Abstract

We introduce two processes where the BMS equation appears in a context quite different from the original context of non-global jet observables. We note the strong similarities of the BMS equation to the BK and FKPP equations and argue that these, essentially identical equations, can be viewed either in terms of the probability, or amplitude, of something not happening or in terms of the nonlinear terms setting unitarity limits. Mostly analytic solutions are given for (i) the probability that no $c\bar{c}$ pairs be produced in a jet decay and (ii) the probability that no-$c\bar{c}$ pairs be produced in a high energy dipole nucleus scattering. Both these processes obey BMS equations, albeit with very different kernels.
I. INTRODUCTION

The purpose of this paper is to examine the origins and properties of the Banfi, Marchesini, Smye (BMS) equation \[1\] and to compare it with the Balitsky-Kovchegov (BK) \[2, 3\] equation with which it has a strong resemblance. The BMS equation arose in the study of “non-global” observables in jet physics \[4\], in particular it describes the probability that in an $e^+e^-$ annihilation at energy $E$ less than $E_{\text{out}}$ energy flows into a fixed angular region away from the jet-axes \[1, 4\]. On the other hand the BK equation generalizes the linear Balitsky, Fadin, Kuraev, Lipatov (BFKL) \[5, 6\] equation adding a nonlinear term which imposes unitarity at high energy when the scattering gets strong. At first sight these two equations, BK and BMS, would seem to be describing different phenomena \[7–9\]. We shall argue below that this is not the case and that the physics origins of the two are very closely related when one views the equations in a particular way.

Our first object is to argue that the BMS equation is not necessarily tied to jet physics \[10, 11\] and that even when used in jet physics it does not necessarily have to be tied to the details of where decay products go. To that end in Section \[II\] we begin by defining an observable, $G(Q)$, the probability that a jet of virtuality $Q$ have no $c\bar{c}$ pairs in its decay products. We note in Eq. (1) that $G$ obeys a BMS equation which we are able to solve analytically in the region $G = 1 - P$ near one and in the region $G$ near 0. In the region of moderate $Q$ where $P$ is small, $P$ increases according to the usual, angular ordered \[12–14\], formula for jet multiplicity growth \[12, 14, 15\] while in the region where $G$ is small the $Q$-dependence is given by a Levin-Tuchin type of expression \[16, 17\]. We have been able to get analytic answers when $P$ or $G$ is small both using a fixed coupling and using a running coupling.

So why does a nonlinear BMS equation emerge for this observable? We believe that one must have two conditions for a BMS or BK equation to emerge. First, there must be a stochastic branching of one object to go to two objects. In the example of Section \[II\] the stochastic branching is $g \rightarrow gg$. Secondly, there should be a probability of something not happening. In the example of Section \[II\] we evaluate the probability that no $c\bar{c}$ pairs be produced. When $g \rightarrow g_1g_2$ the probability that no $c\bar{c}$ pairs be produced becomes the probability that $g_1$ not have $c\bar{c}$ pairs in its decay products times the probability that $g_2$ not have $c\bar{c}$ decay products. This is the nonlinear term on the right hand side of Eq. (1).

In order to understand these conditions better in Section \[III A\] we review a classic result in statistical physics \[18–21\]. If one has a branching (one particle going to two particles) random walk in one spatial dimension, the $x$-axis, starting with a single particle at the origin then the probability that no particle reach a definite position $x$ at time $t$ is given by the solution to the Fisher; Kolmogorov, Petrovsky, Piscounov (FKPP) equation \[22, 23\]. (See Eq. (22) below.) The argument for this equation is almost identical to that given in Section \[II\]. However, there is a difference between Eqs. (1) and (22). For Eq. (22) the initial condition is given by Eq. (23). That is at $x < 0$ the initial condition is at the stable fixed point of Eq. (22) while for $x > 0$ it is at the unstable fixed point. Eq. (11) does not have the analog of the variable $x$ so it is not possible to move from one fixed point to another. The final term on the right hand side of Eq. (1) eliminates $G = 1$ as a fixed point so that the natural initial condition is just $G = 1$ at $Q = 2M$, with $M$ the mass of the heavy quark. The term $-\alpha dG(Q)$ drives $G$ away from what would be the unstable fixed point in the absence of the $\alpha d$ term. $\alpha d$ is evaluated in Appendix \[A\].

The BK, or FKPP, equation has two fixed points with the initial condition in some regions
at one of the fixed points and in other regions at the other fixed point. The BMS equation has one less variable and cannot go between the two fixed points. So there must be another term in the equation, the final term on the right hand side of Eq. (1) which allows the initial condition to be \( G = 1 \). In the BMS equation there are always two channels, \( g \to gg \) or \( g \to c\bar{c} \) in the case at hand, with the \(-\alpha dG\) term in Eq. (1) representing the loss in probability that no \( c\bar{c} \) pairs be produced.

