(January 20, 1997)

How well one can copy an arbitrary qubit? To answer this question we consider two arbitrary vectors in a two-dimensional state space and an abstract copying transformation which will copy these two vectors. If the vectors are orthogonal, then perfect copies can be made. If they are not, then errors will be introduced. The size of the error depends on the inner product of the two original vectors. We derive a lower bound for the amount of noise induced by quantum copying. We examine both copying transformations which produce one copy and transformations which produce many, and show that the quality of each copy decreases as the number of copies increases.

I. INTRODUCTION

One of the greatest differences between classical and quantum information is that while classical information can be copied perfectly, quantum cannot. In particular, we cannot create a duplicate of an arbitrary quantum bit (qubit)\footnote{In what follows we will use a shorthand “copying machine” for a particular unitary transformation applied to the original particle. We do this having in mind that copying unitary transformations under consideration can be realized in terms of a sequence of logical gates.} without destroying the original. This follows from the no-cloning theorem of Wootters and Zurek\textsuperscript{2} (see also [3,4]). There are many consequences of this theorem. For example, if one has a string of qubits which one would like to process in more than one way, it represents a serious limitation. With a string of classical bits, one could simply copy the string and process the original one way and the copy another. Quantum mechanically this is impossible. On the other hand, the fact that information cannot be copied is sometimes an advantage. One can view the impossibility of quantum copying as one of the main reasons why quantum cryptography works.

In a quantum cryptographic system\textsuperscript{2} qubits are exchanged between a sender (Alice) and a receiver (Bob) in such a way that the presence of an eavesdropper (Eve) can be detected. If quantum copying were possible the eavesdropper could simply copy the qubits which Alice is sending to Bob, and they would not be able to detect this procedure. This would leave the eavesdropper with a perfect record of their communication. The fact that quantum information cannot be copied rules out this possibility.

Even though one cannot copy quantum information perfectly, it is useful to know how well one can do. One would like to know to what extent it is possible to split the information in a given qubit among several others. In addition, if it is possible to make close to perfect copies quantum cryptographic schemes could still be at risk\textsuperscript{2}. Finally, quantum copying can become essential in storage and retrieval of information in quantum computers\textsuperscript{2}.

In our previous paper we examined several possible quantum copying machines\textsuperscript{1} and studied how they would perform copying a single arbitrary qubit\footnote{In what follows we will use a shorthand “copying machine” for a particular unitary transformation applied to the original particle. We do this having in mind that copying unitary transformations under consideration can be realized in terms of a sequence of logical gates.}. The copier proposed in Wootters and Zurek’s paper\textsuperscript{2} on quantum cloning copies two orthogonal states perfectly but introduces errors when superpositions of these states are copied. A second copying machine, which we called the universal quantum copying machine, copies all input states to the same accuracy, and, on average, its performance is much better than that of the Wootters-Zurek machine. Here we would like to establish some fundamental limits on how well quantum states can be copied by considering the following problem. Suppose we have two arbitrary vectors in a two-dimensional state space and we want to build a machine which will copy these two vectors. How well we can do? If the vectors are orthogonal, then perfect copies can be made. If they are not, then, as we shall show, errors will be introduced. The amount of error depends on the inner product of the two original vectors. This problem is relevant to the global problem of copying an arbitrary qubit. If one has a lower bound for the amount of noise which must be introduced for the two-state problem, then the best one can do in the general case is the maximum of this lower bound over all pairs of states. Thus we can get a lower bound for the amount of noise induced by a quantum copying machine.

The approach which we use here has the advantage that it allows us to consider more general problems than
simply producing a single copy of an arbitrary qubit. We are able to find a lower bound for the noise which is introduced when \( n \) copies of a qubit are produced simultaneously, and determine how the noise depends on \( n \). In addition, even though our discussion is phrased in terms of qubits, which are two-level systems, our results are more general; the limitations we find on quantum copying apply to systems of arbitrary dimension, because our arguments are completely independent of the dimension of the Hilbert space in which the vectors to be copied lie. Therefore, if one is trying to copy an \( n \)-level system, for example several qubits in an entangled state, then the amount of noise introduced by the copying process must be greater than the lower bounds which are given here.

