**SUMMARY**

We develop a technique to estimate spatially varying seismicity patterns. It is based on a Gaussian approximation of the underlying Poisson Process. A link function is used to estimate local moments of the seismicity from observed catalogues. These are modeled by a nonstationary Gaussian field. We construct a prior based on the local distribution of seismic faults. This allows us to incorporate geological information into the Bayesian inversion of the observed seismicity. In this paper we limit ourself to the \(b\)-value field for which we compute the posterior expectations as well as the uncertainties. The technique however may be applied to other seismically relevant parameters like Omori \(c\) and \(p\)-values.

**Key words:** \(b\)-value maps, non-stationary process of seismicity, Gaussian process analysis, correlation patterns

1 INTRODUCTION

Seismic hazard assessment relies on a reliable characterization of the frequency-magnitude distribution of the earthquakes. The general form of the distribution is usually well described by the Gutenberg-Richter (GR) relation, the most famous statistical characteristic of earthquakes [Gutenberg & Richter 1954]. This widely accepted empirical formula, which has been validated numerous

\(^*\) DFG, SFB 1294
\(^\dagger\) DFG, SFB 1294
\(^\ddagger\) DFG, SFB 1294
times by earthquake catalogs on a local and a global scale, states that the number $N$ of earthquakes with magnitude larger or equal to $m$ is

$$\log_{10} N(m) = a - bm,$$  

(1)

where magnitudes are assumed to be complete above a certain threshold $m_0$ depending on the earthquake catalog. Here the $a$-value defines the total number of $m \geq 0$ events and $b$ the shape of the distribution. While the $a$-value largely varies depending on the region and the considered time and space selection, the $b$-value is found to be rather universal and scatters around one. Nevertheless strong local variations are reported with typical variations within the range $0.4 < b < 2.0$ (Wiemer & Wyss 2002). Laboratory experiments have shown that the $b$-value describing the size distribution of acoustic emission events decreases with differential stress (Scholz 1968; Amitrano 2003; Goebel et al. 2013) which seems to be in agreement with observations for earthquakes (Schorlemmer et al. 2005; Narteau et al. 2009; Spada et al. 2013). Therefore observed variations of the $b$-value in space and time are often interpreted as a stress meter, with an inverse relation between stress level and $b$-value (Scholz 2015).

The most commonly used methods for mapping $b$-values in space are the fixed-radius and the nearest-neighbor methods (Wiemer & Wyss 2002). In the case of the fixed-radius approach, the $b$-value is calculated for earthquakes within a fixed radius and projected to the central point. In contrast, in the case of the nearest-neighbor method, the $b$-value of the grid-point is estimated from the $n$ closest events within a proximity limit. In a more recent work, Kamer & Hiemer (2015) incorporate a partitioning scheme based on Voronoi tessellation, where the number of random Voronoi nodes is determined by the Bayesian Information Criterion.

In this paper now we propose an alternative method, which is based on Gaussian process regression. We formulate it as correlation / covariance based method which has proved useful in the field of geomagnetism, where it has been named ”correlation based modeling” (Holschneider et al. 2016).

2 LOCAL MOMENTS OF SEISMICITY

We suppose that in a region, the occurrence of earthquakes can be described through a non-stationary space, time, magnitude Poisson point process (ppp). In order to simplify the formulas, we consider the time stationary case only, but extension to non-stationary processes is immediate. Then, the Poisson intensity reads

$$\Lambda(x, m) = \alpha(x)\beta(x)e^{-\beta(x)(m-m_0)}, \quad m \geq m_0,$$  

(2)

with $m_0$ the lower completeness bound for the magnitude $m$, the function $\alpha(x)$ is the local seismic rate of events and $\beta(x)$ the local Gutenberg Richter exponent, which is linked to the classical $b$-value.
The likelihood of the Poisson point process generating an observed catalogue \( \{(x_i, m_i)\} \) is

\[
\log L((x_i, m_i)|\alpha(x)\beta(x)) = \sum_i \log \alpha(x_i) - \log \beta(x_i) - \beta(x_i)(m_i - m_0) - \int \alpha(x)dx.
\]

A possible approach is to equip the fields \( \alpha \) and \( \beta \) with a suitable prior or penalizing structure \( P(\alpha, \beta) \) for instance in form of a Gaussian process prior, and then obtain the posterior information via

\[
P(\alpha, \beta|(x_i, m_i)) \sim L((x_i, m_i)|\alpha(x)\beta(x))P(\alpha, \beta).
\]

A straightforward application of this approach is feasible but numerically demanding, see e.g. (Gu & Qiu 1993). In particular if not only the maximum a posteriori (MAP) estimator is to be deduced but also posterior uncertainties are of interest.

