(Dated: March 31, 2022)

The generation of an entangled coherent state is one of the most important ingredients of quantum information processing using coherent states. Recently, numerous schemes to achieve this task have been proposed. In order to generate travelling-wave entangled coherent states, cross phase modulation, optimized by optical Kerr effect enhancement in a dense medium in an electromagnetically induced transparency (EIT) regime, seems to be very promising. In this scenario, we propose a fully quantized model of a double-EIT scheme recently proposed [D. Petrosyan and G. Kurizki, Phys. Rev. A 65, 33833 (2002)]: the quantization step is performed adopting a fully Hamiltonian approach. This allows us to write effective equations of motion for two interacting quantum fields of light that show how the dynamics of one field depends on the photon-number operator of the other. The preparation of a Schrödinger cat state, which is a superposition of two distinct coherent states, is briefly exposed. This is based on non-linear interaction via double-EIT of two light fields (initially prepared in coherent states) and on a detection step performed using a 50 : 50 beam splitter and two photodetectors. In order to show the entanglement of an entangled coherent state, we suggest to measure the joint quadrature variance of the field. We show that the entangled coherent states satisfy the sufficient condition for entanglement based on quadrature variance measurement. We also show how robust our scheme is against a low detection efficiency of homodyne detectors.

I. INTRODUCTION

The generation of a Schrödinger cat state is a superposition of two distinct coherent states, and an entangled coherent state, which is an entanglement of the coherent states, serves the first step towards quantum information processing using coherent states. Numerous schemes have been proposed in order to generate such a kind of coherent superposition. Cavity quantum electrodynamics (CQED) seems to be a promising environment to this task and, in order to investigate their properties with respect to decoherence, recently a scheme to generate a mesoscopic version of a cat state using trapped ions has been proposed. However, most of the suggested schemes for quantum computation using coherent states is based on travelling-wave fields. Yurke and Stoler’s suggestion to produce a travelling-wave cat state was far from the experimental realization because of nonlinear Kerr interaction while the suggestion primarily depends on it.

Recently, it has been proved that the interaction of two travelling fields of light in an atomic medium is able to show giant Kerr non-linearities by means of the so-called cross phase modulation. Measured values of the parameter are up to six orders of magnitude larger than usual. This can open the way toward the use of this kind of non-linear processes even for the very low photon-number case. Usually, the approach to such processes is restricted to a semiclassical level: the medium is treated quantum mechanically while the interacting fields are assumed to be classical objects. Nevertheless, a fully quantum treatment of non-linear dynamics is relevant with respect to many aspects of quantum information processing. For example, huge Kerr non-linearities can be exploited in order to perform computation, as said above and as described in refs. , to perform quantum teleportation of an unknown state or for quantum non-demolition measurements. In all these examples, a complete quantum treatment of the fields involved is required.

A full quantum analysis of the cross phase modulation problem has been explicitly performed by Lukin and Imamoglu in ref. , where a rather involved atomic system, realized by mixing two different isotopes of the same alkali species, has been used. In order to suggest a more feasible experimental realization of the process, Petrosyan and Kurizki suggested a modification of the atomic model that allows the use of just a single species. Their analysis, however, was again semiclassical.

In this paper, we investigate the fully quantum-mechanical description adopting a completely Hamiltonian approach. To the best of our knowledge, this method has never been used in this context. We envisage in a Y_{2}SiO_{5} crystal doped with Pr^{3+} ions a good candidate to physically embody the atomic model we discuss: the scheme of the atomic energy levels, in this system, seems quite appropriate to be used for our purposes. The Pr^{3+} doped Y_{2}SiO_{5} has been used for
the experimental demonstrations of EIT [20] and giant Kerr nonlinearity [21,22]. Using realistic values for the atomic parameters relative to this solid state system we find that a giant rate of non-linearity is obtained in our fully quantum-mechanical model. We derive the relative equations of motion for the involved quantum fields. This allows us to write the interaction Hamiltonian in a form that explicitly depends on the photon-number operators of the two quantum fields. Starting from this point, we show how entangled coherent states and Schrödinger cat states are generated when the initial states of the fields are two independent coherent states.

The paper is structured as follows: in Section II we describe the Hamiltonian approach we have chosen and apply it to model cross phase modulation via electromagnetically induced transparency (EIT) [19]. In Section III we apply this method to the atomic scheme for double-EIT suggested in [17] and we derive the equations of motion for the quantized fields. Section IV is devoted to the Bloch equations for the atomic density matrix elements, which are solved in steady state conditions. The solutions are, then, inserted into the Maxwell equations, and we get rid of the atomic variables, obtaining a set of equations of motion for the Rabi frequencies that, in the slowly varying envelope approximation (SVEA), reads:

$$\left( \frac{\partial}{\partial z} + \frac{1}{c} \frac{\partial}{\partial t} \right) \Omega_j = -\frac{N d_j^2 \omega_j}{2 \hbar \omega c} \left\langle \frac{\partial H}{\partial \Omega_j} \right\rangle, \quad \forall j.$$  (4)

Changing the reference frame into $\xi = z, \tau = t - z/c$, the above equation can be reduced to:

$$\frac{\partial \Omega_j}{\partial \xi} = -\frac{N d_j^2 \omega_j}{2 \hbar \omega c} \left\langle \frac{\partial H}{\partial \Omega_j} \right\rangle.$$  (5)

This approach has been used in ref. [23] to investigate the problem of resonant forward four-wave mixing based on EIT. It is particularly convenient if an open-system Hamiltonian model is used to incorporate ab initio the decay rates of the atomic levels and if the atoms follow adiabatically the fields evolution. While the first condition can be satisfied using an effective complex Hamiltonian, the second point needs more explanations.

Solving the Bloch equations that describe the atomic density matrix evolution, one usually invokes the so-called weak coupling limit: the fields that couple an initially prepared, collective, atomic state to other states of the atomic model are assumed to be very weak (usually, there is less than one photon per atom on average). Thus, the probability that, after the interaction, a state different from the initial one is populated is very small. This qualifies the initial state as a stationary state and the ent from the initial one is generated when the initial states of the fields are generated.

In other words:

$$P_j = \left\langle \frac{\partial H}{\partial E_j^*} \right\rangle e^{-i(\omega_j t - k_j z)} + \text{c.c.}$$  (3)

where $\Omega_j$ is the Rabi frequency relative to the $j$-th field, $d_j$ is the dipole matrix element of the corresponding transition and $N$ is the density of the atomic medium.

Introducing this equation into the Maxwell-Bloch equations, we find that explicitly depends on the photon-number operators of the two quantum fields. Starting from this point, we show how entangled coherent states and Schrödinger cat states of light are generated when the initial states of the fields are two independent coherent states.

The detection scheme is based on the total variance criterion for continuous variable states [18].

II. THE HAMILTONIAN METHOD

The standard method to describe the interaction of electromagnetic fields in a resonant medium is to derive the Bloch equations for the atomic density matrix elements, which are solved in steady state conditions. The solutions are, then, inserted into the Maxwell equations to show the propagation of the fields. However, when the number of fields involved in the problem is high and the atomic system consists of several energy levels, this procedure can be quite cumbersome.

A much simpler way to derive the field equations is given by a fully Hamiltonian approach [19]. According to it, the polarization of the medium can be expressed as the partial derivative, with respect to the electric field amplitude, of the averaged free-energy density of the atomic medium. In other words:

$$P = -\left\langle \frac{\partial H}{\partial E^*} \right\rangle$$  (1)

where $H$ is the interaction part of the Hamiltonian, $E$ is the complex amplitude of the electromagnetic field and $P$ is the polarization of the medium [14]. When several electromagnetic fields interact with the medium, $H$ can be expressed, following [19], as:

$$-H = \sum_j \chi^{(1)}(\omega_j) |E_j|^2 + \frac{1}{2} \sum_{ij} B_{ij} |E_i E_j|^2 + \ldots.$$  (2)

where $B_{ij}$ are the diagonal elements of the non-linear third-order susceptibility, responsible for the non-linear terms of the refractive index at frequency $\omega_j$. Thus, the polarization due to the $j$-th electromagnetic field can be written as:

$$P_j = \left\langle \frac{\partial H}{\partial E_j^*} \right\rangle e^{-i(\omega_j t - k_j z)} + \text{c.c.}$$  (3)

where $\Omega_j$ is the Rabi frequency relative to the $j$-th field, $d_j$ is the dipole matrix element of the corresponding transition and $N$ is the density of the atomic medium.

