k)\) (an even function of \(k\)) is approximated as follows:
\[ \tilde{V}_{12}(k) \approx \tilde{V}_{12}(k_0) + \frac{V''(k_0)}{8k_0^2} (k^2 - k_0^2)^2. \]  
(23)

To calculate \(\tilde{G}_{\alpha\beta}(k)\) in the Brazovskii-type approximation, we solve Equations (19)–(21) with respect to \(\tilde{C}_{\alpha\beta}(k_0)\) and from \(G = C^{-1}\), we obtain
\[ \tilde{G}_{11}(k) = \frac{\tilde{C}_{22}(k_0)}{D(k)}, \quad \tilde{G}_{22}(k) = \frac{\tilde{C}_{11}(k_0)}{D(k)}, \]  
(24)
\[ \tilde{G}_{12}(k) = -\frac{\tilde{C}_{12}(k_0) + \beta \Delta \tilde{V}_{12}(k)}{D(k)}, \]  
(25)
where
\[ D(k) = \tilde{C}_{11}(k_0)\tilde{C}_{22}(k_0) - (\tilde{C}_{12}(k_0) + \beta \Delta \tilde{V}_{12}(k))^2, \]  
(26)
and \(\Delta \tilde{V}_{12}(k) = \tilde{V}_{12}(k) - \tilde{V}_{12}(k_0) \approx \frac{V''(k_0)}{8k_0^2} (k^2 - k_0^2)^2\) (see Equation (23)).

In MF, the correlation functions are given by Equations (24)–(26), but with \(\tilde{C}_{\alpha\alpha}(k)\) approximated by \(A_{\alpha\alpha}\), and \(\tilde{C}_{\alpha\beta}(k)\) approximated by \(A_{12} + \beta \tilde{V}_{12}(k)\). The correlation functions diverge for vanishing denominator in (24)–(25). From the MF equation \(D(k) = A_{11}A_{22} - (A_{12} + \beta \tilde{V}_{12}(k))^2 = 0\) one can get the expressions for both the gas–liquid spinodals and the \(\lambda\)-surfaces:
\[ T^*_{sp} = -\left( \frac{3}{4\pi} \right)^2 \left( 1 + \alpha^6 \right) \frac{\tilde{V}_{12}(0)}{\alpha^3 \sqrt{A_{11}A_{22} + A_{12}}}, \]  
(27)
\[ T^*_{\lambda} = \left( \frac{3}{4\pi} \right)^2 \left( 1 + \alpha^6 \right) \frac{\tilde{V}_{12}(k_0)}{\alpha^3 \sqrt{A_{11}A_{22} - A_{12}}}, \]  
(28)
where \(T^* = k_B T/\epsilon\), and
\[ \tilde{V}_{12}(k_0 = 0) = -\frac{4}{3} \pi (a^3 - 1), \]
\[ \tilde{V}_{12}(k_0 = 4.062, a = 1.2) \approx 0.644. \]  
(29)

### 3.3. Free energy for a mixture of hard spheres with unequal diameters

We present the free-energy density of the reference system as follows:
\[ f_0(\xi_1, \xi_2) = \xi_1 \ln \xi_1 + \xi_2 \ln \xi_2 + f_{ex}(\xi_1, \xi_2), \]  
(30)
where in the Carnahan–Starling approximation $f_{\text{ex}}(\zeta_1, \zeta_2)$ has the form [42]:

\[
f_{\text{ex}}(\zeta_1, \zeta_2) = \frac{6}{\pi} \left( \frac{1 + \alpha}{2\alpha} \right)^3 (\zeta_1 + \alpha^3 \zeta_2)
\times \left[ -1 - \frac{3}{2} (1 - y_1 + y_2 + y_3)
+ \frac{3y_2 + 2y_3}{1 - \zeta} + \frac{3}{2} (1 - y_1 - y_2 - y_3/3)
+ (y_3 - 1) \ln(1 - \zeta) \right],
\]