II. TWO-STATE PROBLEM

Suppose we have two states \( |s_1⟩_a \) and \( |s_2⟩_a \), in a two-dimensional state space which we would like to copy. If the initial state of the copy machine is \( |Q⟩_x \), then the action of the copying machine on our two vectors can be expressed as

\[
|s_j⟩_a ⟨Q⟩_x \rightarrow |Ψ_j⟩_{abx} = |s_j⟩_a ⟨s_j⟩_b ⟨Q⟩_x + |Φ_j⟩_{abx},
\]

where \( j = 1, 2 \). In our analysis we do not specify the \( in \)-state of the copy mode (this possible eavesdropper’s mode we denote as the \( b \)-mode). We only require that it is the same for all inputs into the \( a \) mode, and that it is normalized to unity. In Eq. (1) we have expressed the full output state of the copy machine as the sum of two parts, the first representing the ideal output state and the second what is left over. The two parts can be expressed in terms of the projection onto the two mode state \( |s_j⟩_a |s_j⟩_b \) as

\[
|Γ_j⟩_{abx} ≡ |s_j⟩_a ⟨s_j⟩_b ⟨Q⟩_x = P_j |Ψ_j⟩_{abx};
\]

\[
|Φ⟩_{abx} ≡ (I − P_j) |Ψ⟩_{abx},
\]

where the projectors \( P_j \) are defined as

\[
P_j = (|s_j⟩⟨s_j|)_a ⊗ (|s_j⟩⟨s_j|)_b.
\]

This definition implies that

\[
|abx⟩⟨Γ_j|_{abx} = 0; \quad j = 1, 2.
\]

In addition we also assume that the initial quantum-copying machine state is normalized to unity, i.e. \( ⟨Q|Q⟩_x = 1 \). In order to produce good copies we want to make the norms \( ||Q_1|| \) and \( ||Q_2|| \) as large as possible and \( ||Φ_1|| \) and \( ||Φ_2|| \), which represent the size of the errors, as small as possible. The norm of the state vector \( |A⟩ \) is defined as \( ||A|| = ⟨A|A⟩^{1/2} \).

The copying machine can be represented as a unitary operator and this unitarity impose constraints on the transformations shown in Eq. (1). In particular, we have that

\[
1 = ||Q_j||^2 + ||Φ_j||^2, \quad j = 1, 2
\]

and

\[
z = z^2 x ⟨Q_1|Q_2⟩_x + abx ⟨Γ_1|Φ_2⟩_{abx} + abx ⟨Φ_1|Γ_2⟩_{abx} + abx ⟨Φ_1|Φ_2⟩_{abx},
\]

where \( z = a ⟨s_1|s_2⟩_a \). We note that in derivation of Eq. (2) we have utilized the fact that the \( in \)-state of the copy mode is normalized to unity. From these equations it is possible to derive a number of inequalities which restrict the behaviour of the copy machine. We shall begin with the strongest restriction, which is relatively difficult to work with, and then we proceed to weaker ones which are more transparent.

Let us first find an upper bound on \( |abx⟩⟨Γ_1|Φ_2⟩_{abx} \) and \( |abx⟩⟨Γ_1|Γ_2⟩_{abx} \). We begin by expressing \( ⟨Γ_1⟩_{abx} \) as

\[
⟨Γ_1⟩_{abx} = P_2|Γ_1⟩_{abx} + |Γ_1⟩_{abx},
\]

where \( |Γ_1⟩_{abx} = (I − P_1)|Γ_1⟩_{abx}. \) The two states on the right hand side of Eq. (3) are orthogonal which implies that

\[
η_{11} = η_{11} |z|^4 + ||Γ_1||^2,
\]

where \( η_{ij} = ⟨Q_i|Q_j⟩_x \), so that

\[
||Γ_1'||^2 = [η_{11}(1 − |z|^4)]^{1/2},
\]

Similarly, if we express \( |Γ_2⟩_{abx} \) as

\[
|Γ_2⟩_{abx} = P_2|Γ_2⟩_{abx} + |Γ_2⟩_{abx},
\]

where \( |Γ_2⟩_{abx} = (I − P_1)|Γ_2⟩_{abx}, \) we find

\[
||Γ_2'||^2 = [η_{22}(1 − |z|^4)]^{1/2}.
\]

Because \( P_2|Φ_2⟩_{abx} = 0 \) we have that

\[
|abx⟩⟨Φ_2|Γ_1⟩_{abx} = |abx⟩⟨Φ_2|Γ_1⟩_{abx} ≤ ||Γ_1'|| ||Φ_2|| = (1 − η_{22})^{1/2} [η_{11}(1 − |z|^4)]^{1/2}
\]

and similarly

\[
|abx⟩⟨Φ_1|Γ_2⟩_{abx} ≤ (1 − η_{11})^{1/2} [η_{22}(1 − |z|^4)]^{1/2}.
\]