We will use the southern California catalog of (Hauksson et al. 2012). The purpose of this paper is to propose an easily computable estimate of the field \( \beta(x) \) using techniques of Gaussian process regression or correlation based modeling (see e.g. ). As prior information we shall include geological features like dominant fault directions (see section 3). For this we shall use a Gaussian approximation of suitable moments that characterizes the distribution locally.

The first step is to realize that when the \( \beta \) value in the GR-law, which is a scaling parameter, becomes a translation parameter on a log scale. More precisely, consider \( C \) is the Euler-Mascheroni constant

\[
u = \log(m - m_0) + C, \quad C = 0.577215\ldots
\]

and

\[
u = -\log \beta.
\]

Then the density of \( m \) (i.e. the Gutenberg Richter law) becomes

\[
\beta e^{-\beta m}dm = h(u - \nu)du, \quad h(u) = \exp(u - C - e^{u-C}).
\]

The parameter \( \nu \) is now the mean value of \( u \)

\[
\mathbb{E}(u|\nu) = \int uh(u - \nu)du = \nu.
\]

and the variance of \( u \) is the same for all \( \nu \)

\[
\mathbb{V}(u|\nu) = \int u^2 h(u - \nu) - \nu^2 = \frac{\pi^2}{6}.
\]

This mean value can be estimated from local arithmetic means. In addition, the uncertainties of these
local means and their covariance properties may be estimated. This opens the way to a Gaussian posterior calculation.

In order to make this more precise, consider a small region $Q$ with center at $x$. For a function $f(m)$ we define the local empirical moment as

$$S_Q = \sum_{e_i \in Q} f(m_i) \quad M_Q = \frac{1}{N_Q} S_Q \quad N_Q = \# \{\text{events in } Q\}$$

where the sum runs over all events $e_i = (x_i, m_i)$ in the region $Q$ and $N_Q$ is number of observed events in $Q$. We assume that $N_Q > n \geq 2$ for some fixed $n$. We propose to use

$$u = f(m) = \log(m - m_0) + C, \quad C = 0.577215 \ldots$$

so that $f$ takes values in all of $\mathbb{R}$. We therefore base our analysis on the following local seismicity moments

$$M_Q = \frac{1}{N_Q} \sum_{e_i \in Q} \log(m_i - m_0) + C.$$  (3)

In order to assess the statistical properties of this quantity we transform the Poissonian intensity function to the field of new point observables $(x_i, u_i)$, $u(x) = f(m(x))$. It then reads

$$\Lambda(x, u) = \alpha(x) h(u - \nu(x)), \quad \nu(x) = -\log(b(x)),$$

Here are the formulas that link the traditional $b$-value to $\beta$ and to our newly introduced quantity $\nu$

$$\nu(x) = -\log \beta(x) = -\log \log 10 - \log b(x) \approx -0.83403 - \log b(x)$$

$$\approx 0.16597 - b(x) \quad \text{(for } b \approx 1)$$

$$\beta(x) = \log(10)b(x) \approx 2.30258 b(x)$$

$$b(x) = \frac{e^{-\nu(x)}}{\log(10)} \approx 0.4342944 e^{-\nu(x)}$$

We propose to perform a Bayesian inversion for the $\nu$ field. For this we choose the prior information about $\nu = -\log(\beta)$ to be a Gaussian process described through prior mean and prior covariance of the form

$$E(\nu(x)) = \mu(x), \quad \mathbb{V}(\nu(x), \nu(x')) = \Gamma(x, x')$$

In section 3 we will see, how to choose the covariance $\Gamma$ to take into account geological prior information about the seismicity generating structures. But even without this geological information, a Gaussian process description is useful for its flexibility and its direct computability. For the total seismicity $\alpha(x)$ we do not consider a random prior although this would be possible. We approximate
Figure 1. The local moments of Eq. 3. This is the surrogate data directly obtained from a catalogue. The size of each pixel patch is $10 \times 10$ km$^2$. It serves as input to Gaussian process inversion yielding the Bayesian posterior distribution of $\nu = -\log(\beta)$.