Introducing this equation into the Maxwell-Bloch equations, we find that explicitly depends on the photon-number operators of the two quantum fields. Starting from this point, we show how entangled coherent states and Schrödinger cat states of light are generated when the initial states of the fields are two independent coherent states.

The detection scheme is based on the total variance criterion for continuous variable states [18].
suffices to derive the field equation of motion directly. The quantization of the fields is then performed in the canonical way, just replacing the classical field variables in the effective Hamiltonian represented by the explicit expression of $\lambda$ and assigning appropriate commutation rules to them [24]. Starting from this effective, fully quantized Hamiltonian, the quantum generalization of the equations of motion for the fields is easily derived. We want to stress here that adopting this Hamiltonian approach we do not introduce any other approximation with respect to the semiclassical case: we just eliminate the atomic variables evolution from that of the fields without solving the corresponding Bloch equations.

Here, we propose an example to illustrate the power of the Hamiltonian approach and to show how to get huge non linear effects using the interaction of a field with a macroscopic atomic ensemble in the EIT regime.

We refer explicitly to ref. [11] (the atomic model is sketched in Fig. 1) where, using the usual semiclassical approach, it has been proved that giant values of the third-order atomic susceptibility $\chi^{(3)}$ can be obtained. This result is a consequence of the a.c. Stark shift experienced by the assumed metastable state $|3\rangle$ because of the dispersive coupling, induced by field $E_2$, between $|3\rangle$ and $|4\rangle$. The Hamiltonian that describes this interaction, with a canonical transformation and introducing the decay rates of states $|2\rangle$ and $|4\rangle$, in the basis $\{|1\rangle, |2\rangle, |3\rangle, |4\rangle\}$ have the effective matrix representation:

$$H' = \hbar \left( \begin{array}{cccc} 0 & \Omega_1^* & 0 & 0 \\ \Omega_1 & -i\gamma_2 & \Omega_d & 0 \\ 0 & \Omega_d^* & 0 & \Omega_2^* \\ 0 & 0 & \Omega_2 & \Delta - i\gamma_4 \end{array} \right). \quad (7)$$

Assuming, as in [10], that $|\Omega_1|, |\Omega_2| \ll |\Omega_d|, \Delta, \gamma_4$, the secular equation for $H'$ results in a fourth-order polynomial whose coefficients can be expanded in power series of $|\Omega_{1,2}|/|\Omega_d|$. Retaining just the first significant terms of these expansions, the relevant eigenvalue is found to be:

$$\lambda_{SI} \simeq -\hbar \frac{|\Omega_1|^2 |\Omega_2|^2}{(\Delta - i\gamma_4) |\Omega_d|^2}. \quad (8)$$

Taking the limit $|\Omega_1|, |\Omega_2| \to 0$, $\lambda_{SI}$ tends to zero, which is the energy of the initially prepared state $|1\rangle$, as assumed in [11].

Having $\lambda_{SI}$, the technique described in the preceding section can be straightforwardly applied: deriving $\lambda_{SI}$, which now represents an effective interaction Hamiltonian, with respect to $\Omega_1^*$ allows us to get an expression for $P_1$, polarization of the medium at frequency $\omega_1$. According to Eq. (3), we have:

$$P_1(\omega_1) = \frac{N |d_{12}|^2 |d_{34}|^2}{(\Delta - i\gamma_4) |\Omega_d|^2} \frac{|E_2|^2 E_{\omega_1}}{\epsilon_0}, \quad (9)$$

and then:

$$\chi^{(3)}(\omega_1) = \frac{N |d_{12}|^2 |d_{34}|^2}{\epsilon_0(\Delta - i\gamma_4) |\Omega_d|^2 \hbar^3}. \quad (10)$$

This is exactly the main result obtained by Schmidt and Imamoglu [10]. Taking the real part of the complex $\chi^{(3)}$ we get the rate of non-linearity of this process. Note that, differently from the works in refs. [10, 25], here we do not have any $\chi^{(1)}$ because of the assumed perfect resonance in the transition $|1\rangle \leftrightarrow |2\rangle$ and the zero atomic decay rate from state $|3\rangle$. Measured values of the non linear refractive index, for this model, are of the order of $10^{-1} \text{cm}^2/\text{Watt}$, resulting in an enhancement of the Kerr effect up to six orders of magnitude with respect to the best measured values for the case of cold trapped Cs atoms [11].

The main result of this section has been to show that the chosen Hamiltonian approach is able to reproduce correctly the results obtained by solving the equations of motion for the atomic density matrix elements. Starting from it, we will straightforwardly derive the full quantum description of a model for double-EIT.

III. CROSS PHASE MODULATION VIA A DOUBLE EIT EFFECT

We refer again to Fig. 1 for the details of the following discussion. As explained above, in the EIT regime, the
field $E_1$ travels in the medium with a very slow group velocity (17 m/sec in [1] and 45 m/sec in [2]) while $E_2$ has a very high propagation velocity. Harris and Hau proved [12] that the total phase shift experienced by field $E_1$ is limited by the time that the faster of the two fields spends inside the medium. The efficiency of the non-linear interaction is, thus, strongly affected by any velocity mismatch. In order to get rid of this bottleneck, strategies to induce EIT for both $E_1$ and $E_2$ (double-EIT regime) have been developed. This will maximize the interaction time, optimizing the efficiency of the process. While the scheme suggested in ref. [10], even if extremely stimulating, seems to be hard to be experimentally realized, Petrosyan and Kurizki [17] proposed another scheme for double-EIT to simplify the model. Even if it implies a complication of the atomic energy spectrum, it appears simpler under a realizable point of view. The energy manifold in the interaction picture:

$$H = \hbar \Delta \left( \begin{array}{cccc} 0 & 0 & 0 & \Omega_a^* \\ 0 & 0 & 0 & 0 \\ \Omega_a & 0 & \Omega_b & 0 \\ -\Omega_a^* & -\Omega_b^* & 0 & 0 \end{array} \right) \Delta$$

(11)

The solution of the Schrödinger equation for a state

$$\Psi = \sum_{i=1}^{6} A_i(t) |i\rangle$$

is obtained assuming the weak field limit $|\Omega_d|, \gamma, \Delta \gg |\Omega_{a,b}|$ and that both $\gamma^{-1}$ and $\Delta^{-1}$ are larger than $T$, the characteristic interaction time of the applied fields with the atomic medium. Under these conditions, we can use the SVEA for the atomic probability amplitudes $A_i(t)$ ($i = 1, \ldots, 6$) and for the field amplitudes $E_a$ and $E_b$: this is equivalent to require that the amplitudes of the applied weak fields do not change too much during $T$. Neglecting the highly oscillating terms, in such a way just to get the following matrix representation of $H'$ for the atomic basis $\{|1\rangle, |2\rangle, |3\rangle, |4\rangle, |5\rangle, |6\rangle\}$:

$$H' = \hbar \left( \begin{array}{cccccc} 0 & 0 & 0 & \Omega_a^* & -\Omega_b^* \\ 0 & 0 & 0 & 0 & \Omega_b e^{2i\Delta t} \\ \Omega_a & 0 & \Omega_b & 0 & 0 \\ -\Omega_a^* & -\Omega_b^* & 0 & \Delta - i\gamma & 0 \\ 0 & -\Omega_b & -\Omega_d & 0 & 0 & -i\gamma \end{array} \right) \frac{1}{\sqrt{2}}$$

(12)

FIG. 2: This figure shows the atomic model used to get a double-EIT regime for fields $E_a$, with frequency $\omega_a$, and $E_b$, with $\omega_b$. The fields that have frequencies $\omega_{a1}, \omega_{a2}$ are assumed to be classical, in the sense that their intensities is much greater than that of $E_a$ and $E_b$. The splitting $\Delta_{ul}$ is assumed to be different with respect to $\Delta_L$. $|\Delta| = |\Delta_u - \Delta_L|$ is the detuning of field $E_u$ relatively to the transition $|1\rangle \leftrightarrow |5\rangle$ and of field $E_b$ with respect to $|3\rangle \leftrightarrow |5\rangle$. The excited states decay rates are assumed to be equal to $\gamma$, for sake of simplicity.
that a kind of rotating wave approximation (RWA) is performed, the probability amplitudes reach stationary values. Note that this second assumption agrees with an adiabatic solution of the equations of motion.