with

\[
y_1 = \Delta_{12} \frac{1 + \alpha}{\sqrt{\alpha}}, \quad y_2 = \Delta_{12} \frac{\zeta_1 + \alpha \zeta_2}{\sqrt{\alpha} \zeta},
\]

\[
y_3 = \frac{(\zeta_1 + \alpha \zeta_2)^3}{(\zeta_1 + \alpha^3 \zeta_2)^2},
\]

\[
\Delta_{12} = \frac{\zeta_1 \zeta_2 (\alpha - 1)^2 \sqrt{\alpha}}{(\zeta_1 + \alpha^3 \zeta_2)^2},
\]

and $\zeta = \zeta_1 + \zeta_2$ ($\zeta_\alpha = \pi \rho_0 \sigma_\alpha^3/6$). For $\alpha = 1$, $f_{\text{ex}}(\zeta_1, \zeta_2)$ reduces to the free energy density for a one-component case $f_{\text{ex}}(\zeta)$.

Using Equations (30) – (33), one can get explicit expressions for $A_{\alpha\beta}$ and $A_{\alpha\beta\nu\nu}$. For the fixed diameter ratio $\alpha$, they are functions of both the total packing fraction $\zeta$ and either the mole fraction $x = \rho_2/\rho$, or the fraction of the occupied volume $c = \zeta_2/\zeta$ of the bigger particles.

4. Results

4.1. Case $\alpha = 0.8$

4.1.1. Theoretical results

We start with the case of small size asymmetry $\alpha = 0.8$ ($\sigma_2 = 1.25 \sigma_1$). In Figure 2, we present the $T^* - \zeta$-plots of the MF boundaries of the stability of the disordered phase (see Equations (27)–(28)) for a set of fixed concentrations. In Figure 2, the curves with maxima are the gas–liquid spinodals, while the $\lambda$-lines are presented as straight lines. As one can see, the dependence of $T^*$ on the concentration at the fixed $\zeta$ is non-monotonic (for both types of instability). This is in contrast to the case of a size-symmetric mixture [34].

First, we calculate the MF correlation functions in Fourier representation above the $\lambda$-surface. The corresponding correlation functions $\tilde{\zeta}_{\alpha\beta}(k)$ are shown in Figure 3(a) for $T^* = 0.52$, $\zeta = 0.4$ and $c = 0.57$. The maximum (minimum) of $\tilde{\zeta}_{\alpha\beta}(k)$ corresponds to the maximum of the interaction potential $\tilde{V}_{12}(k)$ and it is located at $k = k_0$ (see Figure 1).

Now, we go beyond MF and calculate the correlation functions in Fourier representation, taking into account the effect of fluctuations. We fix the total volume fraction at $\zeta = 0.4$ and consider the temperatures above and below the $\lambda$-surface. In Figure 3(b), $\tilde{G}_{\alpha\beta}(k)$ are compared with the MF result for the same values of temperature, total volume fraction, and concentration. It is seen that the maxima (minimum) of the correlation functions for the temperature above the $\lambda$-surface become very flat when the fluctuations are taken into account and $k_0$ is not shifted in this case. In Figure 4, we present the results for $\tilde{G}_{\alpha\beta}(k)$ for the temperature $T^* = 0.1$, the total volume fraction $\zeta = 0.4$ and for two values of the bigger particle concentration: $c = 0.33$ (panel a) and $c = 0.57$ (panel b). These thermodynamic states are located below the $\lambda$-surface and beyond the MF gas–liquid spinodal (see the state denoted by the filled square in Figure 2). It should be noted that the correlation functions $\tilde{G}_{\alpha\beta}(k)$ at $k_0$ take their maximal (minimal) values for the concentration $c \approx 0.57$. For $c = 0.33$, $\tilde{G}_{11}(k)$ and $\tilde{G}_{22}(k)$ coincide; the maximum of $\tilde{G}_{11}(k)$ becomes larger (smaller) than the maximum of $G_{22}(k_0)$ for $c < 0.33$ ($c > 0.33$).