the total seismicity in a small region $Q$ through $N_Q$ and we shall use

$$\alpha(x) \simeq \frac{N_Q}{|Q|}, \quad x \in Q.$$  \hspace{1cm} (4)

We now cover the observational region with rectangles $Q_i$, where we retain only those, in which we have a minimal number of events. We take squares of $10 \times 10$ km$^2$ and we use only those bins, for which we have $N_i \geq 5$. This leaves us with 1968 bins which comprise in total 593292 events, whereas 2253 events have been discarded. As shown in the appendix our random model of seismicity the expectation of the local observational moment $S_i = S_{Q_i}$ for a realization of $\beta$ can be computed (see Appendix, Eq. 7)

$$\mathbb{E}(S_i|\nu) = \int_{Q_i} \alpha(x) \nu(x) dx \simeq \frac{N_i}{|Q_i|} \int_{Q_i} \nu(x).$$

Actually, using local moments $M_i = S_i/N_i$, we measure the average value of $\nu$ over $Q_i$

$$\mathbb{E}(M_i|\nu) = \frac{1}{|Q_i|} \int_{Q_i} \nu(x).$$

Under the random model of $\beta$ we have, as shown in the Appendix the following prior covariance
properties for the local sum $S_i$

$$E(S_i) = \int_{Q_i} \alpha(x)\mu(x)dx$$

$$V(S_i) = \int_{Q_i} \alpha(x)\Gamma(x, x')\alpha(x') + \int_{Q_i} \alpha(x)(\Gamma(x, x) + \mu(x)^2 + \frac{\pi^2}{6})dx.$$ 

$$V(S_i, S_j) = \int_{Q_i} \int_{Q_j} \alpha(x)\Gamma(x, x')\alpha(x')dx'dx'$$

The prior covariance between the moments $S_i$ and the field $\nu$ is

$$V(\nu(x), S_i) = \int_{Q_i} \alpha(x')\Gamma(x, x')dx'.$$

In general the local seismicity rate $\alpha$ is not known and must be estimated. We do not assume, that $Q_i$ is small since we will take into account the average of $\nu$ over $Q_i$ and not only the value of $\nu$ at the center of $Q_i$, which would be the "small $Q_i$" approximation. So, provided the seismicity in $Q_i$ may be replaced with its average value, $Q_i$ may take any shape and size. In a forthcoming article, we will also remove the constraint on $\alpha$, by proposing a joint inversion of $\beta$ and $\alpha$. In this paper, however we take $\alpha$ as fixed, or at least locally estimated through the event count. Upon using the estimate we end up with the following correlation structure for the average moments $M_i$ ($i \neq j$)

$$E(M_i) = \frac{1}{|Q_i|} \int_{Q_i} \mu(x)dx,$$

$$V(M_i) = \Gamma_{i,i} = \frac{1}{|Q_i|^2} \int_{Q_i} \int_{Q_i} \Gamma(x, x')dx'dx' + \frac{1}{N_i} \int_{Q_i} (\Gamma(x, x) + \mu(x)^2 + \frac{\pi^2}{6})dx.$$

$$V(M_i, M_j) = \Gamma_{i,j} = \frac{1}{|Q_i||Q_j|} \int_{Q_i} \int_{Q_j} \Gamma(x, x')dx'dx'.$$

The first equation is used to compute the prior expectation of the observables (i.e. the moments). The covariance between the observed moments and the field $\nu$ reads

$$V(\nu(x), M_{Q_i}) = \Gamma_{x,i} = \frac{1}{|Q_i|} \int_{Q_i} \Gamma(x, x')dx' = \Gamma_{x,Q}.$$

It is this covariance that allows us to infer on $\nu(x)$ from the observations of the $M_i$. The precise formulation is given by Bayes theorem as exposed in the next section. All these quantities we need for the prior covariance structure may be computed a priori using numerical quadrature.
Figure 2. The posterior expectation of $\nu$. Dark regions correspond to high $\nu$, which corresponds to small $b$-values. We observe how regions of high $\nu$ are localized near the major faults.