The BK equation, reviewed in Section III B is in the same universality class as the FKPP equation [21, 24]. If one writes this equation in terms of the \( S \)-matrix, as in Eq. (25). The interpretation is the same as for the FKPP equation. \( S \) is the amplitude for no inelastic interaction happening when a dipole of size \( x_{01} = |x_0 - x_1| \) passes through a large nucleus. The initial condition goes from the unstable fixed point, when \( x_{01} < 1/Q_s \), to the stable fixed point, when \( x_{01} > 1/Q_s \). For the BK equation to be more than a mean field approximation a large nuclear target is necessary [3]. The BK equation properly treats the fluctuations (stochasticity) of the projectile, but not of the target. Thus it is necessary, in the case of scattering, to choose a target which is not stochastic. In the BMS equation of Section II there is no target so this issue does not arise, however, in our example in Section IV the BMS equation will only be correct, beyond a mean field approximation, for a large nuclear target.

In Section IV \( G \) stands for the probability that no \( c\bar{c} \) pairs be produced in a high energy dipole-nucleus collisions. In order to make the problem solvable near \( G = 0 \) and near \( G = 1 \) we limit the rapidity region \( \Delta y \) where there are to be no \( c\bar{c} \) pairs produced to be near the rapidity of the nucleus but with rapidity high enough to make the coherence length of the \( c\bar{c} \) pairs larger than the nuclear diameter. The simplicity of this choice is that the saturation momentum, \( Q_s \), in Eq. (28) can be taken to be rapidity independent and equal to the McLerran-Venugopalan saturation momentum. When \( G \) is near one we find a BFKL growth of \( 1 - G \) while when \( G \) is near zero a Levin-Tuchin form emerges.

Our purpose here is mainly conceptual though both of the nonjet BMS processes that we have discussed here could have phenomenological interest. In particular if one were to choose \( \Delta y \) in Section IV to be the whole LHC rapidity interval one should get into the nonlinear regime of Eq. (27). However, because of the rapidity dependence of \( Q_s \) the resulting equation is not exactly solvable, even in the \( G \simeq 1 \) region and so numerical solutions would be necessary.

Finally, a comment on the way we have viewed the BMS and BK equations. We have taken the view that both BMS and BK can be viewed as the probability, or amplitude, of something not happening. This is very natural for BMS examples, but perhaps less natural for the BK equation. For the BK equation, Eq. (24), the nonlinear term cuts down the rate of growth of \( T \) so as to stay below the unitarity limit. One can also view the BMS equation as a unitarity imposing equation. If one writes the BMS equation Eq. (1) in terms of \( P \) (The linear part of this equation is given in Eq. (4).) then the nonlinear terms in \( P \) require that \( P \), the probability of at least one \( c\bar{c} \) appearing in the decay, remains below one. This is indeed a unitarity condition just like the BK equation for \( T \) given in Eq. (24) where \( T = 1 - S \) is the scattering amplitude.

II. THE PROBABILITY OF NO \( c\bar{c} \) PAIRS IN A GLUON JET

In this section we set up, and approximately solve, the equation for the probability of a gluon jet, of virtuality \( Q \), not having any charm-anticharm pairs in its decay products.
When $Q$ is not too much greater than the charm threshold, $2M$, we expect that probability to be near one while for extremely large values of $Q$ we expect the probability to be near zero. As will be shown below we are able to analytically solve for the $Q$-dependence of this probability when it is near one or when it is small, and we will give an equation for the probability for any value of $Q$.

A. Fixed coupling evaluation

\[ Q \frac{\partial}{\partial Q} G(Q) = \frac{2\alpha N_c}{\pi} \int_0^1 \frac{dx}{x} [G(xQ)G((1-x)Q) - G(Q)] - \alpha dG(Q) \]  

with $G(Q)$ the probability that no $c\bar{c}$ pairs have appeared in the branching up to $Q$, and with the initial condition $G(Q) = 1$ for $Q = 2M$. ($Q$ is given by the energy of the gluon, $E$, times the opening angle allowed at which it has been produced, $\Theta$, so that $Q = E\Theta$ is the natural evolution variable in an angular ordered jet cascade.) The three terms on the right hand side of Eq. (1) correspond to the three terms on the right hand side in Fig. 1. At the moment we use a fixed coupling with the running coupling generalization given later on. $\alpha d$ in the final term in Eq. (1), is evaluated in Appendix A as

\[ \alpha d = \frac{\alpha}{3\pi} \left( 1 + \frac{2M^2}{Q^2} \right) \sqrt{1 - \frac{4M^2}{Q^2}}. \]  