If all the atoms in the ensemble are initially prepared in state |2⟩, in the weak fields limit we can take \( A_2(t) \approx 1 \), \( \forall t \leq T \). Ref. [17] shows that the atomic polarizability of the medium at frequency \( \omega_a \) is given by:

\[
\alpha_a = \frac{2i\alpha_0\gamma |\Omega_b|^2}{(\gamma + i\Delta)|\Omega_d|^2},
\]

(14)

where \( \alpha_0 = N\sigma_0 \) and \( \sigma_0 \) is the resonant absorption cross section, generally defined by \( \sigma_0 = \frac{|d|^2\omega}{2\omega_0\hbar\gamma} \). Eq. (14) shows explicitly the effect of the cross phase modulation induced by the interaction between the two weak (but classical) fields: the polarizability at frequency \( \omega_a \), due to field \( E_a \), depends on the intensity of field \( E_b \). Since a completely analogous expression holds for the polarizability \( \alpha_b \) at frequency \( \omega_b \), the cross effect is evident. Here, we are assuming that the atomic ensemble is maintained at a sufficiently low temperature to discard any Doppler broadening. Rigorously speaking, the thermal distribution of the atomic velocities has an influence on the value of the susceptibility of the medium, that has to be averaged over the velocity distribution function. If the temperature of the sample is kept low (orders of 10\(^{-4}\) K in [17]) and if we adopt a co-propagating beams configuration in order to get rid of residual Doppler shifts, the broadening can be made small and the average can be avoided [17].

Introducing \( \alpha_a \) into the equation of motion for \( E_a \) we get the solution:

\[
E_a(L, t) = E_a(0, t - \frac{L}{c}) \exp \left\{ i \int_0^L \alpha_a dz \right\}
\]

(15)

where \( L \) is the interaction length of the fields. \( E_a \) experiences, thus, a phase shift due to the presence of the second field [16, 17].

We now apply the Hamiltonian approach, to show that the results obtained solving perturbatively both the Maxwell equations for the fields and the equations for the atomic probability amplitudes can be obtained just by looking for the eigen-energy of the system that, for \( |\Omega_{a,b}| \rightarrow 0 \), gives the energy of state |2⟩ (that is the initial state of the system).

The secular equation for the matrix \( H' \) given in Eq. (12) is a six-order polynomial expression whose coefficients depend on the Rabi frequencies \( \Omega_{a,b,d} \). In the weak field limit, we use a series expansion of \( \Omega_{a,b,d} \). Retaining just the first orders and performing that kind of RWA that allows us to neglect all the very highly oscillating terms, we finally get:

\[
\lambda \approx \frac{2\hbar |\Omega_a|^2 |\Omega_b|^2 |\Omega_d|^2}{i\gamma |\Omega|^3 - \Delta |\Omega_d|^2 |\Omega|^2}.
\]

(16)

with \( |\Omega| = \sqrt{|\Omega_a|^2 + |\Omega_b|^2 + |\Omega_d|^2} \).

As pointed out, this equation has to be contrasted with that for the eigen-energy of state |2⟩ in absence of the weak probes. If these fields are absent, it is easy to verify that the atomic model shown in Fig. 5 can be mapped into an effective five-level system that does not include state |2⟩. The diagonalization of the resulting Hamiltonian (obtained from Eq. (12) getting rid of the second row and column of the matrix) shows that the states |1⟩ and |4⟩ are dressed by the intense field with frequency \( \omega_a \), while the field with frequency \( \omega_d \) dresses the transition |6⟩ ↔ |3⟩. This shows that |2⟩ is the only state that, in absence of weak fields but with the strong classical ones shined on the medium, has zero energy. Since, for \( |\Omega_{a,b}| \rightarrow 0 \), we have \( \lambda \rightarrow 0 \), Eq. (16) is the right solution.

Assuming once more the weak field limit, we have \( |\Omega| \approx |\Omega_d| \) and the expression for \( \lambda \) can be approximated to:

\[
\lambda \approx \frac{2\hbar |\Omega_a|^2 |\Omega_b|^2}{(i\gamma - \Delta)|\Omega_d|^2}.
\]

(17)

The partial derivative of Eq. (17) with respect to \( \Omega_a^\ast \) gives us an explicit expression for the polarization of the medium at frequency \( \omega_a \) and the equation of motion for \( \Omega_a \). The latter, finally, reads:

\[
\frac{\partial \Omega_a}{\partial \xi} = \frac{2iN\sigma_0\gamma |\Omega_b|^2}{(i\gamma + \Delta)|\Omega_d|^2} \Omega_a,
\]

(18)

that exactly corresponds to the result semi-classically obtained in ref. [17]. In the same way, the partial derivative with respect to \( \Omega_b^\ast \) leads to the polarizability at frequency \( \omega_b \) and to the equation of motion for the Rabi frequency \( \Omega_d \). Because of the symmetry of the system with respect to the two fields, we easily recognize that their group velocities are both equal to \( v_g \approx |\Omega_d|^2/N\sigma_0\gamma \ll c \). This inequality holds using the values reported in [17]. As explained above, this equally slow propagation of the two fields inside the medium optimizes the cross phase modulation effect.

To have an efficient non-linear process, the rate of two-photon-absorption has to be negligible with respect to the rate of non-linearity. Since the former quantity is proportional to the imaginary part of the polarizability while the latter is proportional to his real part [12], we can consider the following figure of merit for the non-linear interaction:

\[
\eta = \frac{\Re \{ \alpha_a \}}{\Im \{ \alpha_a \}} = \frac{\Delta}{\gamma}.
\]

(19)

If the experimental conditions are such that \( \Delta \gg \gamma \), then any absorption can be neglected and the process can be seen just as a mutually induced phase-shift of the fields. Note that this is fully consistent with the requirement advanced in the original theory of giant Kerr non-linearity by Schmidt and Imamoglu [16]. Adopting the values chosen in ref. [17], an interaction length of
the order of cm and an interaction time of some μsec lead, for two focused beams \( E_a \) and \( E_b \), to a total phase shift (obtained integrating \( \omega_0 \) over the interaction length) that can easily reach \( \pi \). With these orders of magnitude, the total two-photon-absorption probability is smaller than 1%.

The quantization of the fields, now, proceeds as follows: we replace the complex Rabi frequencies that appear in Eq. (17) with the positive and negative frequency components of the corresponding field operators (that satisfy the bosonic commutation rules \( \{ \hat{a}_i, \hat{b}_j \} = \delta_{ij} \mathbb{1} \), with \( \delta_{ij} \) the Kronecker symbol, \( \mathbb{1} \) the identity operator and \( i, j = a, b \)), multiply the expression that is thus obtained by the density of the atoms in the ensemble (\( N \)) and integrate over the interaction volume \( V = A L \), with \( A \) the effective cross section of the fields. Following this recipe, we get an effective Hamiltonian operator that describes, in a completely quantum picture, the non-linear interaction of two quantum fields that propagate inside a dense medium in condition of double-EIT:

\[
\hat{H}_{eff} = \frac{2\hbar A N}{(i\gamma - \Delta)} \int_0^L \frac{\hat{\Omega}_a \hat{\Omega}_a^\dagger \hat{\Omega}_b}{|\Omega_d|^2} dz. \tag{20}
\]