We can now take these results and insert them into Eq. (2). This gives us

\[
|z| ≤ |z|^2 [η_{12} + (1 − η_{11})^{1/2} (1 − η_{22})^{1/2} + (1 − |z|^4)^{1/2} [η_{11}(1 − η_{22})^{1/2} + η_{22}(1 − η_{11})^{1/2}]]^{1/2}.
\]

For a given value of \( |z| \) this inequality restricts the values of \( ||Q_1||, ||Q_2||, \) and \( η_{12} = ⟨Q_2|Q_1⟩ \). It defines a region in a 3-dimensional parametric space in which the values of the parameters can lie. For \( |z| ≠ 0 \) this region does
not include the line $|Q_1| = |Q_2| = 1$ which implies that perfect copying is impossible. It is only for $|z| = 0$, i.e., $|s_1\rangle$ and $|s_2\rangle$ are mutually orthogonal, that we can have $|Q_1| = |Q_2| = 1$ which implies error-free copying.

In order to simplify these results we use the Schwarz inequality from which it follows that

$$|\eta_2| \leq ||Q_1|| \cdot ||Q_2|| = (\eta_1 \eta_2)^{1/2}. \quad (16)$$

This last inequality allows us to rewrite the right-hand side of the relation $\Phi_j$ in terms of only two parameters, $\eta_1$ and $\eta_2$. It is useful to express the resulting inequality in terms of the size of the errors. We introduce the quantities $X_j = (1 - \eta_j)^{1/2} = ||\Phi_j||$ (for $j = 1, 2$) which are associated with the amount of noise induced by copying the vectors $|s_j\rangle_a$. In particular, the smaller $X_1$ and $X_2$ are the better is the copying procedure, and in the limit $X_j \to 0$ two perfect copies $|s_j\rangle_a$ and $|s_j\rangle_b$ of the initial state $|s_j\rangle_a$ are obtained at the output of the copying machine. If we now express the inequality which follows from Eqs. (15) and (16) in terms of $X_1$ and $X_2$ we have

$$|z| \leq |z|^2 (1 - X_1)^{1/2} / 2 + X_1 X_2 \quad (17)$$

It is easiest to understand the implications of Eq. (17) if we look at particular cases.

(A) Let us first suppose that $X_1 = ||\Phi_1|| = 0$, i.e., $|s_1\rangle$ is copied perfectly, which implies that $||Q_1|| = 1$. From Eq. (17) we find

$$|z| \leq |z|^2 (1 - X_1^2)^{1/2} + (1 - |z|^4)^{1/2} \quad (18)$$

which in turn implies that

$$X_2 \geq |z| \left[ (1 - |z|^2)^{1/2} / \left( 1 + |z|^2 \right) \right]^{1/2} \quad (19)$$

Therefore, if $|s_1\rangle$ is copied perfectly, then $||\Phi_2||$, which represents the size of the error made in copying $|s_2\rangle$, must be at least as large as the right-hand side of Eq. (19). For small $|z|$ the right-hand side of this inequality is approximately $|z|$. We note that the maximum value of the lower bound on the error $X_2$ given by the right-hand side of Eq. (19) is equal to $(2/27)^{1/2} \approx 0.272$ and is obtained for $|z| = 1/\sqrt{3} \approx 0.577$.

(B) Let us now consider the case $X_1 = X_2 = X$, i.e., equal errors in both copies. Making use of Eq. (17) we then have that

$$|z| \leq |z|^2 (1 - X^2) + X^2 \left[ (1 - |z|^4) / (1 - X^2) \right]^{1/2} \quad (20)$$

which implies that

$$X \geq \left[ \frac{r_1 - 2r_2^{1/2}}{r_3} \right]^{1/2} \quad (21)$$

$$r_1 = 2 + 3z^2 + 2z^4 + |z|^3; \quad r_2 = 1 + 3z^2 + 3z^4 + 3|z|^3 + 3|z|^5 + |z|^6; \quad r_3 = 5 + 5z + 3z^2 + 3z^3. \quad (22)$$

For $|z|$ small the right-hand side is approximately $|z|^2/2$. If both vectors are copied equally well, then there is a minimum value to the copying error. The right-hand side of Eq. (21) takes its maximum value approximately equal to 0.129 when $z \approx 0.553$.