The correlation functions in real-space representation, obtained by the inverse Fourier transformation of $\tilde{G}_{\alpha\beta}(k)$, are shown in Figure 5 for $T^* = 0.1$, $\zeta = 0.4$ and $c = 0.57$. It is seen from Figure 5 that $G_{\alpha\beta}(r)$ show exponentially damped oscillatory behaviour with the period of damped oscillations $\lambda/\sigma_2 \simeq 1.54$ which is close to $2\pi/k_0 \simeq 1.547$. In addition, $G_{11}(r)$ and $G_{aa}(r)$ exhibit
Figure 3. (Colour online) Correlation functions \( \tilde{G}_{\alpha\beta}(k) \) for \( \alpha = 0.8 \) in MF approximation (panel a) and with the effect of fluctuations taken into account (panel b) for the thermodynamic state above the \( \lambda \)-surface: \( T^* = 0.52, \zeta = 0.4 \) and \( c = 0.57 \) (\( \chi = 0.4 \)). Upper solid lines: \( \tilde{G}_{11}(k) \), dashed lines: \( \tilde{G}_{22}(k) \), and lower solid lines: \( \tilde{G}_{12}(k) \).

Figure 4. (Colour online) Correlation functions in Fourier representation for \( \alpha = 0.8 \) with the effect of fluctuations taken into account. Upper solid lines: \( \tilde{G}_{11}(k) \), dashed lines: \( \tilde{G}_{22}(k) \) and lower solid lines: \( \tilde{G}_{12}(k) \). \( T^* = 0.1, \zeta = 0.4 \) and \( c = 0.33 \) (panel a), \( c = 0.57 \) (panel b).

their extrema at the same values of \( r \) and the maximum of \( G_{\alpha\alpha}(r) \) coincides with the minimum of \( G_{12}(r) \). In general, \( G_{\alpha\beta}(r) \) for \( r \gg 1 \) are described by the functions [15]

\[
G_{\alpha\beta}(r) = A_{\alpha\beta} e^{-\alpha_0 r} \sin(\alpha_1 r)/r. \tag{34}
\]

In (34), \( \alpha_0 \) and \( \alpha_1 \) are the imaginary and real parts of the leading order pole of \( \tilde{G}_{\alpha\beta}(k) \) which is determined as the complex root \( k = \alpha_1 \pm i\alpha_0 \) of the equation \( D(k) = 0 \) (see Equation (26)) having the smallest imaginary part. All the \( \tilde{G}_{\alpha\beta}(k) \) have the same pole structure and the same \( \alpha_1 \) and \( \alpha_0 \). For the above-mentioned thermodynamic state, we get \( \alpha_0 \sigma_{12} \simeq 0.49, \alpha_1 \sigma_{12} \simeq 4.1, A_{11} \simeq 0.038, A_{22} \simeq 0.0525 \) and \( A_{12} \simeq -0.045 \). It should be noted that the amplitudes \( A_{\alpha\beta} \) satisfy the rule

\[
A_{12}^2 = A_{11} A_{22}, \tag{35}
\]
derived from general considerations [43].

The decay length, \( \alpha_0^{-1} \), and the period of oscillations, \( \lambda = 2\pi/\alpha_1 \), are shown in Figure 6 as functions of the

Figure 5. (Colour online) Case \( \alpha = 0.8 \). Correlation functions in real space for \( T^* = 0.1, \zeta = 0.4 \) and \( c = 0.57 \) with the effect of fluctuations taken into account. \( G_{11}(r) \) (solid line), \( G_{22}(r) \) (dashed line) and \( G_{12}(r) \) (dash-dotted line). \( r \) is in \( \sigma_{12} \) units.
concentration \( c \) for the total volume fraction \( \zeta = 0.4 \) and for two values of temperature, \( T^* = 0.082 \) and 0.1.