The three terms on the right hand side of Eq. (1) are easy to understand. If there were no gluon branching, but only the possibility of decaying into the $c\bar{c}$ pair only the last term on the right hand side of Eq. (1) would be present and $G$ would decrease exponentially in $\ln Q$. This would be exactly as in the decay of unstable elements, with $\ln Q$ serving as a time. The first term on the right hand side of Eq. (1) simply says that if a $g \rightarrow g_1 + g_2$ branching occurs the probability that no $c\bar{c}$ be produced is the probability that neither $g_1$ nor $g_2$ have a $c\bar{c}$ as part of their subsequent branchings. The second term on the right hand side of Eq. (1) is a probability conserving term associated with $g \rightarrow g_1 + g_2$ branchings. Eq. (1) is identical in form to Eq. (30), or Eq. (34), of BMS.

Eq. (1) cannot be solved exactly. However, there are two limits where analytic solutions can be obtained, (i) $1 - G \ll 1$ and (ii) $G \ll 1$.

When $1 - G \ll 1$ it is convenient to introduce

\[ G = 1 - P \]  

FIG. 1.

Consider a gluon of virtuality $Q$ decaying either into two gluons or into a $c\bar{c}$ pair as illustrated in Fig. 1. The process obeys the equation
and to linearize the resulting equation for $P$. $P$ corresponds to the multiplicity of $c\bar{c}$ pairs in the decay. This gives

$$Q \frac{\partial}{\partial Q} P(Q) = \frac{2\alpha N_c}{\pi} \int_0^1 \frac{dx}{x} [P(xQ) + P((1 - x)Q) - P(Q)] + \frac{\alpha}{3\pi} \Theta(Q - 2M)$$  \hspace{1cm} (4)$$

where we have simplified Eq. (2) using the fact that, when $\alpha$ is small, decays of $g \to c\bar{c}$ are unlikely to occur near threshold. To the differential equation Eq. (4) we add the initial condition, $P(2M) = 0$, reflecting the fact that there can be no $c\bar{c}$ production below threshold.

Eq. (4) is easily solved by introducing

$$\rho = \ln \frac{Q}{2M}, \quad \rho' = \ln \frac{xQ}{2M}$$  \hspace{1cm} (5)$$

giving

$$\frac{\partial}{\partial \rho} P(\rho) = \frac{2\alpha N_c}{\pi} \int_0^\rho d\rho' P(\rho') + \frac{\alpha}{3\pi} \Theta(\rho),$$  \hspace{1cm} (6)$$

where we have set $P((1 - x)Q) - P(Q)$ equal to zero in our double logarithmic approximation, and where we now view $P$ as a function of the variable $\rho = \ln \frac{Q}{2M}$ rather than $Q$. Taking another derivative in $\rho$ gives

$$\left( \frac{\partial^2}{\partial \rho^2} - \frac{2\alpha N_c}{\pi} \right) P(\rho) = \frac{\alpha}{3\pi} \delta(\rho).$$  \hspace{1cm} (7)$$

Eq. (6), along with $P(0) = 0$ and $P(\rho) = 0$ for $\rho < 0$, as well as $\partial P/\partial \rho = \alpha/3\pi$ at $\rho = 0$, give

$$P(\rho) = \frac{1}{6} \sqrt{\frac{\alpha}{2\pi N_c}} \left( e^{\sqrt{\frac{2\alpha N_c}{\pi}} \rho} - e^{-\sqrt{\frac{2\alpha N_c}{\pi}} \rho} \right) \Theta(\rho).$$  \hspace{1cm} (8)$$

Of course Eq. (8) can only be used when $P \ll 1$, the region where the linearization of Eq. (1) is valid. The growing exponential in Eq. (8) corresponds to the growth of the total multiplicity of gluons \[12, 14, 15\] in a jet decay in the leading double logarithmic, angular ordered, approximation.

We can also solve Eq. (1) analytically in the regime where $G \ll 1$. In this region of $\rho$ only the virtual term in Eq. (1) is important so

$$\frac{\partial}{\partial \rho} G(\rho) = -\frac{2\alpha N_c}{\pi} \int_{\rho_0}^\rho d\rho' G(\rho')$$  \hspace{1cm} (9)$$

where $\rho_0$ is chosen to be such that $G(\rho')$ is small when $\rho' > \rho_0$. This gives

$$G(\rho) = e^{-\frac{\alpha N_c}{\pi} (\rho - \rho_0)^2} G(\rho_0)$$  \hspace{1cm} (10)$$

identical to the form found by Levin and Tuchin \[16\]. Eq. (10) is valid when $G(\rho_0) \ll 1$.