III. GENERAL BOUND

Taking into account, that

$$0 \leq X_1^2 \leq 1; \quad 0 \leq |z|^2 \leq 1 \quad (23)$$

we can simplify the inequality in Eq. (17), i.e.,

$$|z| \leq |z|^2 + X_1 + X_2 + X_1 X_2 \quad (24)$$

This allows us to go beyond specific cases and to derive a general result.

We shall adopt the quantity $X_1 + X_2$ as a measure of the total error made in copying the two states $|s_1\rangle$ and $|s_2\rangle$. The copies are perfect if $X_1 + X_2 = 0$ and become progressively worse as its value increase. Solving Eq. (24) for $X_2$ we find

$$X_2 \geq \frac{|z|(1 - |z|) - X_1}{1 + X_1} \quad (25)$$

which implies that

$$X_1 + X_2 \geq \frac{|z|(1 - |z|) + X_1^2}{1 + X_1} \quad (26)$$

Minimizing the right-hand side with respect to $X_1$ we find that

$$X_1 + X_2 \geq 2 \left[ 1 + |z|(1 - |z|)^{1/2} - 1 \right] \quad (27)$$

A general quantum copying machine will have to copy pairs of vectors with all values of $|z|$. In particular, it will have to copy two vectors for which $|z| = 1/2$, a value which maximizes the right-hand side of Eq. (27). For such a pair of vectors we have

$$X_1 + X_2 \geq \sqrt{5} - 2 \quad (28)$$

This to be true, it must be the case that either $X_1 \geq (\sqrt{5} - 2)/2$ or $X_2 \geq (\sqrt{5} - 2)/2$. This means, that for a general quantum copying machine one has to expect that for at least one vector the size of the copying error is $(\sqrt{5} - 2)/2 \approx 0.118$.

These considerations are closely related to recent work by Fuchs and Peres [10]. They considered the tradeoff between disturbance and information acquisition in quantum cryptography. Alice sends a qubit to Bob, but in between, it is intercepted by Eve. She allows it to interact with another qubit and sends the original on to Bob.
Eve wants to disturb the qubit she sends to Bob as little as possible yet have the qubit she keeps contain as much information about the qubit Alice sent as possible. Fuchs and Peres found a relation between the discrepancy rate for Bob (disturbance) and the mutual information (Eve’s information gain). In our case we consider an interaction which produces copies. That is Eve puts into the copy machine her qubit and Alice’s qubit and what emerges are, she hopes, two reasonably good copies of Alice’s original qubit. The assumption is then that if the copies are good the disturbance will be small and the information gain large.

IV. MULTIPLE COPIES

Suppose that instead of making only two copies of $|s_1\rangle$ and $|s_2\rangle$ we want to construct a device which will produce $(n+1)$ copies (n actual copies plus the original). We would like to find out what the limitations on the quality of the copies are. Let us assume the copying transformation to be

\[
|s_j\rangle_a|Q\rangle_x \rightarrow |s_j\rangle_a|s_j\rangle_{b_1}...|s_j\rangle_{b_n}|Q\rangle_x
+|\Phi_j\rangle_{a b_1...b_n}; \quad j = 1, 2.
\]

(29)

As before we let

\[
|\Gamma_j\rangle_{a b_1...b_n} = |s_j\rangle_a|s_j\rangle_{b_1}...|s_j\rangle_{b_n}|Q\rangle_x,
\]

(30)

and assume that $|\Gamma_j\rangle|\Phi_j\rangle = 0$ (j = 1, 2) [in what follows we will omit state vectors subscripts indicating the modes under consideration, instead of $|\Gamma_j\rangle_{a b_1...b_n}$ we will write $|\Gamma_j\rangle$.] What we might expect is that the more copies we want to construct a device which will produce copies as many times as we wish. The case $|z\rangle = 0$ is essentially trivial, because here the two states $|s_1\rangle$ and $|s_2\rangle$ are up to a phase factor equal, so we are dealing with only one state. What we also see from the figure is that for a given value of $|z\rangle$ the bound $X_{\text{min}}$ increases as a function of $n$, that is

\[
\frac{\partial X_{\text{min}}}{\partial n} \bigg|_{|z\rangle=\text{const}} \geq 0.
\]

(34)

This relation represents the tradeoff between the number of copies and the noise induced by the copying procedure, i.e. the larger the number of copies the larger the noise. Fig. ?? also reveals a striking asymmetry with respect to the point $|z\rangle = 1/2$ of $X_{\text{min}}$ as a function of $|z\rangle$. We see that the maximum value of the function $X(|z\rangle)$ shifts towards $|z\rangle = 1$ as $n$ increases.

