Cytotoxicity of *Eupatorium cannabinum* L. ethanolic extract against colon cancer cells and interactions with Bisphenol A and Doxorubicin

Edna Ribeiro-Varandas¹, Filipe Ressurreição¹, Wanda Viegas¹ and Margarida Delgado¹,²*

**Abstract**

**Background:** *Eupatorium cannabinum* L. has long been utilized in traditional medicine, however no information is available regarding cellular effects of full extracts. Here we assessed the effects of *E. cannabinum* ethanolic extract (EcEE) on the colon cancer line HT29. Potential interactions with bisphenol A (BPA) a synthetic phenolic compound to which humans are generally exposed and a commonly used chemotherapeutic agent, doxorubicin (DOX) were also evaluated.

**Methods:** HT29 cells were exposed to different concentrations (0.5 to 50 μg/ml) of EcEE alone or in combination with BPA or DOX. Cell viability was analyzed through resazurin assay. Gene transcription levels for NCL, FOS, p21, AURKA and bcl-xl were determined through qRT-PCR. Cytological analysis included evaluation of nuclear and mitotic anomalies after DAPI staining, immunodetection of histone H3 lysine 9 acetylation (H3K9ac) and assessment of DNA damage by TUNEL assay.

**Results:** Severe loss of HT29 cell viability was detected for 50 μg/ml EcEE immediately after 24 h exposure whereas the lower concentrations assayed (0.5, 5 and 25 μg/ml) resulted in significant viability decreases after 96 h. Exposure to 25 μg/ml EcEE for 48 h resulted in irreversible cell damage leading to a drastic decrease in cell viability after 72 h recovery in EcEE-free medium. 48 h 25 μg/ml EcEE treatment also induced alteration of colony morphology, H3K9 hyperacetylation, transcriptional up regulation of p21 and down regulation of NCL, FOS and AURKA, indicating reduced proliferation capacity. This treatment also resulted in drastic mitotic and nuclear disruption accompanied by up-regulation of bcl-xl, limited TUNEL labeling and nuclear size increase, suggestive of a non-apoptotic cell death pathway. EcEE/BPA co-exposure increased mitotic anomalies particularly for the lowest EcEE concentration, although without major effects on viability. Conversely, EcEE/DOX co-exposure decreased cell viability in relation to DOX for all EcEE concentrations, without affecting the DOX-induced cell cycle arrest.

**Conclusions:** EcEE has cytotoxic activity on HT29 cancer cells leading to mitotic disruption and non-apoptotic cell death without severe induction of DNA damage. Interaction experiments showed that EcEE can increase BPA aneugenic effects and EcEE synergistic effects with DOX supporting a potential use as adjuvant in chemotherapeutic approaches.

**Background**

*Eupatorium cannabinum* L., commonly known as hemp-agrimony is a robust perennial herbaceous plant of the Asteraceae family and the only species of the Eupatorium genus found in Europe occurring also throughout North Africa and Asia [1]. *E. cannabinum* has long been used for medicinal purposes being referred to by Greeks and Romans as well by the medieval Persian physician Avicenna, for what is also known as *Eupatorium of Avicenna*, and later by the Portuguese Renaissance pioneer in tropical medicine, Garcia da Orta (1563) [2]. Presently, hemp-agrimony is used in both Chinese [3] and Indian [4] traditional medicine as well as in natural medicine in western countries [5] with very diverse therapeutic indications including influenza-like illnesses [6], hypertension [3,4,6] and as an anti-tumour agent [4]. *E. cannabinum* extracts has been previously characterized and reveal the

presence of sesquiterpenes [7], pyrrolizidine alkaloids [3,8] as well as several phenolic compounds [9,10].

Sesquiterpenes were found to be a major fraction (43.3%) of essential oil from *E. cannabinum* aerial parts [11], being eupatoriopicrin the main component [7]. Eupatoriopicrin has been associated with induction DNA damage in Ehrlich ascites tumour [12] as well as with cytostatic activity and both *in vitro* and *in vivo* tumour growth inhibition properties in Lewis lung carcinoma and FIG 26 fibrosarcoma [13].

