Abstract. We have used digital fluorescence imaging techniques to explore the interplay between mitochondrial Ca$^{2+}$ uptake and physiological Ca$^{2+}$ signaling in rat cortical astrocytes. A rise in cytosolic Ca$^{2+}$ ([Ca$^{2+}]_{cyt}$), resulting from mobilization of ER Ca$^{2+}$ stores was followed by a rise in mitochondrial Ca$^{2+}$ ([Ca$^{2+}]_{m}$, monitored using rhod-2). Whereas [Ca$^{2+}]_{cyt}$ recovered within ~1 min, the time to recovery for [Ca$^{2+}]_{m}$ was ~30 min. Dissipating the mitochondrial membrane potential ($\Delta$Vm), using the mitochondrial uncoupler carbonyl cyanide p-trifluoromethoxy-phenyl-hydrazone (FCCP) with oligomycin) prevented mitochondrial Ca$^{2+}$ uptake and slowed the rate of decay of [Ca$^{2+}]_{cyt}$ transients, suggesting that mitochondrial Ca$^{2+}$ uptake plays a significant role in the clearance of physiological [Ca$^{2+}]_{cyt}$ loads in astrocytes. Ca$^{2+}$ signals in these cells initiated either by receptor-mediated ER Ca$^{2+}$ release or mechanical stimulation often consisted of propagating waves (measured using fluo-3). In response to either stimulus, the wave traveled at a mean speed of 22.9 ± 11.2 μm/s (n = 262). This was followed by a wave of mitochondrial depolarization (measured using tetramethylrhodamine ethyl ester [TMRE]), consistent with Ca$^{2+}$ uptake into mitochondria as the Ca$^{2+}$ wave traveled across the cell. Collapse of $\Delta$Vm to prevent mitochondrial Ca$^{2+}$ uptake significantly increased the rate of propagation of the Ca$^{2+}$ waves by 50%. Taken together, these data suggest that cytosolic Ca$^{2+}$ buffering by mitochondria provides a potent mechanism to regulate the localized spread of astrocytic Ca$^{2+}$ signals.

Key words: intracellular Ca$^{2+}$ waves • astrocytes • mitochondria • negative feedback • Ca$^{2+}$ buffering

of mitochondrial function in X enopus oocytes (Jouaville et al., 1995).

The impact of mitochondrial calcium uptake on the spatio-temporal characteristics of intracellular Ca\(^{2+}\) signals has been controversial (Gunter, 1994). The high capacity, low affinity (\(K_d \text{ for Ca}^{2+} = 5–10 \mu M\)) of [Ca\(^{2+}\)\(_{\text{mit}}\) uptake pathway has often been considered relevant in the regulation of [Ca\(^{2+}\)\(_{\text{mit}}\)]\(_{\text{tot}}\) only in response to pathological Ca\(^{2+}\) elevations (Carafoli, 1987). The uptake pathway is an electrochemical gradient across the inner mitochondrial membrane, whereas [Ca\(^{2+}\)\(_{\text{cyt}}\)]\(_{\text{tot}}\) efflux relies on 2 Na\(^+\)/Ca\(^{2+}\) and 2 H\(^+\)/Ca\(^{2+}\) exchangers (Denton and McCormack, 1990; Hansford, 1994). A third nonspecific pathway, the mitochondrial permeability transition pore, can be induced under pathological (Crompton and A ndreeva, 1993; Bernardi et al., 1994) and perhaps some physiological (Ichas et al., 1997) conditions. Recently, however, Ca\(^{2+}\) uptake into mitochondria in response to physiological Ca\(^{2+}\) signals has been observed directly in a number of different cell types in culture such as endothelial cells (Lawrie et al., 1996), HeLa cells (Rizzuto et al., 1993), myocytes (Trollinger et al., 1997; Zhou et al., 1998), oligodendrocytes (Simpon and Russel, 1996), astrocytes (Jou et al., 1996; Simpson et al., 1998), hepatocytes (Hajnoczky et al., 1995), rat gonadotropes (Hehl et al., 1996), T lymphocytes (Oth et al., 1997), and the propagation of intracellular Ca\(^{2+}\) waves. Some of this work has been described in abstract form (Duchen, M.R., A. Leysens, M. H. M ojet, and S. P euchen. 1996. J. Physiol. Lond. 494:6-7; Bol ter, E., R. Rea, and M. R. Duchen. 1999. Biophys. J. 76:A223).