For the case of pulses propagating inside the non-linear medium, we can follow a treatment analogous to that developed in [27]. Thus, adopting the narrow bandwidth approximation and assuming a finite range of frequencies involved in the superpositions that build up the pulses, we introduce the slowly varying positive frequency operator \( \hat{\Omega}_a(z,t) = d_{24} \sum_k \sqrt{\frac{\omega_a}{2\pi \hbar \nu_a}} \hat{a}_k(t)e^{-i(\omega_k - \omega_a^\text{car})z/c} \) and the analogous for \( \hat{\Omega}_b(z,t) \), where we explicitly introduced the annihilation operators \( \hat{a}_k \). Here, \( \nu_a \) is the quantization volume, \( k \) is a label for the different wavelengths appearing in the superposition and \( \omega_a^\text{car} \) is the central (carrier) frequency of the pulse: the narrow bandwidth approximation consists in assuming that the width of the pulses, in the frequency domain, is smaller than the carrier frequency itself. When the spatial integration is carried on, assuming that the medium length is longer than all the wavelengths in the pulses, the main contribution to \( \hat{H}_{eff} \) is due to terms as \( \sum_k \hat{a}_k^\dagger(t)\hat{a}_k(t) \) (and the same for field \( E_b \)) which define the total photon number operator in the pulse \( \hat{N}_a \) (\( \hat{N}_b \)). In the case of single-mode field, as a cw laser beam, the sum that appears in the definition of \( \hat{\Omega}_a, \hat{\Omega}_b \) collapses and \( \hat{\Omega}_a(z,t) = d_{24} \sqrt{\frac{\omega_a}{2\pi \hbar \nu_a}} e^{-i(\omega_a t - k_a z)} \). Assuming \( \nu \gg 1 \) and properly collecting all the non-operatorial quantities into a rate of non-linearity \( \chi \), we can write Eq. (20) as:

\[
\hat{H}_{eff} = \hbar \chi \hat{a}_a^\dagger \hat{a}_b \tag{21}
\]

with

\[
\chi = \mathcal{R} \left\{ \frac{N \omega_0 |d_{24}|^2 |d_{26}|^2}{2\hbar^2 c_0^2 (i\gamma - \Delta) |\Omega_d|^2 V} \right\}, \tag{22}
\]

where we have assumed that the interaction volume coincides with the quantization one. This is the counterpart, specialized to the particular atomic model we have adopted here, of the rate of non-linearities obtained by Lukin and Imamoglu in [14].

Let us briefly turn to some experimental details. A promising candidate to embody the atomic model we used for the double-EIT regime is a crystal of Y2SiO5 doped with Pr\(^{3+}\) ions (Pr:YSO) [26], both for an interesting similarity between the energy-level scheme described here and that of the transition \( ^2H_4 \rightarrow ^1D_2 \) in this crystal and for the possibility we have, in a solid state system, to limit the effect of the Doppler broadening. This solid state system is notable for its relatively narrow-linewidth EIT that, very recently, enabled the observation of ultrashort group velocity (approximatively 45 m/sec) and storage of light pulses (measured delay times greater than 65 μsec) [22]. For the \( ^2H_4 \rightarrow ^1D_2 \) transition at a wavelength of \( \sim 600 \text{ nm} \) considered in [22], the ground state population lifetime is of the order of minutes. The crystal sample can be taken as long as 1 mm and the laser beams used in the non-linear interaction can be focused, by a lens, to have a typical diameter of 100 μm (Full-Width-at-Half-Maximum). A realistic value for the excited states decay rate \( \gamma \) range between 10 and 100 kHz (close to the measured values for a sample at a temperature of 5 K) that, for detuning \( \Delta \sim 1 \text{ MHz} \) and coupling field Rabi frequency \( |\Omega_d| \sim 1 \text{ MHz} \) allows us to consider \( \gamma \ll \Delta \), \( |\Omega_d| \), in accordance with our treatment. The electric dipole matrix elements for the system in exam are three orders of magnitude weaker than those, for the same range of frequencies, in alkali atoms. Taking, as typical values for an alkali atom \( d \sim 10^{-29} \text{ Cm} \), we can assume \( |d_{24}| \sim |d_{26}| \sim 10^{-32} \text{ Cm} \). Finally, the atomic density is taken as \( N \sim 10^{15} \text{ cm}^{-3} \). Putting these values in Eq. (22) we find that interaction times \( \tau \) in the range of μsec allow to reach a cross-phase shift \( \varphi = \chi \tau \sim \pi \) even when the intensity of the beams involved (proportional to \( \langle \hat{n}_{a,b} \rangle \)) is no more than a few photons. We will see in the next section how important, for the purposes of this paper, is the ability to get a π cross-phase shift of the interacting fields.

For the case of pulses interacting in the atomic sample, some experimental difficulties arise. First of all, effects of diffraction, focusing and defocusing on \( E_a \) and \( E_b \) are to be considered: they are due to the transverse intensity profile of \( \Omega_d \) that leads to variations in the radial refractive index experienced by the weak probes (this effect is known in literature as electromagnetically-induced-focusing (EIF) [25]). EIF changes the size of the weak beams from point to point inside the medium, thus modifying the interaction volume (that becomes a function of the position) and influencing the rate of non-linearities. The effect, present even in the cw regime, is less controllable in the case of pulses because of the different frequencies involved in the propagating packets. These non-linear effects, indeed, seem to depend on the sign of the detunings between the components of the probes.
and the frequency of the atomic transitions that they guide. This implies, for example, focusing for some components of a probe pulse accompanied by defocusing of all the other components (of the same pulse) that have a detuning of opposite sign. The result is that different harmonics, in a pulse, are subject to different radial evolutions, thus complicating the control on the dynamics of the field itself.

Another relevant point to be treated is that of the different phase shifts acquired by the different parts of the cross-interacting pulses. As it can be seen solving the Heisenberg equations of motion for the field operators \( \hat{E}_a \) and \( \hat{E}_b \) interacting as described in Eq. (20), and as it is proved in [16], the evolution of the probe fields is given by:

\[
\hat{E}_{a,b}(L,t) = \hat{E}_{a,b}(0,t')e^{\{i\chi\hat{E}_{a,b}(0,t')\hat{E}_{a,b}(0,t')\}}
\]  

(23)

with \( t' = t - L/v_g \) and \( \chi \) the rate of non-linearity specific for this case (that reduces to Eq. (22) when we consider cw fields). Note that this solution is the exact quantum analogous of what has been found, in the semiclassical context, in the case of static fields. Note also that this solution is valid for any number of harmonics, in a pulse, are subject to different radial evolutions, thus complicating the control on the dynamics of the field itself.

IV. SCHRÖDINGER CAT STATES

In this section we want to apply the results obtained with our fully quantized picture of the cross phase modulations induced by double-EIT in order to show that this specific system can be used to produce a Schrödinger cat state [1] of a single mode of field.

Given the interaction Hamiltonian (21), we derive the equations of motion for the annihilation operators \( \hat{a} \) and \( \hat{b} \). Adopting the usual notation \( \hat{n}_a = \hat{a}^\dagger \hat{a} \) and \( \hat{n}_b = \hat{b}^\dagger \hat{b} \) for the photon-number operators of the two fields, these are:

\[
\partial_t \hat{a} = -i\chi[\hat{a}, \hat{n}_a \hat{n}_b] = -i\chi \hat{a} \hat{n}_b \\
\partial_t \hat{b} = -i\chi[\hat{b}, \hat{n}_a \hat{n}_b] = -i\chi \hat{b} \hat{n}_a
\]

(24)

which, arranging the time scale in such a way that \( t = 0 \) is the instant in which the interaction starts, lead to the time-dependent operators:

\[
\hat{a}_{\text{out}}(t) = e^{-i\chi t \hat{n}_a} \hat{a}(0) \\
\hat{b}_{\text{out}}(t) = e^{-i\chi t \hat{n}_a} \hat{b}(0).
\]

(25)

Note that, in the approximation of a pure cross shift process, \( \hat{n}_{a,b} \) do not evolve because of the non-absorption character of the interaction considered. Defining \( \varphi = \chi t \), the above evolution is attributed to the action of the unitary time-evolution operator \( \hat{U}(\varphi) = e^{-i\chi \hat{n}_a \hat{n}_b} \) on the field operators. We want to specialize the present analysis to the case in which the initial state of the two interacting fields is \( |\psi(0)\rangle_{ab} = |\alpha\rangle_a \otimes |\gamma\rangle_b \), where the coherent state \( |\alpha\rangle_a = \hat{D}_a(\alpha)|0\rangle_a \) with the displacement operator \( \hat{D}_a(\alpha) = \exp(\alpha \hat{a}^\dagger - \alpha^* \hat{a}) \). The coherent state \( |\gamma\rangle_b \) has been defined likewise.