As it is seen, both \( a_0^{-1} \) and \( \lambda \) exhibit a non-monotonic behaviour with the concentration: \( a_0^{-1} \) has a pronounced maximum for \( c \approx 0.57 \), whereas \( \lambda \) exhibits a wide, flat maximum region. The decay length increases noticeably when the temperature decreases, while the temperature dependence of \( \lambda \) is very weak. Similarly, \( a_0^{-1} \) varies quite rapidly on increasing (decreasing) the total volume fraction, whereas \( \lambda \) changes only very slightly (see Table 2).

### 4.1.2. Simulation results

The details of simulations of a binary mixture with \( \alpha = 0.8 \) are given in Table 1 (see System I).

In Figure 7, the pair distribution functions \( g_{\alpha\beta} = G_{\alpha\beta}/\sigma_{\alpha\beta} + 1 \) and a representative configuration are presented for \( T^* = 0.1 \), \( \zeta = 0.4 \) and \( c = 0.57 \). On the snapshot, darker colour is used to denote bigger particles and lighter colour is used for smaller particles. One can see that smaller and bigger particles are located next to each other.

For the pair distribution functions \( g_{\alpha\beta}(r) \), an oscillatory decay with the period of the damped oscillations \( \lambda \approx 1.1\sigma_1 \approx \sigma_{12} \) can be seen (Figure 7). Simultaneously, the minima of \( g_{12}(r) \) more or less coincide with the maxima of \( g_{\alpha\alpha}(r) \) only for large distances. This deviations from the theoretical predictions can be related to the effect of the hard sphere packing which becomes important for the large density.

In Figure 8, we present \( g_{\alpha\alpha}(r) \) obtained from the theory and from the simulations for \( T^* = 0.1 \), \( \zeta = 0.4 \) and \( c = 0.57 \). It is seen that the theoretical results are in good agreement with the simulation findings. The theory and simulations show oscillatory decay and the periods of damped oscillations which are close to each other. The maxima and minima of the oscillations occur for similar \( r \).

The theory summarised in Section 3a can be valid only for \( r \gg 1 \), i.e. it allows to study ordering on the mesoscopic length scale. It is interesting, however, to analyse the local ordering of the smaller particles in the attractive shell of the bigger one. The degree of order is not only described by the pair distribution function that tells about the average number of the particles at a given distance from the considered one, but also by the fluctuation of this number. This information can be inferred from simulations by determining the probability...
Figure 7. (Colour online) Pair distribution functions and a representative configuration of the model with $\alpha = 0.8$ for $T^* = 0.1$, total volume fraction $\zeta = 0.4$ and concentration $c = 0.57$. $r$ is in $\sigma_1$ units.

Figure 8. Concentration–concentration distribution function $g_{cc}(r)$ for $\alpha = 0.8$. Panel a: theoretical results and panel b: results of simulations. $T^* = 0.1$, $\zeta = 0.4$ and $c = 0.57$. $r$ is in $\sigma_1$ units.

distribution $P(N_1)$ of finding $N_1$ smaller particles at a distance $\sigma_{12} < r < 1.2\sigma_{12}$ from the centre of the bigger one (corresponding to the attractive shell).

The histograms $P(N_1)$ are presented in Figure 9. The results for $\alpha = 0.8$ (panel a) indicate that the bigger particle is most likely to have eight nearest neighbours. This implies that the periodic ordering resembling ionic crystal structure can occur on the mesoscopic length scale. However, fluctuations of $N_1$ in the attractive shell are quite large.

Figure 9. Histograms of the probability to find $N_1$ smaller particles at a distance $\sigma_{12} < r < 1.2\sigma_{12}$ from the centre of a bigger particle. Panel a: $\alpha = 0.8 \,(T^* = 0.1, \zeta = 0.4, c = 0.57)$, panel b: $\alpha = 0.6 \,(T^* = 0.1, \zeta = 0.5, c = 0.54)$ and panel c: $\alpha = 0.25 \,(T^* = 0.6, \zeta = 0.4, c = 0.67)$. 
4.2. Case $\alpha = 0.6$

4.2.1. Theoretical results

Now we consider the case of a moderate size-asymmetry, $\alpha = 0.6$ ($\sigma_2 \simeq 1.7\sigma_1$). For this mixture, the MF boundaries of stability for the fixed values of concentration are presented in Figure 10. As for $\alpha = 0.8$, the dependence of $T^*$ on the bigger particle concentration for fixed $\zeta$ is non-monotonic. Now, the $\lambda$-lines are no longer straight lines for lower values of concentration.