Pyrrolizidine alkaloids are generally associated with genotoxicity and tumourigenic activities [14], however the isomers intermedine and lycopsamine indentified in *E. cannabinum* have low genotoxic potency [15] and lycopsamine was shown to be non-tumourigenic in rats [16]. Additionally the phenolic compounds identified in this plant have been described to have anti-inflammatory [9], anti-parasitary [17], as well as anti-proliferative effects in several cell lines [18]. In particular, jaceosidin cytotoxic effects have been demonstrated in normal and cancer endometrial cells [19] and hispidulin was shown to efficiently inhibit growth of gastric cancer cells [20] and liver carcinoma cells without significant toxic effect in normal liver cells [21].

Although the effects of specific components of *Eupatorium cannabinum* L. extracts have been described, the cellular effects of the full extracts have not, until now, been investigated. Thus, here different concentrations of *Eupatorium cannabinum* L. ethanolic extract (EcEE) were evaluated on the colon cancer cell line HT29. Moreover we also analyzed its interactions with the synthetic phenolic compound bisphenol A (BPA) as well as with the chemotherapeutic agent Doxorubicin (DOX). Human exposure to BPA is considered generalized in the common population and its adverse health effects are the focus of intense investigation [22,23]. On the other hand, DOX is a commonly used chemotherapeutic agent to which cell resistance can emerge [24,25]. Plant constituents are a major source of bioactive compounds and several plants have been investigated aiming to identify potential synergistic effects with DOX (reviewed in [26]).

**Methods**

*Eupatorium cannabinum* L. ethanolic extract

*Eupatorium cannabinum* L. (Asteraceae) aerial parts were collected in the Rossas fields of Arouca village, Portugal, in August during mass flowering. Formal identification of plant material was performed by A.P. Paes from “João de Carvalho e Vasconcellos Herbarium” at Instituto Superior de Agronomia (Lisboa, Portugal). A voucher specimen was deposited in the same herbarium under the number LISI 1503/2013. Plant material was dried and powdered using a grinder and ethanolic extract (EcEE) was obtained by soaking the material in absolute ethanol for 48 h at room temperature with gentle shaking. The extract were filtered and concentrated under vacuum on a rotary evaporator at 40°C and stored at −20°C for further use.

**Cellular cultures, reagents and treatments**

HT29 cells were purchased from European Collection of Cell Cultures (ECACC, UK) and cultivated in RPMI medium under standard conditions as previously described [27]. Before treatments and experiments HT29, cells were allowed to stabilize for 24 h in standard medium and further cultivated in EcEE supplemented media for 24 h, 48 h or 96 h. Crude ethanolic extract was dissolved in ethanol to a final work concentration of 50 mg/ml before use and added to the culture media at four different final concentrations (0.5 μg/ml, 5 μg/ml, 25 μg/ml and 50 μg/ml). Bisphenol A (Sigma-Aldrich) was freshly diluted in ethanol and added to the culture media to the final concentration of 1 μg/ml (4.4 μM) that corresponds to the established Tolerable Daily Intake (TDI) level of 50 μg/kg BW/day [28,29] considering an average body weight of 70 Kg and daily consumption of 3 litres of preformed water. Doxorubicin (DOX) (AppliChem) was dissolved in water at stock concentration of 1 mg/ml and added to the culture media to final concentration of 2.5 μg/ml (4 μM) which corresponds to a therapeutic dosage [30]. For the combined EcEE/BPA or EcEE/DOX exposures, cells were pre-exposed to EcEE for 24 h followed by additional 24 h of simultaneous exposure to EcEE and BPA or EcEE and DOX. Single 24 h BPA or DOX exposure was carried-out in equivalent cell cultures. For evaluation of cell recovery capacity after treatments cells were cultivated for additional 72 h in standard culture medium. Negative controls were performed for all experiments using cells grown in standard culture medium as well as cells grown in medium supplemented with ethanol at final concentration of 170 μM, corresponding to the final concentration of ethanol used as vehicle for all EcEE concentrations as well as for BPA.