The evolution of the initial state by means of \( \hat{U}(\varphi) \) can be expressed as follows:

\[
|\psi(t)\rangle_{ab} = \hat{D}_a(\alpha) \hat{D}_b(\gamma)|0\rangle_a \otimes |0\rangle_b,
\]

(26)

where we have defined the time-dependent displacement operators:

\[
\begin{align*}
\hat{D}_a(\alpha) & \equiv \hat{D}_a(\alpha) \hat{U}^{-1}(\varphi) = e^{(\alpha \hat{a}^\dagger - \alpha^* \hat{a})} \\
\hat{D}_b(\gamma) & \equiv \hat{D}_b(\gamma) \hat{U}^{-1}(\varphi) = e^{(\gamma \hat{b}^\dagger - \gamma^* \hat{b})}
\end{align*}
\]

(27)

with \( \hat{a}^\dagger = e^{-i\varphi \hat{n}_a} \hat{a}^\dagger e^{i\varphi \hat{n}_a} \) and \( \hat{b}^\dagger = e^{-i\varphi \hat{n}_b} \hat{b}^\dagger e^{i\varphi \hat{n}_b} \). Explicitly using the operator expansion theorem [31], we obtain:

\[
\begin{align*}
\hat{a}^\dagger & = \hat{a}^\dagger e^{-i\varphi \hat{n}_b} \\
\hat{b}^\dagger & = \hat{b}^\dagger e^{-i\varphi \hat{n}_a}
\end{align*}
\]

(28)

that is:

\[
\begin{align*}
\hat{D}_a(\alpha) & = e^{(\alpha \hat{a}^\dagger e^{-i\varphi \hat{n}_b} - \alpha^* \hat{a} e^{i\varphi \hat{n}_b})} \\
\hat{D}_b(\gamma) & = e^{(\gamma \hat{b}^\dagger e^{-i\varphi \hat{n}_a} - \gamma^* \hat{b} e^{i\varphi \hat{n}_a})}
\end{align*}
\]

(29)
Introducing Eq. (29) into Eq. (26), we get the time-dependent state of the two fields:

$$|\psi(t)\rangle_{ab} = \mathcal{D}_a(\alpha)\mathcal{D}_b(\gamma)|0\rangle_a \otimes |0\rangle_b = e^{-i\varphi/2}e^{\alpha a^\dagger e^{-i\varphi a}}|\alpha\rangle_a \otimes |\gamma\rangle_b,$$

(30)

where the Campbell-Baker-Haussdorff theorem \cite{34} and the fact that a coherent state is an eigenstate of the annihilation operator have been used. Using the representation of coherent states in the Fock number states we have:

$$|\psi(t)\rangle_{ab} = e^{-i\varphi/2}\sum_{n=0}^{\infty} \frac{\gamma^n}{\sqrt{n!}}|\alpha e^{-i\varphi n}\rangle_a \otimes |n\rangle_b.$$

(31)

If we are experimentally able to set the interaction time and the value of the rate of non-linearity so that $\varphi = \pi$ then, splitting the sum in Eq. (31) into one over the odd values of $n$ and one over the even ones, the evolved state of the two initially non-interacting fields takes the form \cite{24}:

$$|\psi(\pi/\chi)\rangle_{ab} \propto |\alpha\rangle_a \{(|\gamma\rangle + |-\gamma\rangle)_b + |\alpha\rangle_a\} \{(|\gamma\rangle - |-\gamma\rangle)_b.$$

(32)

This is a particular expression for an entangled coherent state: it can be reduced to the more familiar form $|\alpha\rangle_a |\gamma\rangle_b + |\alpha\rangle_a |\gamma\rangle_b$ unitarily acting on the subsystem $b$. To prove the entanglement, we have to show the correlation of the fields of modes $a$ and $b$ as we unitarily transform, gradually, from $|\gamma\rangle_b$ to $|\gamma\rangle_b \pm |-\gamma\rangle_b$. However, this involves another non-linear interaction. We thus discuss an indirect way to prove the production of the entangled coherent state.

In Eq. (22), linear superpositions of the coherent states $|\gamma\rangle_b$ and $|-\gamma\rangle_b$ are Schrödinger cat states:

$$|\gamma\rangle_b + |-\gamma\rangle_b \propto \sum_{j=0}^{\infty} \frac{\gamma^{2j}}{(2j)!} |2j\rangle_b$$

$$|\gamma\rangle_b - |-\gamma\rangle_b \propto \sum_{j=0}^{\infty} \frac{\gamma^{2j+1}}{(2j+1)!} |2j+1\rangle_b$$

(33)

which are sometimes called as the even and odd coherent states. As shown in Eq. (22), a time-controlled interaction of two fields in initially prepared coherent states results in an entangled state: if we properly normalize state $|\psi(\pi/\chi)\rangle_{ab}$ and we look to the reduced density operator of the field $E_a$ alone (tracing over $b$ mode), we find an incoherent mixture of two coherent states which are out of phase by $\pi$ \cite{22}.

Suppose we are, somehow, able to discern the state in which field $E_a$ is, after its crossing through our model of highly non-linear medium. Because of the entangled structure of Eq. (22), the state of field $E_b$ is projected onto one of the equally weighted superpositions of $\pi$-out-of-phase coherent states $|\gamma\rangle_b \pm |-\gamma\rangle_b$: it collapses into a Schrödinger cat state. The point, now, is to show how to reliably discern the state of field $E_a$.

To achieve this target, we need a 50 : 50 beam splitter (BS). After passing through a beam splitter, two coherent input fields $|\alpha\rangle|\beta\rangle$ become \cite{33}:

$$\hat{B}_{ac}|\alpha\rangle_a|\beta\rangle_c = \left|\frac{\alpha + \beta}{\sqrt{2}}\right\rangle_a \left|\frac{-\alpha + \beta}{\sqrt{2}}\right\rangle_c,$$

(34)

where $\hat{B}_{ac} \equiv e^{i(\alpha a^\dagger - \gamma \hat{A}^\dagger)}$, with $a$ ($\tilde{a}$) and $c$ ($\tilde{c}$) as the input (output) modes of the beam splitter.

Thus, taking $\beta = \alpha$ and referring to Fig. 3, we have the following read-out scheme: if the input mode $a$ is in the state $|\alpha\rangle_a$, then Detector 1 will click, revealing that some photons arrived at it while Detector 2 will not click. In this case, the field mode $b$ will be projected in the even coherent state. In the opposite occasion, the field mode $b$ will be in the odd coherent state. Of course, there is a possibility to have both the detectors not to click. In this case, we do not know where the mode $a$ is so we have to repeat the experiment till we have one detector to click.

![FIG. 3: Detection scheme to infer the state of the field mode $a$. In this figure it is shown the symbol used to represent a photodetector and that for the 50:50 beam splitter (BS). According to Eq. (34), Detector 1 (2) clicks just if the state of mode $a$ is $|\alpha\rangle_a$ ($|\gamma\rangle_b$). Using this read-out scheme, we have the possibility to generate an even or an odd coherent state of the field mode $b$.](image)

V. DETECTION OF A CAT STATE

The quantum state of an electromagnetic field is completely and unambiguously determined once all the moments of its statistical distribution function are determined \cite{31}. To get this task, we need the density matrix $\hat{\rho}$ of the state of the field: it contains all the available information about the given quantum state and, having $\hat{\rho}$, the most complete statistical description of the system can be performed. On the other hand, it is possible to demonstrate a biunique correspondence between the density matrix $\hat{\rho}$ and the Wigner function of a radiation
For any separable state, it is possible to show that the correspondence is useful under an observable point of view: numerous theoretical schemes for the reconstruction of the Wigner function of a radiation mode have been proposed. They are essentially based on heterodyne or homodyne detection [35]. The mathematical manipulation of the data collected by the homodyne detector allows also for the reconstruction of \( \rho \) [36, 37]. Recently, this homodyne tomographic technique has been experimentally realized [38]. This approach, however, may be limited by imperfect detection efficiency.