2.1 Bayesian inversion

After having computed all covariances, we may apply the Bayesian inversion for correlated Gaussian variables (see Appendix 5.2). The key is the covariation of $\nu(x)$ and the $M_i$. In this setting the full posterior distribution of $\nu(x)$ given a collection of moment observations $M_{Q_i}$ in disjoint regions $Q_i$, $i = 1, \ldots$ can be computed by standard Gaussian process calculus and we have

$$\mathbb{E}(\nu(x)|\{M_{Q_i}\}) = \mu(x) + \sum_k \Gamma_{x,Q_k} \left( \frac{1}{\int_{Q_i} \mu(x) dx} \right)$$

The matrix $\Gamma$ with entries $\Gamma_{k,l}$ are the ones given by [5]. We may also deduce the posterior uncertainty. It is described through a posterior covariance matrix which reads

$$\mathbb{V}(\nu(x), \nu(x')|\{M_{Q_i}\}) = \Gamma(x, x') - \sum_{k,l} \Gamma_{x,Q_k} \Gamma_{k,l}^{-1} \Gamma_{Q_l,x'}.$$  \hspace{1cm} (6)

Observe that in principle the Bayesian inversion gives us a sub pixel image of the seismicity, since we predict point values of $\nu(x) = -\log \beta(x)$ from averages of seismicity in the regions $Q_i$. Clearly however, the prior covariance will influence the posterior blurriness of the inversion.
3 NON STATIONARY PRIOR SELECTION

In the Bayesian inversion, we have incorporated as prior information the geometry of the fault system. For this we need a prior correlation, that reflects the underlying fault geometry. A dominant geological feature of a seismogenic zone is the non isotropy of the fault directions. We propose to take this feature into account for the Bayesian inversion for the $\beta$ field in the following way.

In a first step we determine at each point the dominant fault direction. For this we coarse grained the entire region into patches of $40 \times 40 km$. In each patch we applied a median filter on the directions of the local fault segments in that region as they are present in the data set (U.S. Geological Survey, 2006, Quaternary fault and fold database for the United States, accessed 08/08/2011, from USGS web site: http://earthquakes.usgs.gov/regional/qfaults/). This is arguably not a very refined method to estimate the local main direction of expected correlation from geological data. However this paper is not concerned with fully exploiting the possibilities such prior choices offer. We merely want to show, how in principle such information can be taken into account in an estimation of a non-homogeneous $b$-field. In Fig. 3 you can see the direction field obtained that way.

This direction field is then used to construct a prior covariance kernel $\Gamma(x, x')$ in the following way. We suppose that along the main fault direction the a priori correlation length is $\sigma_1 = 20 km$.
whereas orthogonal to it we only assume a correlation length of $\sigma_2 = 5\text{km}$. If there are no faults in a $40\text{km}$ distance, we set the prior correlation length to $\sigma_1 = \sigma_2 = 10\text{km}$. This gives rise to a covariance matrix

$$
\Sigma_e = R^t_e \text{diag}(\sigma_1^2, \sigma_2^2) R_e.
$$

This defines a bell shaped correlation kernel

$$
g(e, x) \sim \exp -\frac{1}{2} \left( \frac{(e^t x)^2}{\sigma_1^2} + \frac{x^t x - (e^t x)^2}{\sigma_2^2} \right).
$$

There is an implicit amplitude that is not written but shall be picked later. Now consider uncorrelated standard white noise

$$
\mathbb{E}(\omega(x)) = 0, \quad \mathbb{V}(\omega(x), \omega(x')) = \delta(x - x').
$$

Upon convolving $\omega$ with the kernel $g$ in a non-stationary way, taking at each point the local dominant fault direction, we may define a random field that reflects the non-isotropic geology.

$$
s(x) = \int g(e_x, x - x'') \omega(x'') dx''.
$$
Figure 5. The major direction of the faults. This is used as a basis for the directional covariance prior structure.