**Cell viability**

Cell viability was evaluated by CellTiter-Blue assay (Promega) following manufacturer’s instructions. Cells were plated on 96-well plates at a density of 3.2 × 10^4 cells/well and after treatments were incubated for 4 h with CellTiter-Blue Reagent. Additional negative controls were performed in the absence of cells to guarantee that the utilized media did not interfere with fluorescence readings. Experiments were repeated at least three times with a minimum of three replicates per experiment.

**DAPI staining, TUNEL assay and immunodetection**

For cytological analysis cells were grown over glass coverslips coated with 0.2% (v/v) gelatin (Sigma-Aldrich)
and after treatments fixed in 4% (p/v) formaldehyde in PBS. For evaluation of colony morphology, mitotic index as well as mitotic and nuclear anomalies cells were DAPI stained and mounted on glass slides with antifade AF1 (Citifluor). DNA damage assessment with TUNEL assay (Roche) was performed according to manufacturers’ instructions. Immunodetection of H3K9ac and α-tubulin was performed in fixed cells as previously described [27] using the primary antibodies anti-acetyl-histone H3(Lys 9) (ab10812, Abcam) and anti-α-Tubulin (T9026, Sigma-Aldrich) detected with FITC or Cy3 conjugated secondary antibodies. Images were captured using the appropriate excitation and emission filters and recorded using an epi-fluorescence microscope Zeiss Axioskop2 equipped with a Zeiss AxioCam MRc5 digital camera. ImageJ software (http://rswebw.nih.gov/ij/) was used for nuclear area measurements. The analysis was performed in the pooled results of at least two independent experiments with at least two replicates.

cDNA isolation and real-time quantitative PCR
Transcriptional analysis was performed by quantitative real-time PCR (qRT-PCR) for the CellTiter-Blue assay was utilized and effects of different concentrations of EcEE (0.5 μg/ml, 5 μg/ml, 25 μg/ml and 50 μg/ml) were evaluated after 24 h, 48 h and 96 h of exposure (Figure 1-A). The higher EcEE concentration (50 μg/ml) resulted in a severe decrease of cell viability after 24 h exposure and complete loss of viability at subsequent time points analyzed (48 h and 96 h). On the other hand, no decrease in cell viability was detected after 24 h or 48 h for the lower EcEE concentrations, and a slight increase in fluorescence was observed after 24 h and 48 h for 25 μg/ml EcEE. However, significant decreases in cell viability were detected for the three lower EcEE concentrations after 96 h of exposure, and particularly for 25 μg/ml EcEE (~18.89%, −14.55% and −73.25% for 0.5 μg/ml, 5 μg/ml and 25 μg/ml, respectively). Taken together, these results indicate more severe effects after prolonged exposure. This is further shown by IC50 values of 46.75, 44.64 and 13.38 μg/ml for 24, 48 and 96 h, respectively.

**Statistical analysis**
Student’s t test was used for statistical analysis of gene transcription, cell viability, nuclear area and nuclear fragmentation. No significant differences were detected between control and vehicle for all parameters analysed, and results are shown in relation to control. GraphPad Prism 6 software was used for determination of IC50 values.

**Results**
*E. cannabinum* ethanolic extract decreases HT29 cell viability
Assessment of cell viability was performed to test potential cytotoxic effects of *E. cannabinum* ethanolic extract (EcEE) on HT29 cells. For this, CellTiter-Blue assay was utilized and effects of different concentrations of EcEE (0.5 μg/ml, 5 μg/ml, 25 μg/ml and 50 μg/ml) were evaluated after 24 h, 48 h and 96 h of exposure (Figure 1-A). The higher EcEE concentration (50 μg/ml) resulted in a severe decrease of cell viability after 24 h exposure and complete loss of viability at subsequent time points analyzed (48 h and 96 h). On the other hand, no decrease in cell viability was detected after 24 h or 48 h for the lower EcEE concentrations, and a slight increase in fluorescence was observed after 24 h and 48 h for 25 μg/ml EcEE. However, significant decreases in cell viability were detected for the three lower EcEE concentrations after 96 h of exposure, and particularly for 25 μg/ml EcEE (~18.89%, −14.55% and −73.25% for 0.5 μg/ml, 5 μg/ml and 25 μg/ml, respectively). Taken together, these results indicate more severe effects after prolonged exposure. This is further shown by IC50 values of 46.75, 44.64 and 13.38 μg/ml for 24, 48 and 96 h, respectively.
To detect possible deferred effects of the EcEE exposure, cell viability was also evaluated after 72 h of recovery in standard culture media (Figure 1-B) and revealed a severe decrease exclusively for 48 h exposure to 25 μg/ml EcEE (−75.59%).