B. Running coupling evaluation

It is not hard to generalize our discussion to the case where running coupling effects are included. The running coupling is naturally put into Eq. (6) as

$$\frac{\partial}{\partial \rho} P(\rho) = \frac{2N_c}{\pi} \int_0^\rho d\rho' \alpha(\rho') P(\rho') + \frac{\alpha(\rho)}{3\pi} \Theta(\rho),$$  \hspace{1cm} (11)$$
where the leading order form for $\alpha(\rho)$,

$$\alpha(\rho) = \frac{1}{2b(\rho + \bar{\rho})}, \quad \bar{\rho} = \ln \frac{2M}{\Lambda},$$

will be used and with $\Lambda$ the usual QCD parameter and $b = \frac{(11N_c - 2N_f)}{12\pi}$. It is convenient to write Eq. (11) as

$$\frac{\partial^2}{\partial \rho^2} P(\rho) - \frac{N_c}{\pi b(\rho + \bar{\rho})} P(\rho) = -\frac{\Theta(\rho)}{6\pi b(\rho + \bar{\rho})^2} + \frac{1}{6\pi b(\rho + \bar{\rho})} \delta(\rho)$$

which can be solved in terms of $I_1$ and $K_1$ Bessel functions. For $\rho/\bar{\rho}$ and $(\rho + \bar{\rho})$ large the solution to Eq. (13) takes the form

$$P(\rho) = C(\bar{\rho}) \sqrt{(\rho + \bar{\rho})} \frac{N_c}{\pi b} I_1 \left( \sqrt{2(\rho + \bar{\rho})} \frac{N_c}{\pi b} \right)$$

where $C(\bar{\rho})$ is a constant, in $\rho$, given as an integral over $K_1$ and the terms on the right hand side of Eq. (13). One again recognizes the $I_1$ function as giving the angular ordered, and running coupling, growth of the gluon multiplicity.

Similarly it is straightforward to put running coupling effects into Eq. (9) which gives

$$\frac{\partial}{\partial \rho} G(\rho) = \frac{2N_c}{\pi} \int_{\rho_0}^{\rho} d\rho' \alpha(\rho') G(\rho)$$

or

$$\frac{\partial}{\partial \rho} G(\rho) = -\frac{N_c}{\pi b} \ln \frac{\rho}{\rho_0} G(\rho).$$

Thus

$$G(\rho) = \exp \left[ -\frac{N_c}{\pi b} \left( \rho \ln \frac{\rho}{\rho_0} - (\rho - \rho_0) \right) \right] G(\rho_0)$$

replaces Eq. (10) in the running coupling case.

III. THE ORIGIN OF NONLINEAR EVOLUTION EQUATIONS

Now that we have seen how the nonlinear BMS equation can appear in evaluating certain properties of $c\bar{c}$ production in jet decay it is perhaps useful to review two other circumstances, besides non-global logarithms in jet decays, where conceptually identical nonlinear equations come up. After this review we shall attempt to give a more general picture when such nonlinear evolutions can be expected.

A. Branching random walks and the FKPP equation

Our first example is from statistical physics and concerns properties of a branching random walk. Let us first review the phenomenon and then note the similarity with what we have just done in Section II.

Consider a branching random walk of particles on the real $x$-axis starting from a single particle at $x = 0$ at time $t = 0$. A particle has a rate, $r_{12}$, to turn into two particles at the
same \( x \)-value as the parent. A particle at \( x \) also can carry out diffusion, moving to the left or right of \( x \) over a time interval \( dt \) according to \( x \rightarrow x + \nu \sqrt{dt} \). \( \nu \) is a gaussian random variable obeying
\[
\langle \nu \rangle = 0, \quad \frac{1}{2} \langle \nu^2 \rangle = x_0^2,
\]
and where the diffusion occurs at a rate \( r_d \). Suppose \( Q(x, t) \) is the probability that, at time \( t \), the rightmost particle in the branching random walk, starting from a single particle at \( x = 0 \) when \( t = 0 \), has not yet reached the value \( x \), where \( x > 0 \). It is simple to write an equation for \( Q \) by taking a short time interval \( dt \) and noting that, following the early branching or diffusions [20, 21],
\[
Q(x, t + dt) = r_{12}dt Q^2(x, t) + r_d \left( Q(x - \nu \sqrt{dt}, t) - Q(x, t) \right) + (1 - r_{12}dt)Q(x, t).
\]
(19)

The first term on the right hand side of Eq. (19) represents splitting times the product of the probabilities that neither of the daughter particles have descendents which reach \( x \) by time \( t \). The second term represents the requirement that none of the descendents of the original particle reach \( x \) by time \( t \) when the original particle diffuses over the time interval \( dt \). The third term conserves probability and represents the probability that the parent does not branch during the time interval \( 0 \leq t \leq dt \). To first order in \( dt \), Eq. (19) gives
\[
Q(x, t + dt) - Q(x, t) = dt \left[ r_{12}Q^2 + r_d x_0^2 \frac{\partial^2}{\partial x^2} Q - r_{12}Q \right],
\]
(20)
or
\[
\frac{\partial Q}{\partial t} = r_d x_0^2 \frac{\partial^2 Q}{\partial x^2} - r_{12}Q + r_{12}Q^2.
\]
(21)