This is a zero mean random field and the covariance is (upon exchanging expectation and integration and using \( \mathbb{E}\omega(t)\omega(t') = \delta(t - t') \))

\[
\mathbb{V}(s(x), s(x')) = \int g(e_x, x - x'')g(e_{x'}, x' - x'') dx''
\]

which by standard rules for the integration of Gaussians (see Appendix 5.3) reads

\[
\mathbb{V}(s(x), s(x')) = \Gamma(x, x')
= \frac{\sigma^2 |\Sigma_x|^{1/4} |\Sigma_{x'}|^{1/4}}{|\Sigma_x + \Sigma_{x'}|^{1/2}} \exp - \frac{1}{2} (x - x')^T(\Sigma_x + \Sigma_{x'})^{-1}(x - x')
\]

The amplitude \( \sigma^2 \) is chosen to reflect the a priori uncertainty of \( \nu = -\log(\beta) \). Since we expect \( b \)-values to variate about 20% we have set \( \sigma^2 = 0.4 \).

In Fig. 5 you can see the prior covariance kernel we are using. It clearly shows that the correlation tends to be oriented along the dominant fault directions.

At this stage this is not an exhaustive analysis of the possibilities this method opens, but it is a feasibility study that shows, how in principle geological or other prior information may be build into the estimation of the space (time) \( b \) respectively \( \nu \)-value distribution.
4 CONCLUSION

We have introduced a Bayesian inversion of catalog data for $b$-value maps. It is based on the observation of local moments, which are approximated by local averages of magnitudes. The $b$-value field has been transformed using a log as link function into a field for which a Gaussian process prior is assumed to hold. The covariance function could then incorporate additional information about the seismicity patterns. As an example, we have used local direction of faultings to include preferred correlation directions into the prior covariance pattern. The statistics of the local averages has been discussed in great detail, paying attention to fluctuations which come from the uncertainty of the field as well as of the Poissonian nature of catalog generating filed. For this we have developed an extension of Campbell’s sampling formula for random Poisson processes. As an illustration we have applied this technique to the estimation of $\nu = C - \log(\beta)$ value maps in southern California.
5 APPENDIX

In this appendix we have collected the mathematical tools needed for the analysis exposed in the paper. We have decided to separate this technical part from the rest of the paper for the convenience of the reader.

5.1 Likelihood of Poisson point process

Let $\Lambda(x)$ be the Poissonian intensity of a point process over a domain $\Omega$. The the likelihood to observe a random catalog $x_1, x_2 \ldots x_N$ is

$$\log L(N, x_1, x_2 \ldots x_N | \Lambda) = \sum_i \log \Lambda(x_i) - \int \Lambda(x) dx + \text{Const.}$$

Recall that $N$ is a Poissonian random variable with frequency $\lambda = \int_\Omega \Lambda$ and given $N$, the points $x_1, x_2 \ldots x_N$ are uniformly distributed with density $\Lambda(x)/\lambda$.

5.2 Gaussian Bayesian calculus

Let $X$ and $Y$ be two jointly Gaussian random vectors with prior mean $\mu_X, \mu_Y$ and covariances $\Gamma_{XX}, \Gamma_{YY}$ and $\Gamma_{XY} = \Gamma_{YX}$. Then the posterior information about $X$ that can be inferred from observing $Y$ is again Gaussian. The posterior mean value is

$$E(X|Y) = \mu_X + \Gamma_{XY} \Gamma_{YY}^{-1} (Y - \mu_Y)$$

and the posterior variance is

$$\mathbb{V}(X|Y) = \Gamma_{XX} - \Gamma_{XY} \Gamma_{YY}^{-1} \Gamma_{YX}.$$ 

5.3 Integrals of Gaussians

For a symmetric $2 \times 2$ matrix $\Sigma$ and $\mu \in \mathbb{R}^2$ consider

$$g_{\mu, \Sigma}(x) = \frac{1}{2\pi |\Sigma|^{1/2}} e^{-\frac{(x-\mu)^T \Sigma^{-1} (x-\mu)}{2}}$$

This function satisfies

$$\int g_{\mu, \Sigma}(x) dx = 1$$

Since this is the pdf of a two dimensional Gaussian r.v. with mean $\mu$ and variance $\Sigma$ we have, upon considering the sum of two such r.v.s (recall that the pdf of the sum of two independent r.v.s is their convolution)

$$g_{\mu, \Sigma} * g_{\mu', \Sigma'} = g_{\mu+\mu', \Sigma+\Sigma'}$$
and thus upon evaluation this expression at \( x = 0 \) and using \( g_{\mu,\Sigma}(-x) = g_{-\mu,\Sigma}(x) \)
\[
\int g_{\mu,\Sigma}(x)g_{\mu',\Sigma'}(x)dx = g_{\mu-\mu',\Sigma+\Sigma'}.
\]