To better understand the effects of EcEE immediately after 48 h exposure, gene transcription analysis was carried out for three proliferation-associated genes, namely nucleolin (NCL), p21, and FOS (Figure 1-C). Similarly to the cell viability results, no significant differences in transcription levels were detected after 48 h exposure to EcEE concentrations equal to or lower than 5 μg/ml. Conversely, 25 μg/ml EcEE exposure resulted in significant differences in mRNA levels of all three genes, corresponding to down regulation of both NCL and FOS (Log2 fold change = −0.813 ± 0.248 and −0.741 ± 0.078, respectively), and up regulation of p21 (Log2 fold change = 1.393 ± 0.128). Evaluation of colony morphology was performed immediately after EcEE treatments by DAPI staining. Again, significant alterations in colony morphology were detected after exposure to 25 μg/ml EcEE for 48 h, evident as cells being more dispersed and showing a flattening of cellular aggregates in comparison to controls with no detectable effect for 5 μg/ml EcEE (Figure 1-D) or 0.5 μg/ml EcEE (not shown).

**E. cannabinum** ethanolic extract induces alterations in nuclear structure and mitotic disruption

A detailed cytological analysis was performed for 0.5 μg/ml, 5 μg/ml and 25 μg/ml EcEE concentrations after 48 h of exposure and again significant nuclear alterations were observed exclusively for 25 μg/ml EcEE (Figure 2-A). This was obvious as the prominent occurrence of micronuclei and highly condensed nuclei (pyknosis) scattered throughout cell aggregates as well as fragmented nuclei (karyorrhexis), revealing irreversible nuclear damage. In addition, TUNEL assay showed that induction of DNA breaks also occurred after 48 h exposure to 25 μg/ml EcEE although at a much lower level than nuclear abnormalities, as many of the abnormal nuclei were not TUNEL positive and in positive nuclei labeling was sparse (Figure 2-B). For the two lower EcEE concentrations (0.5 and 5 μg/ml) no TUNEL positive nuclei were detected (not shown) as observed for control. Importantly, qRT-PCR transcriptional analysis of the anti-apoptotic bcl-xl gene revealed that EcEE exposure induced a significant up
regulation of this gene not only at 25 \( \mu \)g/ml (Log2 fold change = 0.528 ± 0.243) but also at 5 \( \mu \)g/ml, although to a lesser extent (Log2 fold change = 0.158 ± 0.067) (Figure 2-C).

Quantification of the nuclear area of non-pyknotic and non-fragmented DAPI stained nuclei showed a significant increase in this parameter in relation to control for cells exposed to 25 \( \mu \)g/ml EcEE but not to the lower EcEE concentrations (not shown). The increment in nuclear area after the 48 h exposure to 25 \( \mu \)g/ml EcEE corresponded in average to 48.8% (n > 70 for each growth condition, p < 0.0001 for 25 \( \mu \)g/ml EcEE in relation to control) and was accompanied by an evident increase in cellular area revealed by \( \alpha \)-tubulin immunodetection (Figure 2-D). Moreover, evident chromatin enrichment in histone H3 acetylated on lysine 9 (H3K9ac) was detected also for 48 h 25 \( \mu \)g/ml EcEE (Figure 2-E) whereas no alteration was observed for either 0.5 \( \mu \)g/ml or 5 \( \mu \)g/ml EcEE (not shown).