We focus on the region below the $\lambda$-surface and calculate the correlation functions in Fourier representation taking into account fluctuations (Equations (24)–(26) complemented by Equations (19)–(21) for $\tilde{C}_{\alpha\beta}(k_0)$). We consider the thermodynamic state denoted by the filled square in Figure 10. The results for $T^* = 0.1$, $\zeta = 0.5$ and for two values of concentration, $c = 0.34$ and $c = 0.54$, are presented in Figure 11. For $c > 0.1$, a maximum of $G_{22}(k)$ is higher than a maximum of $G_{11}(k)$. The opposite situation is observed for $c < 0.1$.

The correlation functions in real space for $T^* = 0.1$, $\zeta = 0.5$ and $c = 0.54$ are presented in Figure 12. As for $\alpha = 0.8$, $G_{\alpha\beta}(r)$ have the form (34) and show exponentially damped oscillatory decay with the period of damped oscillations $\lambda/\sigma_{12} \simeq 1.54$. A maximum of $G_{\alpha\alpha}(r)$ coincides with a minimum of $G_{12}(r)$. In the present case, however, the oscillations are more long-ranged. For the considered thermodynamic state,
Figure 13. The correlation length $1/\alpha_0$ (panel a) and the period of oscillations $\lambda = 2\pi/\alpha_1$ (panel b) of the correlation functions $G_{\alpha\beta}(r)$ for $\alpha = 0.6$ as functions of the concentration $c$ for two values of temperature: $T^* = 0.08$ (dashed line) and $T^* = 0.1$ (solid line). $\alpha_0$ and $\alpha_1$ are in units of $\sigma_{12}^{-1}$.

$\alpha_0 \sigma_{12} \simeq 0.19$, $\alpha_1 \sigma_{12} \simeq 4.1$, $A_{11} \simeq 0.075$, $A_{22} \simeq 0.13$, and $A_{12} \simeq -0.096$. As for $\alpha = 0.8$, the amplitudes satisfy Equation (35).

In Figure 13, the decay length $\alpha_0^{-1}$ and the period of damped oscillations $\lambda$ are presented as functions of the concentration $c$ for fixed total volume fraction ($\zeta = 0.5$) and for two values of the temperature: $T^* = 0.08$ and $T^* = 0.1$. In general, the dependence of both quantities on $c$ is similar to the behaviour observed for $\alpha = 0.8$. However, for $\alpha = 0.6$ the decay length is larger than in the case $\alpha = 0.8$ (for comparison, see also Table 2 where the results are shown for $\zeta = 0.4$ and 0.5).

4.2.2. Simulation results

The details of simulations for a binary mixture with $\alpha = 0.6$ are given in Table 1 (see System II).

The pair distribution functions $g_{\alpha\beta}(r)$ and a representative configuration are presented in Figure 14 for $T^* = 0.1$, $\zeta = 0.5$ and $c = 0.54$. One can see an oscillatory decay of $g_{\alpha\beta}(r)$ with the period of damped oscillations $\lambda \approx 2\sigma_1$ that agrees with the theoretical results (see Figure 12 noting that $\sigma_{12} \simeq 1.3\sigma_1$). The amplitude of $g_{22}(r)$ is noticeably larger than the amplitude of $g_{11}(r)$, that agrees with theoretical results for $G_{\alpha\beta}(r)$, the minimum of $g_{\alpha\alpha}(r)$ coincides with the maximum of $g_{12}(r)$, and vice versa.