The procedure described above could certainly be used to determine if our scheme for the non-linear interaction of two weak fields inside a Kerr-enhanced medium has been able to generate a Schrödinger cat state. However, as its complete and satisfactory treatment is far beyond our purposes, we want to suggest alternative ways to show the signature of the quantum nature of the state generated. Recently, a sufficient criterion for the inseparability of a continuous variable state has been proposed by Duan et al. [18]. They proved that, for a separable continuous variable state, the total variance of a couple of suitably defined conjugate operators respects a lower bound imposed by the uncertainty relation. For an entangled state, on the other hand, this bound can be violated, providing a sufficient criterion for inseparability of the state. More precisely: assume a continuous variable state composed of subsystems 1 and 2 and take the couple of operators, for both subsystems, \( \{ \hat{X}_i, \hat{P}_i \} (i = 1, 2) \) such that \( [\hat{X}_i, \hat{P}_j] = i \delta_{ij} \). Because of this commutation rule, the simultaneous measurement of both the operators is affected by the Heisenberg uncertainty principle. Following [38], we take an arbitrary, non zero, real parameter \( q \) and define the pair of collective operators:

\[
\begin{align*}
\hat{u} &= |q| \hat{X}_1 + \frac{1}{q} \hat{X}_2 \\
\hat{v} &= |q| \hat{P}_1 - \frac{1}{q} \hat{P}_2.
\end{align*}
\]

(35)

For any separable state, it is possible to show that the following inequality holds [38]:

\[
S = \langle (\Delta \hat{u})^2 \rangle + \langle (\Delta \hat{v})^2 \rangle \geq q^2 + q^{-2},
\]

(36)

with \( \langle (\Delta \hat{u})^2 \rangle \) and \( \langle (\Delta \hat{v})^2 \rangle \) the average variances, calculated over the state of the system, of \( \hat{u} \) and \( \hat{v} \) respectively. In what follows, we will often refer to the total variance \( S \) as to the separability function. It is worthwhile to stress that the criterion is just a sufficient condition for inseparability. The established bound could, thus, be exceeded even by a continuous variable state that is not separable. We will give an explicit example of this possibility in the following discussion.

The criterion by Duan et al. leaves a certain freedom in the choice of the couple of operators to use we need to construct \( \hat{u} \) and \( \hat{v} \). The only limitation imposed is that they have to be conjugate operators.

In problems related to the investigation of the quantum state of light, it is often useful to consider the phase-space of the quadratures:

\[
\begin{align*}
\hat{x} &= \frac{1}{\sqrt{2}} (\hat{b} + \hat{b}^\dagger) \\
\hat{p} &= \frac{i}{\sqrt{2}} (\hat{b}^\dagger - \hat{b}).
\end{align*}
\]

(37)

So defined, the quadratures of a field are a couple of conjugate operators, since \( [\hat{x}, \hat{p}] = i \). Operatively, their probability distribution can be reconstructed by a homodyne detection scheme [3, 35]: the input mode to measure is mixed, at a 50 : 50 beam splitter, with the coherent state of a local oscillator whose phase is directly controllable during the experiment and whose intensity is so high to consider it classically. The difference between the number of photons in the output modes is, then, measured by two photodetectors (one for each output mode). The data collected are proportional to the expectation value of the operator:

\[
\hat{O}_\vartheta = \frac{1}{\sqrt{2}} (\hat{b} e^{i\vartheta} + \hat{b}^\dagger e^{-i\vartheta}).
\]

(38)

that, for \( \vartheta = 0 \) coincides with \( \hat{x} \), while for \( \vartheta = \pi/2 \) is equal to \( \hat{p} \) [33]. The couple of quadratures \( \{ \hat{x}_a, \hat{p}_a \} \), \( \{ \hat{x}_b, \hat{p}_b \} \) relative to the field modes in Eq. (32) are thus well suitable to construct operators \( \hat{u} \) and \( \hat{v} \) for the joint system of modes \( a \) and \( b \). What we need, to calculate the total variance function \( S \), is just the variance of single quadrature (such as \( \langle (\Delta \hat{x}_a)^2 \rangle \) for example) and the expectation value of correlations as \( \langle \hat{x}_a \hat{x}_b \rangle \) or \( \langle \hat{p}_a \hat{p}_b \rangle \), measurable collecting the coincidences at the detectors [38].

We take \( q = 1 \), so that the bound value for the separability of the input state is 2. Unfortunately, the calculation of the separability function \( S \) for the entangled superposition in Eq. (34) leads to \( S \geq 2 \), whatever are the amplitudes \( \alpha \) and \( \gamma \). As we stressed above, this certainly does not mean that the state is separable but just makes this criterion unsuitable to reveal the entangled nature of the investigated state. Because the behaviour of \( S \) is very state-dependent, to bypass the negative result we obtain using Eq. (34) directly, we propose the following strategy. Assume we generated, as described at the end of section 14, an even coherent state of mode \( b \). We then mix it with the vacuum of mode \( c \) at a 50 : 50 BS. Specializing the general rule of a beam splitter in Eq. (34) for \( \beta = 0 \), the joint state of the BS output modes can be written as:

\[
|\phi \rangle_{bc} = N \left\{ \left| \frac{\gamma}{\sqrt{2}} \right\rangle - \left| \frac{\gamma}{\sqrt{2}} \right\rangle + \left| \frac{\gamma}{\sqrt{2}} \right\rangle \right\}_{bc}.
\]

(39)

with \( N = \frac{1}{\sqrt{2(1 + \gamma^2)}} \). This is an entangled coherent state of two field modes: note that, using this procedure, this output state can be obtained only if the radiation mode \( b \) is in an even coherent state. More generally, to
describe the state of mode $b$, we can take the density matrix:

$$\hat{\rho}_b = A \left\{ (\gamma | \gamma \rangle + c|\gamma \rangle \langle -\gamma| + c(|\gamma \rangle \langle -\gamma| + |\gamma \rangle \langle -\gamma|) \right\}_b,$$

(40)

with $0 \leq |c| \leq 1$ and $A$ a normalization constant. For $c = 0$, the state is a statistical mixture; $c = 1$ ($c = -1$) gives us the density matrix of an even (odd) coherent state while, the general case in which $0 < c < 1$ corresponds to a non-optimal generation of the Schrödinger cat state. After the action of the $50 : 50$ BS, the two output modes $\tilde{b}$ and $\tilde{c}$ (whose initial density matrix was $|0\rangle_c (0)$) will be described by:

$$\hat{\rho}_{\tilde{b}\tilde{c}} = A \left\{ \frac{\gamma}{\sqrt{2}} | \frac{-\gamma}{\sqrt{2}} \rangle \langle \frac{\gamma}{\sqrt{2}} | + \frac{-\gamma}{\sqrt{2}} | \frac{\gamma}{\sqrt{2}} \rangle \langle \frac{-\gamma}{\sqrt{2}} | \right\} _{\tilde{b}\tilde{c}} + c \left\{ \frac{-\gamma}{\sqrt{2}} | \frac{\gamma}{\sqrt{2}} \rangle \langle \frac{-\gamma}{\sqrt{2}} | + \frac{\gamma}{\sqrt{2}} | \frac{-\gamma}{\sqrt{2}} \rangle \langle \frac{\gamma}{\sqrt{2}} | \right\} ,$$

(41)

It is evident that state (39) can be retrieved from this density matrix only if $c = 1$ (we have the case of an odd coherent state in parameter $c = -1$).

The quadrature statistics of the two radiation modes are measured by two homodyne detectors, as described above. The collected data allow to estimate the experimental total variance for the input state. This has to be contrasted with what we get calculating the separability function. We thus test, by means of the sufficient criterion for inseparability, the entanglement properties of state (39) in order to infer the state of the radiation mode $b$. Even if, by this means, we are certainly not sure that the state of modes $\tilde{b}$ and $\tilde{c}$ is exactly the entangled coherent state in Eq. (39), we will show the entangled nature of the detected state.