The effects of exposure to EcEE were further evaluated on mitotic cells after DAPI staining. No significant variation was observed in the mitotic index between control, vehicle and EcEE independently of the concentration assayed (varying between 4.57 and 5.94). On the other hand, although mitotic anomalies, particularly multipolar metaphases and anaphases, are a common feature of HT29 cells and therefore observed both in control and vehicle (6.67% and 11.76% after 24 h; 6.38% and 10.67% after 48 h, for control and vehicle respectively), the percentage of abnormal mitosis increased after exposure to all EcEE concentrations (Figures 3-A and B). Although a slight increase of abnormal mitosis was already detectable for 0.5 \( \mu \)g/ml EcEE, this effect was greater for 5 \( \mu \)g/ml EcEE (41% and 44% after 24 h or 48 h, respectively). After exposure to 25 \( \mu \)g/ml EcEE, most mitotic cells presented abnormalities (80% and 63% after 24 and 48 h, respectively). Although the frequency of abnormal mitosis was greater after 24 h at the higher EcEE concentration, these results clearly indicate that EcEE induces mitotic disruption in a dose dependent manner. Interestingly, qRT-PCR analysis revealed a significant down regulation of AURKA (Log2 fold change = −0.938 ± 0.146), a
gene that encodes a key protein for mitotic chromosome segregation (Figure 3-C).

**E. cannabinum** ethanolic extract increases Bisphenol A induced mitotic disruption

Interactions between EcEE and the environmental pollutant BPA at reference level (1 μg/ml) were evaluated. Co-exposure to EcEE and BPA did not affect cell viability immediately after treatments, as no significant differences were detected in relation to control (Figure 4-A). After 72 h recovery in standard medium, a severe decrease in cell viability (−93.48%) was exclusively observed for 25 μg/ml EcEE/BPA (Figure 4-A) which was even greater than that observed for 25 μg/ml EcEE alone (Figure 1-B).

Cytological evaluation of mitotic disruption after DNA DAPI staining (Figure 4-B) revealed that BPA exposure alone increased the level of mitotic anomalies to 20.5%. Interestingly, a stronger effect of BPA co-exposure was observed for the lowest EcEE concentration assayed (0.5 μg/ml), which resulted in 41% of abnormal mitosis (Figure 4-B) compared to 25% observed for EcEE alone (Figure 3-B). In contrast, no evident effect of BPA was
detected for the intermediate EcEE concentration, evident as an identical level of 44% for 5 μg/ml EcEE alone or in combination with BPA. Co-exposure to the higher EcEE concentration (25 μg/ml) and BPA resulted in a particular high level of mitotic anomalies (75%), although the difference in relation to EcEE alone (63%) was smaller than that observed for the lower EcEE concentrations.

**Cytotoxic effects of Doxorubicin are enhanced by E. cannabinum**

Potential interactions between different concentrations of EcEE and the chemotherapeutic drug doxorubicin (DOX) at a therapeutic concentration of 2.5 μg/ml were investigated. Immediately after exposure, DOX alone resulted in a slight decrease in cell viability (−4.15%) (Figure 5-A). Interestingly, the loss of cell viability was significantly more pronounced after co-exposure to EcEE/DOX for all EcEE concentrations (−10.03%, −19.88% and −18.67% for 0.5 μg/ml, 5 μg/ml and 25 μg/ml, respectively) (Figure 5-A) contrasting with the lack of effects observed for 48 h exposure to EcEE alone (Figure 1-A). Recovery experiments showed that the effects of both DOX and 25 μg/ml EcEE/DOX have long lasting negative effects on viability, apparent as prominent decreases in cell viability after 72 h recovery in standard medium in relation to what was observed immediately after exposure (Figure 5-A). After recovery, EcEE 25 μg/ml/DOX exposure resulted in an even more pronounced loss of cell viability (−93.95%) than that observed for exposure to 25 μg/ml EcEE alone (Figure 1-B). Conversely, for the lower EcEE concentrations, no significant differences were detected between exposure to DOX alone and in combination with EcEE (Figure 1-B).