One can see on the snapshot that the bigger particles are surrounded by the smaller particles, and stay apart from one another, except from very few cases. The distribution of the small particles within the attractive shell around the bigger particle is shown in Figure 9(b). The most probable number of smaller particles in the attractive shell of the big one is $N_1 = 15$, but as in the case of $\alpha = 0.8$, the fluctuations of $N_1$ are large.

The concentration–concentration distribution function obtained from our theory and by MC simulations for $T^* = 0.1$, $\zeta = 0.5$ and $c = 0.54$ is shown in Figure 15.

Figure 14. (Colour online) Pair distribution functions and a representative configuration of the model with $\alpha = 0.6$ for $T^* = 0.1$, total volume fractions $\zeta = 0.5$ and concentration $c = 0.54$. $r$ is in $\sigma_1$ units.
We can see that the theoretical and simulation results are in reasonable agreement: in both cases, the distribution function $g_{cc}(r)$ shows oscillatory decay with the same period of damped oscillations: $\lambda \approx 2\sigma_1 = 1.5\sigma_{12}$. The amplitudes are in semi-quantitative agreement, but the correlation length obtained in the theory is larger.

4.3. Case $\alpha = 0.25$

4.3.1. Theoretical results

Finally, we focus on a large size asymmetry of the particles of different species, namely, we consider a binary mixture with $\alpha = 0.25$ ($\sigma_2 = 4\sigma_1$). In this case, the MF boundaries of stability for the fixed values of concentration have the form presented in Figure 16. As for a smaller size asymmetry, the dependence of $T^*$ on the concentration at the fixed $\xi$ is non-monotonic. In addition, the form of the $\lambda$-lines changes significantly: starting from a certain value of $\xi$, they become almost parallel to the $y$-axis.

We calculate the correlation functions in Fourier representation for $T^* = 0.6, \xi = 0.4$ and for two values of the concentration of the big particles: $c = 0.49$ and $c = 0.67$ (the corresponding thermodynamic state is denoted by the filled square in Figure 16). The results are presented in Figure 17. For $c = 0.67$, the dependencies of $\tilde{G}_{\alpha\beta}(k)$ on $k$ show narrow peaks at $k = k_0$ (Figure 17(b)) which widen already for $c = 0.62$ and simultaneously the heights of the peaks reduce. For $c = 0.49$, the extrema of $\tilde{G}_{\alpha\beta}(k)$ become flat (Figure 17(a)). It should be noted that for the considered thermodynamic states, Equations (18) – (21) have no solutions for $c \geq 0.7$.

In Figure 18, the correlation functions in real space representation are presented for $T^* = 0.6, \xi = 0.4$ and $c = 0.67$. As for a smaller size asymmetry, the correlation functions $G_{\alpha\beta}(r)$ have the form (34) and show exponentially damped oscillatory decay with the period of damped oscillations $\lambda \approx 1.55\sigma_{12}$. For $T^* = 0.6, \xi = 0.4$ and $c = 0.67$, we have $\alpha_0\sigma_{12} \simeq 0.11, \alpha_1\sigma_{12} \simeq 4.1$. The amplitudes obey the rule Equation (35) and their values are as follows: $A_{11} \simeq 0.12, A_{22} \simeq 0.85$ and $A_{12} \simeq 0.32$.

In Figure 19, the decay length $\alpha_0^{-1}$ and the period of damped oscillations $\lambda$ are presented as functions of the concentration $c$ for the fixed total volume fraction ($\xi = 0.4$) and for two values of the temperature: $T^* = 0.4$ and $T^* = 0.6$. In contrast to the cases of a smaller size asymmetry, the decay length first increases very slowly.
Figure 17. (Colour online) Correlation functions $\tilde{G}_{\alpha\beta}(k)$ for $\alpha = 0.25$ with the effect of fluctuations taken into account. Upper solid lines: $\tilde{G}_{11}(k)$, dashed lines: $G_{22}(k)$ and lower solid lines: $G_{12}(k)$. $T^* = 0.6$, $\zeta = 0.4$ and $c = 0.49$ (panel a), $c = 0.67$ (panel b).