If we calculate $S$ for the case of state $|\Phi\rangle_{\tilde{b}\tilde{c}}$, we get:

$$S_{\text{perfect}} = 2 \left\{ 1 - \gamma^2 \frac{2e^{-2\gamma^2}}{1 + e^{-2\gamma^2}} \right\} ,$$

(42)

A plot of $S_{\text{perfect}}$ as a function of the amplitude $\gamma$ is given in Fig. 4: the total variance function stays below the bound $S = 2$ just until $\gamma \simeq 2$ (we have $S = 1.995$, for $\gamma = 2$) and except $\gamma = 0$. This gives the signature of the entangled nature of the low intensity state we have generated. The dip of the separability function shows a maximum deviation from the state (39) in order to infer the state of the radiation mode $b$. This effect of loss on the collected data can be modeled replacing a real, inefficient, homodyne detector with a beam splitter (transmittivity $\eta$) followed by a perfect homodyne detector. In Fig. 5 the experimental apparatus that considers inefficient homodyne detectors according to the above equivalent model is sketched. Each beam splitter BS$_{\eta}$, that mixes a mode of the signal to measure with a vacuum state, transmits the signal with probability $\eta$ and reflects it with probability $1 - \eta$. The amount of reflected input field gives a measure of the losses of the detection apparatus, so that the quantum efficiency of this latter can be identified with $\eta$ itself. To avoid stray light to enter in the perfectly efficient homodyne detector, we can imagine that the reflected output field enters a blackbody absorber. Mathematically, this is equivalent to tracing out the degrees of freedom relative to the absorbed field mode. What the perfect homodyne function
detectors measures, thus, is the statistic of the quadratures of the transmitted beams, irrespective of the state of the reflected ones.

![Diagram](image1)

**FIG. 5:** Sketch of the proposed scheme to infer the value of the total variance for the entangled state of modes $b$ and $\hat{c}$ when the inefficiency of homodyne detectors is taken into account. With $D_1$ and $D_2$ we indicate perfect homodyne detectors that have to measure the quadratures of modes $d$ and $e$. These are the fields transmitted (with probability $\eta$) by two beam splitters, $BS_\eta$, whose effect models the inefficiency of the homodyne detectors. The beams reflected by $BS_\eta$ are absorbed by blackbodies. The local oscillators are prepared in very intense coherent states. This allows to treat them as classical fields. Their phases are experimentally controlled and adjustable. $BS_1$ and $BS_1$ are 50 : 50 beam splitters.

![Diagram](image2)

**FIG. 6:** Behavior of the separability function for state (38), as a function of the amplitude $\gamma$, when imperfection in the homodyne detection are taken into account. Here, the dot-dashed curve is for detection efficiency $\eta = 0$, the dashed one is for $\eta = 0.4$ and the solid curve is for $\eta = 0.8$. For lower $\eta$, the minimum values of $S_{\text{imperfect}}$ shift toward higher $\gamma$ values: this is because the lower is the efficiency of the homodyne detectors, the more state (38) resembles a Gaussian state.

The calculation of the total variance for the quadratures of modes $b$, $\hat{c}$ when the detectors have an equal quantum efficiency $\eta$ leads to what is shown in Fig. 6. The separability function seems to keep its functional features even in the case of imperfect detection. However, some differences, with respect to $S_{\text{perfect}}$, appear. As the quantum efficiency of the homodyne detectors reduces, the minimum of the total variance shifts toward higher values of $\gamma$ (see Fig. 6), enlarging the range of amplitudes for which the separability function has values below 2.

This effect can be explained directly referring to the probability that the homodyne detector measures a value $x$ of the quadrature $\hat{x}$. Without loss of generality, but avoiding the lengthy calculation relative to state (39), we investigate an even coherent state. We let this state to be mixed with a vacuum field at a BS of transmittivity $\eta$. As before, the resulting transmitted mode is then measured by a perfect homodyne detector while the reflected field is traced out. We finally get the following probability distribution for the in-phase quadrature $\hat{x}$:

$$P_{\gamma,\eta,0}(x) = \frac{\left\{ 2e^{-x^2-2\gamma^2} + e^{-(x-\sqrt{2}\gamma)^2} + e^{-(x+\sqrt{2}\gamma)^2} \right\}}{2\sqrt{\pi}(1+e^{-2\gamma^2})}. \quad (43)$$

It shows that $P_{\gamma,\eta,0}(x)$ is composed of two Gaussian hills centered at $\pm\sqrt{2}\gamma$ plus a third term that, for $\gamma$ sufficiently large, is negligible with respect to the others (even for $\gamma = 2$ it is negligible). The larger is the amplitude $\gamma$, the larger the Gaussian hills are apart. However, if an efficiency $\eta < 100\%$ is considered, the distance between the Gaussian hills for low values of $\gamma$ is strongly reduced and the joint state appears more and more similar to a Gaussian state. To observe well separated Gaussian bells we have to go toward larger $\gamma$. It is possible to show that the same effect is observed in the probability distribution of an entangled coherent state as Eq. (39), with the suitable modifications due to the different nature of the state. This explains the behaviour of the separability function for an imperfect homodyne detector.

However, the success of the total variance criterion for
low values of the quantum homodyne inefficiency has not to be considered positively. The imperfections in the detection device tend to hide the features of the input state that appears as a Gaussian state even if, in reality, it is well far to be Gaussian. This means that, in order to reliably test the entangled nature of the input state, a sufficiently large \( \eta \) has to be considered. Realistic values of the homodyne detector efficiency range between 0.6 and 0.85. In particular, according to our calculations, \( \eta = 0.8 \) seems to be a good trade off between the reliability of the total variance criterion and the realism of an experimentally achievable quantum homodyne efficiency.

From the above analysis, it appears that for \( \gamma \) larger than \( \gamma \approx 2 \), it is not possible to get any information about the entanglement in the input state of modes \( \tilde{b} \) and \( \tilde{c} \) from the total variance of quadrature amplitudes. We have to look for other detection strategies.

If we still refer to the case of a generated even coherent state in Eq. (33), the characteristic of the superposition of \( |\gamma\rangle_{b} \) and \( |\gamma\rangle_{b} \) is well revealed by homodyne measurements, as pointed out by Yurke and Stoler [3]. As commented above, the amplitude of the components of an even coherent state can be inferred directly from the probability distribution of the in-phase quadrature.

If instead of \( \tilde{x} \) we measure the statistical distribution for \( \vartheta = \pi/2 \) in Eq. (33), the following function has to be found:

\[
P_{\gamma, \eta, \pi/2}(x) = \frac{e^{-x^2} \left\{ 1 + e^{-2(1-\eta)^2} \cos(2\sqrt{2\gamma}x) \right\}}{\sqrt{\pi(1 + e^{-2\gamma^2})}}.
\]

This probability oscillates and is modulated, at the same time, by a Gaussian function (solid curve in Fig. 8). The combination of an even coherent state can be inferred directly from measurements, as pointed out by Yurke and Stoler [3].

If we vary \( \vartheta \) from 0 to \( \pi/2 \), it is, indeed, straightforward to prove that, if instead of a linear combination of \( |\gamma\rangle_{b} \) and \( |\gamma\rangle_{b} \) the input state was the mixed state of Eq. (41) with \( \alpha = 0 \), then this oscillatory behavior would be absent. Thus, a homodyne detection scheme is able to discern a Schrödinger cat state from a mixed state of two coherent states which are mutually \( \pi \) out of phase [3].

It is important to stress the effect, on the oscillatory pattern, due to the Gaussian modulation: as it is evident from Fig. 8, even a small reduction of \( \eta \) leads, for a small amplitude coherent state, to the disappearance of the oscillations. Mathematically, this is due to the factor \( 1 - \eta \) that governs the width of the Gaussian function in front of the oscillatory term: the smaller \( \eta \) is, the more rapidly the Gaussian function goes to zero, washing out the interference pattern. The effect is, clearly, more evident for large values of \( \gamma \). This means that this scheme is very vulnerable to the detection inefficiencies.

An alternative approach to the investigation of the coherences in the quantum superposition of \( |\gamma\rangle_{b} \) and \( |\gamma\rangle_{b} \), when the total variance criterion fails, can be the following. We prepare, once more, the entangled coherent state in Eq. (34) using an even coherent state as input. Similarly to the technique used by Kwiat et al. [4], we operate unitarily on one of the components of \( |\phi\rangle_{b,s} \). Then, we detect the coincidences between the counts collected by two photodetectors facing the output modes \( \tilde{c} \) and \( g \) (see Fig. 9).