After rescaling \( r_{12}t \rightarrow t \), \( r_d x_0 \sqrt{r_{12}} \rightarrow x \) one gets
\[
\frac{\partial Q}{\partial t} = \frac{\partial^2 Q}{\partial x^2} - Q + Q^2,
\]
(22)
the FKPP equation. The initial condition for the process we have described above is [20, 21]
\[
Q(x, 0) = \Theta(x).
\]
(23)

At first sight Eqs. (1) and (22) look very different. Eq. (1) is an equation in a single variable while Eq. (22) has two variables. Nevertheless, they have much in common. They are both nonlinear equations having a stable fixed point at \( G \), or \( Q \), equal zero. Eq. (22) has an unstable fixed point at \( Q = 1 \) while Eq. (1) has a term \( -\alpha dG \) driving the solution away from the \( G = 1 \) fixed point of the remaining part of Eq. (1). Eqs. (1) and (22), and similar equations which we shall review shortly, are used in similar ways in many physics applications. In the case of Eq. (1) one starts at the unstable fixed point at \( G = 1 \) as the boundary condition and then evolution in \( \rho \) drives \( G \) to the \( G = 0 \) stable fixed point. In the branching random walk one also takes an initial condition Eq. (23) which for \( x > 0 \) agrees with the unstable fixed point. Taking \( Q = 0 \) for \( x < 0 \) fits the stable fixed point. The interesting dynamics is in the motion of the stable fixed point solution, as a travelling wave, to take over the whole \( x > 0 \) region. In both Eqs. (1) and (22) it is the flow from \( G \), or \( Q_i = 1 \) to \( G \), or \( Q_i = 0 \) which is of interest.
Equations for $1 - G$, and $1 - Q$, both evolve away from zero in an exponential way, in $\rho$ in Eq. (11) and in $t$ in the solution to Eq. (22). After a period of evolution $G$ goes to zero in a gaussian manner in $\rho$ while $Q$ goes to zero exponentially in $t$. The difference between the gaussian and exponential behavior is a detail. (The exact form of the $\rho$-dependence of $G$ will change when running coupling corrections are included but the fixed point, or near fixed point structure, will not change.

**B. The BK equation**

Let us now turn to a widely used equation for high energy scattering, the Balitsky-Kovchegov (BK) equation. Consider the scattering of a quark-antiquark dipole of size $x_{01} = (x_1 - x_2)$ on a large nucleus. ($x_0$ and $x_1$ are the transverse coordinates of the quark and antiquark, respectively.) If $T$ is the scattering amplitude at rapidity $y$ the BK equation \[2, 3\] is usually written as

$$
\frac{\partial T(x_{01}, y)}{\partial y} = \frac{\alpha N_c}{2\pi^2} \int d^2 x_2 x_{01}^2 x_{21}^2 \left[ T(x_{02}, y) + T(x_{21}, y) - T(x_{01}, y) - T(x_{02}, y) T(x_{21}, y) \right]. \tag{24}
$$

For our purposes it is more useful to write Eq. (24) as

$$
\frac{\partial S(x_{01}, y)}{\partial y} = \frac{\alpha N_c}{2\pi^2} \int d^2 x_2 x_{01}^2 x_{02}^2 x_{21}^2 \left[ S(x_{02}, y) S(x_{21}, y) - S(x_{01}, y) \right] \tag{25}
$$

where

$$S = 1 - T. \tag{26}$$

The initial condition for Eq. (24) or Eq. (25) is just the low energy amplitude $T(x_{01}, 0)$. Just like Eq. (22) and similar to Eq. (1), Eqs. (24) and (25) are nonlinear equations with a stable fixed point at $S = 0$ and an unstable fixed point at $S = 1$. Starting near the unstable fixed point at zero, $T$ grows exponentially in $y$ just as $P(\rho)$ in Eq. (8) grows exponentially. The approach to zero of $S$ as $y$ gets large is identical to the approach of $G$ to zero as given by Eq. (10) with a change of $\rho$ to $y$.