Cytological analysis after DAPI staining showed a complete absence of cells at mitosis after exposure to DOX alone or in combination to EcEE, independently of the EcEE concentration. Conversely, both pyknotic cells and fragmented nuclei were observed after exposure to DOX alone or in combination to EcEE (Figure 5-B). Since identical nuclear alterations were also observed after single exposure to 25 μg/ml EcEE (Figure 2-E), the levels of nuclear fragmentation were compared between single exposure to 25 μg/ml EcEE or DOX alone and the combination of both (Figure 5-C). The results revealed that the induction of nuclear fragmentation is significantly higher for 25 μg/ml EcEE/DOX combined exposure (20.28%) than for either DOX (7.63%) or 25 μg/ml EcEE (8.89%) alone.

**Discussion**

Eupatorium cannabinum L. is a commonly utilized plant for alternative and/or complementary medicine treatments [6] including as an anticancer agent [4]. Although cellular effects of particular phytochemicals known to be present in *E. cannabinum* have been previously described, to our knowledge this is the first study that evaluates the cytotoxic potential of *E. cannabinum* extracts on human cancer cells. Here we demonstrated that *E. cannabinum* ethanolic extract (EcEE) has cytotoxic effects on HT29 colon cancer cells in a time and dose dependent manner. IC50 were similar after 24 and 48 h (46.75 and 44.65 μg/ml, respectively) but considerably lower (13.38 μg/ml) after 96 h of exposure. Cytotoxic activity has also been demonstrated for extracts from other *Eupatorium* species. For *E. perfoliatum* ethanolic extract, IC50 values between 12 and 14 μg/ml were obtained after 24 h exposure in three distinct mammalian cell lines.
[32]. In MCF7 breast cancer cells a time dependent effect was also observed for *E. odoratum* ethyl acetate extract (IC$_{50}$ of 65.72, 83.88 μg/ml and 92.84 μg/ml for 24, 48 and 72 h, respectively) while for acetone extract higher IC$_{50}$ values were obtained but without a direct correlation with exposure time (133.9, 163.0 and 147.8 μg/ml for 24, 48, and 72 h respectively) [33]. The immediate cytotoxicity observed here for EcEE was lower than that obtained for *E. perfoliatum* ethanolic extract and higher than that of ethyl acetate or acetone extracts from *E. odoratum*. Interestingly the time dependent increase in cytotoxicity of EcEE was only detected for the longer exposure time (96 h). Moreover, a delayed effect on cell viability was detected after 48 h exposure to EcEE at 25 μg/ml. This was also associated with disruption of cell colony three-dimensional arrangement, a generalized increase in nuclear area and H3K9 hyperacetylation. Relevantly, gene transcription analysis revealed a significant reduction in the mRNA levels of *FOS*, which encodes for a nuclear protein from AP-1 transcription factor complex, and nucleolin (*NCL*) the most profuse non-ribosomal protein of the nucleolus. Both *FOS* and nucleolin are involved in the regulation of cell proliferation [34,35] as their decreased expression has been related with reduced proliferation capacity of cancer cells including colon cancer cell lines [36,37]. On the other hand, exposure to EcEE (25 μg/ml, 48 h) also resulted in the up regulation of *p21*, a cyclin-dependent kinase inhibitor which is a major regulator of the cell cycle [38]. It was previously shown that histone hyperacetylation induces *p21* over expression [39]. In colon cancer cells inhibition of histone deacetylation results in both up regulation of *p21* [40], and induction of G2/M cell cycle arrest [41]. Relevantly, cell reduction capacity depends on the cell cycle being higher at G2/M [42]. Considering that the cell viability assay used is based on the resazurin reduction and that overall our results were incompatible with EcEE induction of cell proliferation, the slight and transient augment of fluorescence detected after 24 h and 48 h of exposure to 25 μg/ml EcEE was also suggestive of cell arrest at G2 or M. Moreover, the increase of abnormal mitotic cells after exposure to EcEE is also suggestive of a mitotic block. This phenotype was accompanied by a significant down regulation of *p21*, which is consistent with previous results showing that decreased Aurora A levels are associated with mitotic catastrophe and consequent cell death [43]. Induction of cell death after 48 h exposure to 25 μg/ml was evident by the prominent occurrence of pyknotic and fragmented nuclei, characteristic of both apoptotic as well as necrotic cells, and supports the marked loss in cell viability observed after recovery. This was moreover associated with transcriptional up regulation of the anti-apoptotic gene *bcl-xL* suggesting a non-apoptotic cell death pathway [44] which is also supported by limited occurrence of DNA breaks. These observations together with the increase in cell size is compatible with a necrotic cell death or necroptosis, a process which acts as backup death-inducing mechanism when apoptosis is inhibited [45].