Now consider filtered two dimensional white noise \( \omega = dW \)
\[
s(x) = 2\sqrt{\pi}\gamma(x)|\Sigma_x|^{1/4} \int g_{x,\Sigma_x}(x')dW(x'),
\]
with some arbitrary modulating amplitude \( \gamma(x) \). This is a zero mean Gaussian random process and we have for the covariance
\[
\mathbb{V}(s(x), s(y)) = 2\gamma(x)\gamma(y)|\Sigma_x|^{1/4}|\Sigma_y|^{1/4} \frac{1}{|\Sigma_x + \Sigma_y|^{1/2}} \times \exp-(x - y)^T(\Sigma_x + \Sigma_y)^{-1}(x - y)/2.
\]
In particular, setting \( x = y \) we see that the variance at a point \( x \) is precisely \( \gamma(x)^2 \)
\[
\mathbb{V}(s(x)) = \gamma(x)^2.
\]
And the correlation structure changes locally with the chosen matrix valued function \( x \mapsto \Sigma_x \).

### 5.4 Total mean and total variance

A basic tool that we will use is the formula of total mean
\[
\mathbb{E}(A) = \mathbb{E}(\mathbb{E}(A|C))
\]
and of total covariance
\[
\mathbb{V}(A, B) = \mathbb{E}(\mathbb{V}(A, B|C)) + \mathbb{V}(\mathbb{E}(A|C)\mathbb{E}(B|C))
\]
In particular we have for the variance
\[
\mathbb{V}(A) = \mathbb{E}(\mathbb{V}(A|C)) + \mathbb{V}(\mathbb{E}(A|C)).
\]

### 5.5 A random Campbell theorem

For a function \( f \) and random points from a Poisson point process with intensity function \( \Lambda(x) \) consider the random sums of the form
\[
S = \sum f(x_i)
\]
Then Campbell’s theorem states that the expectation reads
\[
\mathbb{E}(S) = \int f(x)\Lambda(x)dx
\]
and that the variance is

\[ \mathbb{V}(S) = \int (f(x))^2 \Lambda(x) dx. \]

An extension of this result for two functions \( f, g \) yields the following covariance

\[ \mathbb{V}(S_f, S_g) = \int f(x)g(x) \Lambda(x) dx. \]

We need an analogue theorem, but where the density function \( \Lambda \) itself is a random process.

We consider only the second order statistics of \( \Lambda \)

\[ \mu(x) = \mathbb{E}(\Lambda(x)), \]
\[ \Gamma(x, x') = \mathbb{V}(\Lambda(x), \Lambda(x')) \]
\[ = \mathbb{E}((\Lambda(x) - \mu(x)) (\Lambda(x') - \mu(x'))). \]

Then Campbell’s theorem gives us \( \mathbb{E}(S|\Lambda) \) and \( \mathbb{V}(S|\Lambda) \). The direct application of the total variance theorem yields

\[ \mathbb{E}(S_f) = \int f(x) \mu(x) dx, \]
\[ \mathbb{V}(S_f, S_g) = \int f(x)g(x) \mu(x) dx + \int f(x)\Gamma(x, x') g(x') dx dx'. \]

We have used the following useful formulas that apply when working with second order properties of the processes \( \Lambda \)

\[ \mathbb{E} \left( \int f \Lambda \right) = \int f \mu, \]
\[ \mathbb{E} \left( \int f \Lambda \right) \int g \Lambda = \int f \Gamma g + \int f \mu \int f \mu \]
\[ \mathbb{V} \left( \int f \Lambda, \int g \Lambda \right) = \int f \Gamma g. \]

We also need the covariance between a linear functional of \( \Lambda \) and the moments \( S_f \). So let

\[ L = \int l(x) \Lambda(x) dx. \]