One usually views Eq. (24) as an equation which gives the BFKL growth to $T$ when $T$ is small and then imposes unitarity as $T$ gets near one. Our previous Eqs. (1) and (22) are not based on unitarity but rather on the probability that something does not happen. Eq. (1) gives the probability that no $c\bar{c}$ pairs are produced while Eq. (22) determines the probability that a one dimensional branching random walk starting at the origin at $t = 0$ have no descendents to the right of $x$ at time $t$. The idea of unitarity seems to be absent from these problems. On the other it does seem that we can interpret Eq. (23) in terms of something not happening. $|S(x_{01}, y)|^2$ is the survival probability for the dipole to go through the nucleus. That is it is the probability that no inelastic collision with the nucleus occurs while the dipole passes through it. $S(x_{01}, y)$ is the amplitude for no inelastic collision to occur. The evolution Eq. (23) just reflects the fact that when the dipole $x_{01}$ splits into two dipoles, $x_{02}$ and $x_{12}$, the amplitude that no interaction with the nucleus occur is the product of the amplitude that no interaction of the nucleus with dipole $x_{02}$ occur times the amplitude for no interaction with dipole $x_{12}$. Thus Eq. (25) has essentially the structure as Eq. (1), the only difference being that (i) the initial condition for Eq. (1) is $G(Q)|_{2M} = 0$ while the initial condition for Eq. (25) is the $S$-matrix at some (generally low) $y_0$ and (ii) the $\alpha dG$ term in Eq. (1) which allows $G(Q)|_{2M} = 0$ to be a good initial condition since $G = 0$ is not a fixed point of Eq. (1).
IV. NO $c\bar{c}$ PRODUCTION IN DIPOLE-NUCLEUS COLLISIONS

As a second example of a nonjet process where a BMS equation emerges we consider the probability, $G(x_{01}, y)$, that no $c\bar{c}$ pairs be produced in a rapidity interval $\Delta y$ in the collision of a dipole of size $x_{01}$ on a large nucleus where the relative rapidity of the dipole and the nucleus is $y$. We specify the $\Delta y$ interval more precisely: Suppose a charm quark has energy $E$. Define $E_0$ by $\frac{2E_0}{M} = 2R_A$ where $R_A$ is the nuclear radius and $M$ the charm quark mass. $E_0$ is then the minimum energy for the charm quark to have a coherence time as long as the nuclear diameter. Let $y_0$ be given by $E_0 = M \cosh y_0$. The requirement on $G(x_{01}, y)$ is that there be no charm quarks in the rapidity interval $y_0$ to $y_0 + \Delta y$. We shall specify the size $\Delta y$ later on. According to the interpretation we gave Eq. (25) of $S$ is Eq. (25) is an amplitude. Nevertheless in each case they represent something not identical to the solution of Eq. (25) for $S$ in getting Eq. (28).

There are two issues that deserve comment. First, as we have noted before the BMS equation Eq. (27) is not identical to Eq. (25) because of the $\alpha^2 N_c v G$ term in Eq. (27). However, as we shall see below its behavior, both near $G = 1$ and near $G = 0$ is essentially identical to the solution of Eq. (25) for $S$. Secondly, $G$ is Eq. (27) is a probability while $S$ is Eq. (25) is an amplitude. Nevertheless in each case they represent something not happening, no inelastic interaction for $S$ and no $c\bar{c}$ production for $G$. This we feel is the essential ingredient in getting a BMS or BK equation.

One may wonder why we have chosen a large nucleus both for Eqs. (25) and (27). The reason is that Eqs. (25) and (27) properly treat fluctuations of the projectile dipole, $x_{01}$, but they do not correctly incorporate target fluctuations. In the case of a large nucleus one expects target fluctuations to be small but there is no good argument for that being the case for, say, a target proton. When Eq. (25) or Eq. (27) are used with a proton target one is attempting to do a mean field evaluation where target fluctuations are neglected.

Now let us solve Eq. (27) analytically first in the $G \approx 1$ region and then in the $G \approx 0$ region. When $G$ is near one it is convenient to define $P = 1 - G$ which obeys a linear equation, with initial condition $P(x_{01}, 0) = 0$,

$$\frac{\partial P(x_{01}, y)}{\partial y} = \frac{\alpha N_c}{2\pi^2} \int d^2x_2 \frac{x_{01}^2}{x_{12}^2 x_{02}^2} \left[P(x_{12}, y) + P(x_{02}, y) - P(x_{01}, y)\right] + c \ln(M^2 x_{01}^2) \Theta(\Delta y - y) \Theta(y)$$

(29)
where we have let $y \to y + y_0$ and with

$$c = \frac{2\alpha^2 N_c Q_s^2}{15\pi^2 M^2}$$

and where $(Q_s/2M)^2 \ll 1$ has been assumed. Eq. (29) is solved in terms of the BFKL characteristic function $\chi(\lambda)$ as

$$P(x_{01}, y) = \int \frac{d\lambda}{2\pi i} \frac{c}{\lambda^2} \frac{2\alpha N_c}{\pi} \chi(\lambda) \left\{ (e^{\frac{2\alpha N_c}{\pi} \chi(\lambda)y} - 1)\Theta(\Delta y - y) e^{\frac{2\alpha N_c}{\pi} \chi(\lambda)y} (1 - e^{-\frac{2\alpha N_c}{\pi} \chi(\lambda)\Delta y})\Theta(y - \Delta y) \right\}. \tag{31}$$