Materials and Methods

Materials

All chemicals were obtained from Sigma Chemical Co. unless stated otherwise. All tissue plastics and tissue culture media were obtained from GIBCO BRL. All fluorescence indicators were from Molecular Probes Inc.

Culture of Adult Rat Cortical Astrocytes

The procedure is essentially as described by Peuchen et al. (1996b) with slight modifications. A sucrose-based separation step was added to the procedure to aid in the removal of cell debris and dense myelin, thereby promoting cell attachment and growth. Earle’s balanced salt solution (EBSS) was used throughout the isolation protocol for incubations and washes.

Cerebri were taken from 5- to 8-wk-old Sprague-Dawley rats. The cortex was separated from the other brain structures, the meninges and blood vessels were removed. The tissue, kept at 4°C, was chopped into small pieces, resuspended in EBSS, and forced through a 280-μm mesh metal plate (tissue pan; Sigma Chemicals Co). The filtered suspension was washed by centrifugation at 400 g for 4 min at room temperature. The pellet was resuspended in a Ca\(^{2+}\)-, Mgf\(^2+\)-free EBSS solution containing 50,000 U/ml trypsin (EC 3.4.21.4, isolated from porcine pancreas), 1.033 U/ml collagenase (EC 3.4.24.3, type X1, isolated from Clostridium histolyticum), 336 U/ml deoxyribonuclease 5'-oligonucleotidohydrolase (EC 3.1.21.1, type IV, isolated from bovine pancreas). The enzymatic digestion was stopped after 15 min at 36°C by the addition of 10% heat-inactivated FBS. The suspension was gravity-filtered through a 140-μm metal mesh and centrifuged at 400 g for 6 min. The pellet, resuspended in EBSS, was layered over a 0.4-M sucrose solution (molecular biology grade; BDH Chemicals Ltd) and centrifuged at 400 g for 10 min. The resulting pellet was washed twice in EBSS, followed by one wash in n-vaned-based minimum essential medium (MEM) with 1% fetal bovine serum (FBS). The pellet was resuspended in α-MEM, which inhibits the growth of fibroblasts and endothelial cells, supplemented with 5% FBS, 2 mM glutamine, and 1 mM Mg\(^2+\), and 1 mM Ca\(^2+\), and transferred to culture tissue flasks precoated with 0.01% poly-o-lysine. The flasks were placed in an incubator (95% air, 5% CO\(_2\), at 36°C) for 20–40 h, after which the medium was refreshed. A 6 h in culture, the cells were supplemented with MEM and supplemented with α-MEM. The cells reached confluency at 12–14 d in vitro and were harvested and resedeed onto 24-mm-diam glass coverslips (BDH) precoated with 0.01% poly-o-lysine for fluorescence measurements.

Fluorescence Digital Imaging

Three or more days before experiment, astrocytes were plated onto glass coverslips with an initial plating density of ~7,000 cells/cm\(^2\). Cells were washed with a physiological saline containing 156 mM NaCl, 3 mM KCl, 2.4 mM Ca\(^{2+}\), 1.25 mM Mg\(^{2+}\), 25 mM Hepes at pH 7.45. Rhod-2 Fluorescence. For the qualitative measurement of [Ca\(^{2+}\)\(_{\text{cyt}}\)]\(_{\text{tot}}\) and [Ca\(^{2+}\)\(_{\text{mit}}\)], the cells were loaded with 4.5 μM rhod-2/AM in the presence of 0.005% Pluronic 127 for 30 min at room temperature and washed thoroughly. Rhod-2 fluorescence was excited at 560 nm and emitted fluorescence was collected through a 580-nm-pass long pass barrier filter. High resolution imaging enabled identification of individual mitochondria for analysis.

Simultaneous Recording of Rhod-2 and Fura-2 Fluorescence. To demonstrate that rhod-2 could be used to monitor changes in nuclear Ca\(^{2+}\), the cells were loaded with 4.5 μM rhod-2/AM and 4.5 μM fura-2/AM in the presence of 0.005% Pluronic 127 for 30 min at room temperature. The dye waves were excited sequentially at 490 (for rhod-2), 340, and 380 nm (for fura-2) using specific filters housed in a computer-controlled filter wheel (Cairn Research Ltd.) and fluorescence at wavelengths longer than 520 nm was measured.