Then, for fixed \( \Lambda \) the quantity \( L \) and \( S \) are independent, and thus using the total variance calculation we obtain

\[ \mathbb{E}(L) = \int l(x) \mu(x) dx \]
\[ \mathbb{V}(LS_f) = \int \int l(x) \Gamma(x, x') f(x') dx dx'. \]
5.6 A hierarchical (marked) family of random intensities

Consider the following hierarchical (or marked) setting. We suppose that $x$ actually has two parts $(x,u)$ and that $\Lambda$ factorises as follows

$$\Lambda(x,u) = P(u|x)\alpha(x).$$

For the conditional distribution we assume that with some probability density function $h$ we have

$$P(u|x) = h(u - \nu(x)),$$

with some random function $\nu$. So, a realization of events from $\Lambda$ are sampled as follows: The function $w$ is chosen and then fixed. We now pick $x$ at random from $\alpha(x)$ and then $u$ is picked at random for each $x$ according to the density $h(u - \nu(x))$

$$\Lambda(x,u) = \alpha(x)h(u - \nu(x))$$

Without loss of generality we may assume that the density function $h$ is such that $u \sim h$ has zero expectation. Then $h$ satisfies

$$\int h(u) = 1, \quad \int uh(u)du = 0, \quad \int u^2h(u) = \sigma^2.$$ 

For the function $\nu(x)$ we assume that it is a realization of a Gaussian process with mean and covariance structure given by

$$\mathbb{E}(\nu(x)) = \mu(x),$$

$$\mathbb{V}(\nu(x),\nu(x')) = \Gamma(x,x').$$

Let $Q$ be a region and let $\chi_Q(x)$ be its indicator function. Then we may apply the general theory of the previous section to the function

$$f(x,u) = \chi_Q(x)u.$$ 

The local sample moments are then

$$S_Q = \sum_{x_i \in Q} u_i.$$ 

We now compute all the moments and their second order statistics for this random family. The $f$ moment for fixed $\nu$ reads

$$\int f(x,u)\Lambda(x,u)dxd\nu = \int_Q \int u\Lambda(x,u)d\nu dx = \int_Q \alpha(x)v(x)dx,$$

which implies that for the moment of two point covariance we can write

$$\int f(x,u)\Gamma(x,u,x',u')f(x',u') = \mathbb{V}(\int f\Lambda)$$

$$= \int_Q \int \alpha_Q(x)\Gamma(x,x')\alpha_Q(x')dxdx'.$$
In the same way we may write
\[
\int_Q \int f(x,u)^2 \mu(x,u) du dx = \mathbb{E} \int_Q u^2 \hat{\alpha}(x) h(u - \nu(x)) du dx
\]
\[
= \sigma^2 \int_Q \alpha(x) dx + \int_Q \alpha(x)(\Gamma(x,x) + \mu(x)^2) dx
\]
For two disjoint regions \( Q \) and \( Q' \) we have \( \int \mu(x)f_Q(x)f_{Q'}(x) dx = 0 \).

To summarize we have the following second order statistics for the local moments \( S_Q \) and \( S_{Q'} \) in two disjoint regions \( Q \) and \( Q' \)
\[
\mathbb{E}(S_Q) = \int_Q \alpha(x)\mu(x) dx.
\]
\[
\mathbb{V}(S_Q) = \int_Q \int_Q \alpha(x)\Gamma(x,x')\alpha(x') dx dx'
+ \int_Q \alpha(x)(\Gamma(x,x) + \mu(x)^2 + \sigma^2) dx
\]
\[
\mathbb{V}(S_Q, S_{Q'}) = \int_Q \int_{Q'} \alpha(x)\Gamma(x,x')\alpha(x') dx dx'
\]
Consider now the functional
\[
l_y(x,u) = \frac{1}{\alpha(x)} \delta(y - x) u,
\]
with \( \delta \) the Dirac unit mass function. It acts as measuring \( \nu \) at the point \( y \) since
\[
L_y = \int l_y(x,u)\Lambda(x,u) dx du = \nu(y)
\]
Its covariance with the \( S_Q \) is the covariance between \( \int l_y \Lambda = \nu(u) \) and \( \int f_Q \Lambda = \int_Q \alpha \nu \), which is
\[
\mathbb{V}(L_y, S_Q) = \mathbb{V}(\nu(y), S_Q) = \int_Q \alpha(x)\Gamma(y,x) dx.
\]