Figure 18. (Colour online) Case $\alpha = 0.25$. Correlation functions in real space with the effect of fluctuations taken into account for $T^* = 0.6$, $\zeta = 0.4$ and $c = 0.67$: $\tilde{G}_{11}(k_0)$ (solid line), $G_{22}(k_0)$ (dashed line) and $G_{12}(k_0)$ (dash-dotted line). $r$ is in $\sigma_{12}$ units.

Figure 19. The decay length $\alpha_0^{-1}$ (panel a) and the period of oscillations $\lambda = 2\pi/\alpha_1$ (panel b) of the correlation functions $G_{\alpha\beta}(r)$ for $\alpha = 0.25$ as functions of the concentration for two values of temperature: $T^* = 0.4$ (dashed curve) and $T^* = 0.6$ (solid curve). $\alpha_0$ and $\alpha_1$ are in units of $\sigma_{12}^{-1}$.
On the other hand, the short-distance structure cannot be determined by our mesoscopic theory, and this complementary information about local ordering can be obtained by our simulation procedure.

In Figure 20, a representative configuration is shown. As it is seen from the snapshot, the big particles are surrounded by the small particles, and have a strong tendency to the periodic ordering. This is also supported by the histogram in Figure 9(c). As one can see, \( P(N_1) \) is quite narrow in contrast to the previously considered cases. The ratio between the standard deviation and the average number of the ‘adsorbed’ particles is quite small, and can be estimated as \( \sim 5\% \). The theoretical results show quite large correlation length for the considered thermodynamic state. We conclude that the periodic ordering on the length scale of \( \sigma_2 \), and the ordering near the surface of the big particles (meaning large number of the small particles in the attractive shell and small fluctuations of this number) go together.

5. Summary and conclusions

We have studied binary mixtures with effective interactions between the particles that favour nearest neighbours of different kind. At low temperature, such interactions lead to a periodic structure with alternating particles of the first and the second component. At higher \( T \) the crystal melts, but a competition between the ordering effect of energy and disordering effect of entropy leads to local periodic order. Our aim was determination of the effect of size asymmetry of the particles of the two species on this local order.

We have calculated correlation functions for small, medium and large size asymmetry within the mesoscopic DFT developed in Ref. [33, 34], at the lowest non-trivial order beyond MF. In our model, three length scales determine the structure in the liquid phase — one associated with the attraction between different particles, and the other two equal to the diameters of the hard cores of the particles. The wavelength of the periodic order induced by the attraction is a bit larger than the sum of the diameters of the two particles. The decay length of this periodic order is the largest, and it determines the asymptotic decay of correlations. In order to disentangle the effect of the hard-spheres packing from the ordering effect of interactions on the intermediate length scale, we calculated the correlation function for the concentration. Our results were favourably compared with the MC simulations on a semi-quantitative level. In addition, the simulations allowed us to determine the distribution of the small particles in the attractive shell of the bigger ones.

We have found that for all considered size ratios \( \alpha \) the correlation functions show exponentially damped oscillations, with the maxima of the correlation function for like species that coincide with the minima of the correlation function for different species. The range and amplitude of the correlations increase with decreasing \( T \) and/or increasing total volume fraction of the particles. In each considered system, the period \( 2\pi/\alpha_1 \) of the damped oscillations is almost independent of their relative volume fraction of the large particles, \( c = \xi_2/\xi \), as long as the correlation length is larger than 1 (in \( \sigma_2 \) units). Moreover, \( \alpha_1 \) is very close to the wave-number corresponding to the first maximum of the interaction between different species in Fourier representation. Only for the correlation length \( 1/\alpha_0 < 1 \), i.e. too small for formation of the periodic structure on the mesoscopic length scale, the period of the damped oscillations decreases. Another common feature of all the considered cases is the fact that the correlations between the bigger particles are the strongest for a large interval of their relative volume fraction \( c \). Only for \( c \) smaller than a value depending on \( \alpha \), the correlations between the smaller particles are larger. This value of \( c \), however, decreases rapidly with decreasing \( \alpha \) (increasing size ratio).