The $\lambda$-integral goes along Re$\lambda = \frac{1}{2}$. Note that Eq. (31) gives $P(x_{01}, y = 0) = 0$ and $\frac{\partial P(x_{01}, y)}{\partial y}_{|y=0} = c \ln(M^2 x_{01}^2)$ as required by Eq. (29) and the condition that no $c\bar{c}$ pairs are produced in a low energy scattering. The BFKL growth of $P$ comes from taking the $\lambda = \frac{1}{2}$ saddle point, valid when $\frac{2\alpha N_c}{\pi} \ln(M^2 x_{01}^2) \gg 1$. One gets, for $(\alpha_P - 1)\Delta y \ll 1$, and with $\alpha_P - 1 = \frac{2\alpha N_c}{\pi} \chi(\frac{1}{2}) = \frac{\alpha N_c}{\pi} 4 \ln 2$,

$$P(x_{01}, y) = c \Delta y (M^2 x_{01}^2)^{1/2} \frac{e^{(\alpha_P - 1)y}}{\sqrt{\pi^2 \alpha N_c \zeta(3)y}} \tag{32}$$

with a $y$-growth identical to that given by Eq. (24) when $T$ is small.

When $G$ is small Eq. (27) becomes

$$\frac{\partial G(x_{01}, y)}{\partial y} = -\frac{\alpha N_c}{2\pi^2} \int \frac{d^2x_2}{x_{12}^2 x_{02}^2} G(x_{01}, y) \tag{33}$$

where the limits of integration in Eq. (33) are determined by $x_{12}^2, x_{02}^2 > 1/Q_s^2(y)$ with $Q_s(y)$ the nuclear saturation momentum at rapidity $y$. Thus

$$\frac{\partial G(x_{01}, y)}{\partial y} = -\frac{\alpha N_c}{\pi} \ln \left[ x_{01}^2 Q_s^2(y) \right]. \tag{34}$$

Using

$$Q_s^2(y) = Q_s^2(MV) e^{\frac{2\alpha N_c}{\pi} \chi(\lambda_0)y} \tag{35}$$

where $\lambda_0$ is the usual saturation line eigenvalue satisfying $-\chi'(\lambda_0)(1 - \lambda_0) = \chi(\lambda_0)$. Using Eq. (33) in Eq. (34) gives

$$G(x_{01}, y) = \exp \left[ - \left( \frac{\alpha N_c}{\pi} \right)^2 \frac{\chi(\lambda_0)}{1 - \lambda_0} (y - y_0)^2 \right] G(x_{01}, y_0) \tag{36}$$

which is identical to the (fixed coupling) Levin-Tuchin result for the $y$-dependence of $S(x_{01}, y)$ when $S$ is small.

Finally we note that in their original paper BMS initiated a study of energy flow, away from the various jet axes, in hadron-hadron collisions where two jets are produced. We believe there is much more to be done in hadron collisions and that there should be many observables where nonlinear equations arise.

Appendix A: A derivation of Eq. (2)

In this appendix we calculate the gluon→c¯c term, the final term on the right hand side of Eq. (1), given by Eq. (2). The first term on the right hand side of Eq. (1) is the gluon splitting term which is well known. What we are going to calculate is the relative values of g→c¯c compared to g→gg by evaluating the graphs given in Fig. 2 without regard to overall normalization. We begin with Fig. 2(a) which in the limit k+/q+ ≪ 1 is given in lightcone gauge as

\[ A_{\alpha\beta} = g_{\alpha\beta}g_{c}(2q_{+})^{2} \int \frac{d^{4}k}{(2\pi)^{4}} 2\pi\delta(k^{2})2\pi\delta((q - k)^{2}) \frac{k_{+}^{2}}{k_{+}^{2}} \]  

(A1)

where the factors of 2q+ come from the eikonal vertices where the soft gluon k hooks to the hard gluon q, and the k^2_+/k^2_+ factor comes from the polarization vector of the gluon k

\[ \epsilon_{\mu}^{\lambda}(k) = (\epsilon_{+}^{\lambda}, \epsilon_{-}^{\lambda}, \epsilon_{\perp}^{\lambda}) = (0, \frac{\epsilon^{\lambda} \cdot k}{k_{+}}, \epsilon^{\lambda}) \]  

(A2)

The dk_⊥ and dk_- integrals are easily done in Eq. (A1) to give

\[ A_{\alpha\beta} = g_{\alpha\beta}Q^{2}2\alpha N_{c} \int \frac{dk_{+}}{k_{+}} \]  

(A3)