Cytostatic activity was previously described for compounds identified in *E. cannabinum* extracts, namely the sesquiterpene eupatoriopicrin [7] and the flavonoids centaureadin, jaceosidin and hispidulin [10]. Severe decrease of tumour cell survival in vitro was associated with eupatoriopicrin concentrations ranging from 1–10 μg/ml [12,13] which was correlated with induction of DNA damage [12]. Also, anti-proliferative effects on distinct cancer cell lines have been described for centaureadin concentrations below 1 μg/ml [18] as well as for jaceosidin in the concentration range of 20–50 μg/ml [19] and hispidulin for 4–30 μg/ml [21]. Relevantly, both jaceosidin [19] and hispidulin [20] effects were associated with increased p21 expression. The results obtained here indicate that the anti-proliferative potency of EcEE is similar to that observed for some of its individual constituents such as eupatoriopicrin, jaceosidin and hispidulin, albeit without marked induction of DNA damage and therefore suggesting a combined action of distinct compounds.

Importantly, EcEE combined exposures with DOX at therapeutic concentration resulted in a clear enhancement of cytotoxic effects, evident as combined treatments significantly decreasing HT29 cell viability immediately after exposure, even for the lower EcEE concentration that *p<* did not affect cell viability. This was accompanied by increased nuclear fragmentation and reduced cell survival after recovery resulting in almost total loss of cell viability. DOX is a commonly utilized antineoplastic drug that acts in tumour cells by induction of apoptosis [46]. Nevertheless different types of cell death can occur simultaneously, independently or through partially common pathways (reviewed in [45]). The severe decrease in cell viability observed after combined exposure to DOX and EcEE can thus result from induction of distinct cell death mechanisms. On the other hand therapeutic concentrations of DOX induces cell arrest at G2/M and/or G1/S checkpoints [47,48]. The results obtained show that EcEE does not counteract DOX-induced cell cycle arrest. Considering that DOX acts by induction of apoptosis [46] to which cell resistance can emerge [24,25] our data substantiates potential adjuvant EcEE properties in chemotherapeutic approaches [49].

On the other hand, no immediate effect on cell viability was associated with co-exposure to EcEE and the synthetic phenolic compound BPA. However, cell recovery capacity after 48 h exposure to 25 μg/ml EcEE decreased by the presence of BPA. Additionally, EcEE/BPA combined exposures resulted in increased mitotic anomalies in relation to either BPA or EcEE alone for 25 μg/ml.
ECEE but also for 0.5 μg/ml EcEE. BPA is characterized as an aneugenic chemical [50] capable of interfering with cell division mechanisms even at very low concentrations [27]. Nonetheless BPA is widely used in a variety of consumer products leading to a generalized human exposure although its risks remain highly controversial [23]. The present results raise the possibility that adverse BPA effects could be enhanced by interactions with other chemicals, an aspect that remains largely unknown and has barely been addressed.

Conclusions

E. cannabinum has been utilized as a medicinal plant for alternative and/or complementary medicine, however the effects or the mode of action of full extracts have not been evaluated at the cellular level. The present work demonstrates that E. cannabinum ethanolic extract has potent cytotoxic activity against HT29 colon cancer cells associated with mitotic disruption and cell death without marked evidences of DNA damage. Relevantly E. cannabinum extract exhibits synergistic effects with doxorubicin in the induction of HT29 cell death indicating its potential use in alternative or complementary therapeutic strategies. On the other hand, the results show also that E. cannabinum can increase aneugenic effects of the environmental pollutant BPA, drawing attention to the possibility that BPA adverse effects may be poteniated by interaction with other chemicals.