In addition to the above similarities, there are significant differences between the properties of the systems with different size ratio \( \alpha \). First of all, correlations increase significantly with increasing size ratio, and are much stronger in the case of \( \alpha = 0.25 \) than for \( \alpha \geq 0.6 \). The amplitude and range of correlations in the case of large size-asymmetry are significantly larger even at \( T \) much higher than in the system with moderate size

Figure 20. (Colour online) A representative configuration of the model with \( \alpha = 0.25 \) for \( T^* = 0.6 \), total volume fraction \( \xi = 0.4 \) and concentration \( c = 0.67 \).
ratio. The dependence of the local order on \( c \) in the system with large size-ratio is qualitatively different than in the systems with moderate or small size asymmetry. In the latter two cases, the correlation length takes a pronounced maximum for comparable volume fractions of the two species. With increasing size asymmetry, the maximum of the correlation length moves to a larger volume fraction of the bigger particles. The difference between the amplitudes of the correlation function between the big particles and the remaining correlation functions increases with increasing size asymmetry too. For \( \alpha = 0.25 \), however, the correlation length is very small for small \( c \), and increases very slowly with \( c \) for \( c < 0.5 \). For \( c > 0.5 \) a rapid increase to large numbers occurs, and both \( 1/\alpha_0 \) and \( 2\pi/\alpha_1 \) are monotonic functions of \( c \), in contrast to the previous two cases. Moreover, the magnitude of the correlations between the big particles becomes much larger than the magnitude of the correlations between the big particles and the remaining correlation. The difference between the amplitudes of the correlation function between the big particles and the remaining correlation functions increases with increasing size asymmetry too. For \( \alpha = 0.25 \), however, the correlation length is very small for small \( c \), and increases very slowly with \( c \) for \( c < 0.5 \). For \( c > 0.5 \) a rapid increase to large numbers occurs, and both \( 1/\alpha_0 \) and \( 2\pi/\alpha_1 \) are monotonic functions of \( c \), in contrast to the previous two cases. Moreover, the magnitude of the correlations between the big particles becomes much larger than the magnitude of the remaining correlations for all values of \( c \) corresponding to \( 1/\alpha_0 > 1 \).

The stronger ordering on the mesoscopic length scale is accompanied by stronger ordering in the attractive shell of the big particles. For \( \alpha = 0.8 \) and \( \alpha = 0.6 \), the average number of the smaller particles located in the attractive shell of the big particle is 8 and 15, respectively. This number, however, fluctuates strongly, and in the considered thermodynamic state, the ratio between the standard deviation and the average number of particles can be estimated as \( \sim 25\% \) and \( \sim 20\% \), respectively. On the other hand, for \( \alpha = 0.25 \) and the considered thermodynamic state, the average number of the small particles inside the attractive shell of the big one is 37.5, and the ratio between the standard deviation and the average number of particles can be estimated as \( \sim 5\% \). Notably, the temperature in this case is much higher than in the above two cases.

Our results show that for all considered cases, the bigger particles are distributed much more uniformly than in the random distribution. Even though the long-range order is lacking, the distance between the nearest neighbours of the same kind is approximately the same, and the big particles are separated by the small ones (see Figure 20). In some way, our models resemble hyperuniform systems [45, 46]. Our results suggest that the larger is the size ratio, the more uniformly are distributed the larger particles.

We focused on the ordering effect of interactions, and its dependence on the concentration fluctuations in mesoscopic regions. The wavelength of the periodic order, however, is of the same order of magnitude as the size of the particles. In future studies, it would be interesting to develop a theory combining the DFT correctly predicting the hard-sphere packing [8] but neglecting the effects of fluctuations, with our theory that takes into account the effect of fluctuations, but neglects the packing of hard spheres.