Fluo-3 Fluorescence. For analysis of [Ca\(^{2+}\)\(_{\text{cyt}}\)]\(_{\text{tot}}\) waves in single astrocytes, the cells were loaded with 4.5 μM fluo-3/AM in the presence of 0.005% Pluronic 127 for 30 min at room temperature. Fluoro-3 was excited at 490 nm and emitted fluorescence was measured.

TMRE Fluorescence. For analysis of changes in mitochondrial membrane potential (ΔΨ\(_{\text{mit}}\)), cells were loaded with 3 μM of tetramethylrhodamine ethyl ester (TMRE) for 15 min at room temperature. TMRE fluorescence was excited at 546 nm and emitted fluorescence was collected through a 590-nm-long pass barrier filter.

Digital Imaging. Fluorescence measurements were obtained via an epi-fluorescence inverted microscope (Nikon Diaphot) equipped with an oil immersion 63× fluorite objective (NA 1.3). Fluorescence was excited using a 75 W xenon arc lamp and emitted light projected onto the face of a slow scan, frame transfer 800 × 600 pixel, 12 bit cooled CCD camera (Digital Pixel Ltd.), acquisition rate ~2 frames per second full frame, binning pixels 3 × 3. To resolve the rising phases of both nuclear and mitochondrial signals and to monitor wave propagation better, fast imaging was carried out using a fast readout, cooled interline transfer CCD camera (model 4880; Hamamatsu Photonics) allowing image acquisition rates up to 50 images per second with pixels binned at 4 × 4. All imaging data were acquired and analyzed using software from Kinetical Imaging. Because rhod-2, fluo-3, and TMRE are single wavelength fluorescent indicators, it was not possible to apply the ratiometric method for quantitative determination of [Ca\(^{2+}\)\(_{\text{cyt}}\)]\(_{\text{tot}}\) and ΔΨ\(_{\text{mit}}\), respectively. Therefore, the information derived from the measurements of rhod-2, fluo-3, and TMRE fluorescence was normalized as a function of the first image. Nuclear Ca\(^{2+}\) [Ca\(^{2+}\)\(_{\text{mit}}\)] monitored by fura-2 was expressed as the ratio of fura-2 fluorescence after excitation at 340 and 380 nm. All imaging experiments were carried out at room temperature. Greater care was taken for the wave propagation experiments with an average temperature of 21 ± 1°C to avoid any artifact due to the temperature-dependence of Ca\(^{2+}\) wave kinetics (Leclecher and Clapham, 1992). E xcitatory light was kept to a minimum with neutral density filters and a computer-controlled shutter to minimize photobleaching and photodynamic injury to cells.
Confocal microscopy was used for colocalization studies and for high spatial resolution of mitochondrial depolarization waves. In brief, astrocytes were dual-loaded with rhod-2/AM as described above and with 20 nM MitoFluor Green/AM for 30 min at room temperature. Cells were imaged using a confocal laser scanning microscope (model 510; Carl Zeiss, Inc.). Cells were illuminated using the 488-nm emission line of an argon laser and fluorescence was collected simultaneously between 505 and 530 nm for MitoFluor Green and at $\lambda = 585$ nm for rhod-2. To spatially resolve waves of mitochondrial depolarization, astrocytes were loaded with TMRE as described above and were illuminated with the 488-nm emission line. Emitted fluorescence was collected at $\lambda \approx 585$ nm.

Statistical Analysis

Statistical data are presented as the mean ± SD. After testing for normality and variance homogeneity, the data were subjected to the unpaired t test. When the variance was heterogeneous, the Mann-Whitney U test was used. The 0.05 level was selected as the point of minimal statistical significance. All the curves shown in figures are representative of at least three measurements performed on four separate cell preparations.