The graph in Fig. 2(b) is given by

\[ B_{\alpha\beta} = -\frac{1}{2}g^{2} \int d^{4}k 2\pi\delta(k^{2} - M^{2})2\pi\delta((q - k)^{2} - M^{2})\text{Tr} \left[ \gamma_{\beta}(\gamma \cdot k + M)\gamma_{\alpha}(\gamma \cdot (q - k) - M) \right] \]  

(A4)

One easily finds

\[ B_{\alpha\beta} = \frac{2\alpha}{3} \left( \frac{Q^{2}g_{\alpha\beta} - q_{\alpha}q_{\beta}}{2q_{+}} \right) \left( 1 + 2\frac{M^{2}}{Q^{2}} \right) \int_{k_{+}^{\text{min}}}^{k_{+}^{\text{max}}} dk_{+} \]  

(A5)
where $k^\text{max}_+ \text{ and } k^\text{min}_+$ are given by the maximum and minimum values of $k_+$ for which the integral $I$, 

$$I = \int_0^\infty dk_+^2 \delta((q - k)^2 - M^2)|_{k_+ = \frac{a^2}{2k_+}}$$

is not zero. One finds

$$\frac{k_+}{q_+} \text{ max, min } = \frac{1}{2} \left[ 1 \pm \sqrt{1 - \frac{4M^2}{Q^2}} \right]$$

so

$$B_{\alpha \beta} = \frac{\alpha}{3} \left( 1 + \frac{2M^2}{Q^2} \right) \sqrt{1 - \frac{4M^2}{Q^2}} (Q^2 g_{\alpha \beta} - q_\alpha q_\beta).$$

The $q_\alpha q_\beta$ term does not contribute to $c\bar{c}$ production in jet decays so comparing the $g_{\alpha \beta}$ term in Eq. (A6) with Eq. (A3) one finds

$$\alpha d = \frac{\alpha}{3\pi} \left( 1 + \frac{2M^2}{Q^2} \right) \sqrt{1 - \frac{4M^2}{Q^2}}$$

Appendix B: Evaluation of Eq. (28)

The last term on the right hand side of Eq. (27) comes from the graph shown in Fig. 3 and is given in Eq. (28) in the limit $Q^2 x^2_{01} \gg 1, Q^2/M^2 \ll 1$, with $Q^2$ the McLerran-Venugopalan saturation momentum. It is not difficult to directly evaluate the graph of Fig. 3, and we have done this calculation, however it can also be obtained in a simple limit of a much more elaborate calculation given by Kovchegov and Tuchin (KT) [31]. We now give a set of steps to get from KT to $\alpha^2 N_c v$ in Eqs. (27) and (28).

(i) Start with Eq. (17) of KT which is a formula for inclusive quark or antiquark production in a proton-nucleus collision. Integrate Eq. (17) of KT over $d^2k$ to get the total quark or antiquark production and divide by 2 to get the pair production. The identification with $\alpha^2 N_c v$ is

$$\alpha^2 N_c v = \frac{1}{4 (2\pi)^2} \int d^2x_1 d^2x_2 \int_0^1 d\alpha \sum_{i,j=1}^3 \Phi_{ij}(x_1, x_2; x_1, x_2, \alpha) \Xi_{ij}(x_1, x_2, x_1, x_2, \alpha)$$

with the notation as in KT.
(ii) In Eq. (14) of KT identify \( \frac{1}{4} x^2_+ \ln(\frac{1}{x \Lambda}) Q_s^2 \) with what we have called \( \frac{1}{8} x^2_+ Q_s^2 (\text{MV}) \) in this paper.

(ii) To evaluate the \( \Phi_{ij} \) from Eq. (12) of KT we must first evaluate \( F_0, F_1, F_2 \) from Eqs. (6) and (7) of KT. Since the heavy quark is the hardest scale in our problem take \( M^2 \gg 1/u^2 \), \( q^2 \) in Eqs. (6)-(8) of KT. This gives

\[
F_0 = 0, \quad F_1 = K_0(M x_{12})/u, \quad F_2 = K_1(M x_{12}) M/u.
\]

(iv) Use the above \( F_i \) in Eq. (12) of KT to get

\[
\Phi_{11} = \Phi_{22} = -\Phi_{12} = 4 \left( \alpha \pi \right)^2 C_F M^2 u \left[ K_0(M x_{12}) + \left( \alpha^2 + (1-\alpha)^2 \right) K_1^2(M x_{12}) \right],
\]

with the \( \Phi_{13} = 0, \ i = 1, 2, 3 \).

(vi) Expand the exponentials in Eq. (14) of KT to first order in \( Q_s^2 \).

(vii) Using Eq. (B2) and the first order expansion of the \( \Xi \) in Eq. (B1) gives Eq. (28).