In the restricted Hilbert space spanned by the orthogonal even and odd coherent states, the rotation of a generic state \( |\delta\rangle_{b} = A|\gamma\rangle_{b} + B|\gamma\rangle_{b} \) can be performed by a displacement operator \( D_k(i\vartheta) \) \( \vartheta \in \mathbb{R} \) that, acting on \( |\delta\rangle_{b} \), transforms it into:

\[
|\Delta\rangle = Ae^{\frac{i\vartheta}{\sqrt{2}}} \left\{ \frac{\gamma}{\sqrt{2}} + i\vartheta \right\}_{\tilde{b}} + Be^{-\frac{i\vartheta}{\sqrt{2}}} \left\{ -\frac{\gamma}{\sqrt{2}} + i\vartheta \right\}_{\tilde{b}}. \tag{45}
\]

If we take \( \vartheta \ll \gamma/\sqrt{2} \), on the Bloch-sphere of the restricted Hilbert space that we are treating, the above equation approximates well the state \( \hat{R}_{\hat{b}}(\alpha)|\delta\rangle_{\hat{b}} \) with \( \hat{R}_{\hat{b}}(\alpha) \) the rotation operator, by an angle \( \alpha/2 = \sqrt{2}\gamma\vartheta \) around the Bloch-sphere z-axis. Experimentally, such a rotation can be accomplished superimposing mode \( \hat{b} \) on the coherent state \( |\mathcal{E}\rangle \) of an auxiliary mode \( f \), using a beam splitter with a high-transmission coefficient \( T \). As shown in [42], the transformation operated by the \( T \rightarrow 1 \) beam splitter (BS2 in Fig. 8) gives an entangled state of two output field modes. The reduced density matrix that describes the state of the output mode \( g \) only can then be approximated by that of a displaced state according to \( \hat{\rho}_g = \hat{D}_b(i\mathcal{E}\sqrt{1-T})\hat{\rho}_b\hat{D}_b^\dagger(i\mathcal{E}\sqrt{1-T}) \) where \( \hat{\rho}_b \) is the density matrix of the input field [42].

If we vary \( \mathcal{E} \) in such a way that \( \vartheta = \mathcal{E}\sqrt{1-T} \ll \gamma/\sqrt{2} \), that is:

\[
\mathcal{E} = \frac{\alpha}{2\sqrt{2(1-T)^{\gamma}}}, \tag{46}
\]

then, just controlling the amplitude of this ancillary mode we can appropriately rotate the state of mode \( \tilde{b} \) by \( \alpha/2 \).
Following this lines, the entangled coherent state in Eq. (39), after the interaction of $b$ with $f$ at the rotation beam splitter BS$_2$, becomes:

$$|\Phi\rangle_{g}\bar{g} = \mathcal{N} \left\{ e^{i\frac{\theta}{2}} \left| \frac{\gamma}{\sqrt{2}} \right\rangle \left| \frac{-\gamma}{\sqrt{2}} \right\rangle + e^{-i\frac{\theta}{2}} \left| \frac{-\gamma}{\sqrt{2}} \right\rangle \left| \frac{\gamma}{\sqrt{2}} \right\rangle \right\} \left| g\bar{g} \right\rangle.$$

(47)

The output modes $\bar{c}$ and $g$ are then sent to detector A and B respectively, where the photo-count coincidences are revealed. We model the photodetectors as Geiger-like On/Off Photo-Detectors (O/O PD). These particular devices just discriminate the vacuum from an input with any photons, irrespective of what the photon number is. Again, losses make the quantum efficiency of the an O/O PD not optimal, so that some of the coincidences will be missed. Quantum mechanically, an inefficient O/O PD can be described by means of a suitably defined Positive-Operator-Valued-Measure (POVM), that is a set of diagonalizable, having positive-eigenvalues, projection operators. The appropriate choice for this case is the following:

$$\begin{cases}
    \Pi_{\text{click}}^{(i)}(\eta) = \sum_{n=0}^{\infty} (1-\eta)^n |n\rangle_i \langle n| & (i = A, B)
    \\
    \Pi_{\text{click}}^{(i)}(\eta) = \mathbb{1} - \Pi_{\text{click}}^{(i)}(\eta),
\end{cases}$$

We assume the same efficiency $\eta$ for both the detectors. In the above definitions $1-\eta$ is the probability that a single detector lacks to reveal a photon and the sum over all the photon populations takes in account the impossibility to distinguish the photon number in the incident field. Within the POVM formalism, the probability that the O/O PD click within the same detection window is given by:

$$P_{2\text{clicks}}(\gamma, \eta, \alpha) = Tr_{g\bar{g}} \left\{ |\Phi\rangle_{g\bar{g}} \langle \Phi| \Pi_{\text{click}}^{(A)}(\eta) \Pi_{\text{click}}^{(B)}(\eta) \right\} = C \left\{ \left( e^{-\frac{\gamma^2}{2}} - e^{-\frac{\eta^2 - \eta^2\gamma^2}{2}} \right)^2 + \cos \alpha \left( e^{-\frac{\gamma^2}{2}} - e^{-\frac{\eta^2 - \eta^2\gamma^2}{2}} \right)^2 \right\},$$

(49)

with $C = 2 e^{-\gamma^2}\lambda^2$. Let us look to the asymptotic behaviour of the above probability: for $\eta \rightarrow 0$, that is for highly inefficient detectors, we get $P_{2\text{clicks}}(\gamma, 0, \alpha) \rightarrow 0$. If the limit $\eta \rightarrow 1$ is instead considered, Eq. (49) shows that $P_{2\text{clicks}}(\gamma, 1, \alpha) \rightarrow 2 \left( 1 + e^{-\gamma^2} \cos \alpha \right)$. The oscillating part in $P_{2\text{clicks}}(\gamma, 1, \alpha)$ is the evidence of the coherences established in the even coherent state. Unfortunately, it has an exponential pre-factor that can cause experimental difficulties (for $\gamma \simeq 2$ and $\eta \simeq 0.75$, a visibility of about 1% is achieved). Furthermore, possible errors connected to the rotation of a Schrödinger cat state have to be considered.

Once the entangled nature of the input state $|\Phi\rangle_{g\bar{g}}$ is recognized, however, the inference about the state of any $b$ is possible: for example, if the non-linear interaction via a Schrödinger cat state, this results in a loss of information relative to the quantum superposition of two coherent states. It is however worthwhile to stress that for high value of $\eta$, the oscillations in $P_{\gamma,\eta,\pi/2}(x)$ survive even for large values of $\gamma$.

The hard task represented by the detection of an even (odd) coherent state or, more generally, of an entangled coherent state can be made easier by the recently improved sensitivity of the available detectors. Values of $\eta \sim 0.8$ are realistic for a detector operating in a Geiger-mode and very sensitive photo-detectors, with an efficiency as high as $\eta \simeq 0.93$, have been developed. They however require a low temperature to properly operate.
VI. CONCLUSIONS

We have proposed a fully quantized picture of the model for double-EIT recently discussed by Petrosyan and Kurizki [17]. Our approach is based on a full Hamiltonian method. This allows to bypass the analytical solution of the equations of motion of the atomic density matrix elements. It simplifies the computational problems related to systems that involve many atomic energy levels coupled by electromagnetic fields.

As shown for the first time in [16], the non-linear interaction of two beams of light that pass through a dense atomic medium is optimized by a double-EIT regime in which both the fields propagate with a strongly reduced, equal, group velocity. The atomic model proposed in [17] seems to be a good candidate to the experimental realization of such a physical condition. In our fully quantum version of this model, we have shown that the quantum dynamics of one of the interacting beams is dramatically dependent on the intensity of the second and viceversa. Our results are consistent with those reported in [16].

Starting from these results, we have written an effective interaction Hamiltonian that, when the field is initially prepared in two coherent states, leads to the possibility to generate entangled coherent states and even or odd coherent states (Schrödinger cat states). In order to investigate the quantum features of a generated even (odd) coherent state, we described a scheme able to measure the total variance function of the involved modes quadratures [39]. For low amplitudes of the investigated entangled coherent state, the value of this total variance is well below the bound imposed by the inseparability criterion suggested in [18]. We also investigated the effects of an imperfect non-linear process and of detection inefficiencies on the above results. We found our scheme robust against homodyne detection losses. For the cases in which the total variance criterion is unuseful, we suggested a detection scheme based on the unitary manipulation of one of the modes in the entangled coherent state followed by the detection of coincidences of photo-counts. We discussed possible sources of errors and experimental difficulties we expect to appear in a real experiment, finding that an optimal detection protocol basically requires high efficiency of the detectors.

Acknowledgments

We want to thanks Dr. Anatoly Zayats for the useful discussions about optical Kerr effect enhancement.