![FIG. 1. We plot the right-hand side of Eq.(32) as a function of $|z\rangle$ for various values of $n$ ($n = 1, 2, 3, 5, 10$ and 100).](image)

Simultaneously the maximum value increases as well and in the limit of large $n$ is approximately equal 0.41. It is also interesting to note, that for $|z\rangle$ small (when the states $|s_1\rangle$ and $|s_2\rangle$ are almost orthogonal) then

\[
X_{\text{min}}(|z\rangle) \simeq \epsilon/2,
\]

(35)

where we put $|z\rangle = \epsilon$ ($\epsilon \ll 1$). The relation (35) represents the fact that the noise induced by copying of states which are almost orthogonal does not depend on the number of copies produced. On the contrary, if we assume that $|z\rangle = 1 - \epsilon$ (i.e. copying of states which are almost equal), then

\[
X_{\text{min}}(|z\rangle) \simeq n\epsilon/2,
\]

(36)

which means that in the multiple-copy production of almost identical states the error increases linearly as a function of the number of copies.
Let us briefly see what happens when $X_1 = 0$, i.e., $|s_1\rangle$ is duplicated perfectly. In the limit $n \rightarrow \infty$ with $|z| < 1$ we find that $X_2 \geq |z|$, but if $|z| = 1$, then the lower bound for $X_2$ is zero for all $n$. For $n$ large but finite, the lower bound is approximately equal to $|z|$ except for a region near $|z| = 1$ where it drops sharply to zero.

Finally, let us examine the $(n+1)$-copy version of Eq. (30). We find

$$|z| \leq |z|^{n+1} + X_1 + X_2 + X_1X_2,$$

which implies that

$$X_1 + X_2 \geq 2 \left\{ |1 + |z| - |z|^{n+1} \right\}^{1/2} - 1 \right\}.$$

The right-hand side achieves its maximum value, which is

$$2 \left\{ \left[ 1 + \left( \frac{1}{n+1} \right)^{1/n} \left( \frac{n}{n+1} \right) \right]^{1/2} - 1 \right\},$$

when $|z| = (n+1)^{-1/n}$. This is an increasing function of $n$ and for large $n$ it goes to the value $2(\sqrt{2} - 1) \approx 0.83$. This is greater than one input state for which $X_1 \geq (\sqrt{2} - 1) \approx 0.41$.

Thus we see that for a quantum copy machine which only copies two vectors or for one which copies arbitrary input states, the lower bound for the error in the copies increases with the number of copies made. There is clearly a tradeoff in number of copies made versus the quality of each copy.

**V. CONCLUSION**

The unitarity of quantum mechanical transformations has allowed us to place limits on how well quantum states can be copied. We do not know if these limits can be realized. For example, the two quantum copy machines which were studied in our previous paper, which we called the Wootters-Zurek machine and the universal quantum copy machine, introduce more than the minimum amount of noise into the copies they make. Finding a quantum copying transformation which comes closest to achieving the noise limits which were derived here is an open problem. Another problem, which we have not addressed in the present paper is how much information is actually transferred to the output (copy/copies and original) states. We hope to address this problem in a future publication.

Our results can also be used to find noise limits in more general kinds of quantum copying problems. When assessing the performance of a quantum copy machine one needs to know not only which states are to be copied, but how often it will be necessary to copy each one. For example, in the case where the states $|s_1\rangle$ and $|s_2\rangle$ are to be copied, if we need to copy $|s_1\rangle$ more often than $|s_2\rangle$, it would be better to use a copy machine which is less noisy for $|s_1\rangle$ than for $|s_2\rangle$. This would result in less noise in the output, on average, than if one were to use a copy machine which copies both states equally well. The bounds presented in the preceding sections can be used to place lower limits on the average amount of noise in the output for this kind of situation.

Finally, the analysis here reveals that the feature of qubits which makes it impossible to copy them, in general, is the fact that different qubits need not be orthogonal. Classical information consists of bits, each of which is in one of two completely distinguishable, and therefore orthogonal, states. Classical information can be copied. Quantum information consists of qubits each of which can be in any superposition of the two basis states. This implies that two different qubits can have a nonzero inner product and are, consequently, not completely distinguishable. It is this basic difference between quantum and classical information which is responsible for their different copying properties.