Results

Rhod-2 Predominantly Localizes within the Mitochondria

A dual rat cortical astrocytes were loaded with rhod-2/AM, a Ca$^{2+}$-sensitive fluorescent indicator (Minta et al., 1989) that accumulates in mitochondria (Hajnoczky et al., 1995; Jou et al., 1996; Abcoc et al., 1997) in response to $\Delta \psi_{m}$. Fig. 1a illustrates a typical image of a rhod-2–loaded adult rat cortical astrocyte showing the localization of rhod-2 within rod-shaped, brightly fluorescent structures of variable organization, reminiscent of mitochondria. However, a diffuse small cytosolic signal and an accumulation of the dye in the nucleus (with rhod-2 also labeling nucleoli) were usually noticed (Trollinger et al., 1997). To confirm that the main rhod-2 fluorescence signal did originate from mitochondria, astrocytes were dual-loaded with rhod-2/AM and MitoFluor Green/AM, an indicator that labels mitochondria independently of mitochondrial function (Poot et al., 1996). The small overlap of the excitation spectra of rhod-2 and MitoFluor Green allows the simultaneous use of both the dyes (Fig. 1a and b). Colocalization of MitoFluor Green (Fig. 1b) and rhod-2 within the cell (Fig. 1a) was confirmed by merging the two images (Fig. 1c) and by the analysis of colocalization shown in Fig. 1d. It should be stated that the relative compartmental loading varied substantially between batches of rhod-2 and between preparations, but the difference was quantitative, not qualitative (i.e., some batches of dye gave much clearer localization into mitochondria, others gave a brighter relative cytosolic [and nuclear] signal, but the partitioning was still between cytosol/nucleus and mitochondria).

Mitochondria Take Up Ca$^{2+}$ in Response to Physiological Stimulation by ATP

Physiological activation of the P$_{2u}$ purinoceptor by ATP in adult rat cortical astrocytes has been shown previously to raise [Ca$^{2+}$]$_{cyt}$ via an IP3-mediated pathway (Peuchen et al., 1996a). We took advantage of the concomitant localization of rhod-2 within the nucleus (a mitochondrion-free volume of the cell) to confirm and monitor changes in [Ca$^{2+}$]$_{cyt}$ in response to ATP challenge, as [Ca$^{2+}$]$_{cyt}$ raises [Ca$^{2+}$]$_{n}$ after a brief pulse of 100 $\mu$M ATP is shown in the time sequence of Fig. 2a. The sequential quantitative changes in [Ca$^{2+}$]$_{n}$ and [Ca$^{2+}$]$_{cyt}$ measured along the longitudinal axis of the cell as indicated by the line in the first image of Fig. 2a, are shown in Fig. 2, b and c. Before agonist application, the rhod-2 fluorescence was relatively dim
and the mitochondrial signal was not obviously brighter than much of the cytosol (Fig. 2 a). Immediately after the mobilization of intracellular Ca$^{2+}$ stores by ATP, an overall increase over both the nucleus (Fig. 2, asterisk) and the cytosol was observed, followed by a delayed increase in signal over mitochondria (selected close to nucleus) that remained elevated long after [Ca$^{2+}$]$_{n}$ recovery. The rise in [Ca$^{2+}$]$_{m}$ presented a wavelike pattern in that mitochondria at one end of the cell tended to respond before those at the other (Fig. 2 a, indicated by black arrows in a and c).

[Ca$^{2+}$]$_{n}$ rose rapidly (time to reach half the peak amplitude, t$_{1/2}$ = 1.95 ± 1.1 s, n = 26), reaching a normalized fluorescence peak of 1.75 ± 0.36 (n = 57), and returned to its resting level within a minute (Fig. 2 a and Fig. 3, a and b, solid circle). A quantitative analysis showed that [Ca$^{2+}$]$_{m}$ returned to resting values with a decay time constant of 4.84 ± 1.75 s (n = 41). In contrast, [Ca$^{2+}$]$_{m}$ rose slowly (t$_{1/2}$ = 3.17 ± 1.3 s, n = 26) and reached a fluorescence [Ca$^{2+}$]$_{m}$ peak corresponding to a 2 ± 0.57-fold increase (n = 63). It remained at a high plateau within the experimental time scale (55 s, Fig. 2). Long-term recording of the ATP-induced changes in [Ca$^{2+}$]$_{m}$ indicated that full recovery to the resting [Ca$^{2+}$]$_{m}$ took 28.6 ± 10.5 min (n = 24, Fig. 3 b).

Plotting changes in [Ca$^{2+}$]$_{m}$ as a function of the changes in [Ca$^{2+}$]$_{n}$ revealed four phases of intracellular Ca$^{2+}$ handling triggered by the IP3-induced mobilization of intracellular Ca$^{2+}$ stores (Fig. 3 c). Immediately after ATP application (phase 1), [Ca$^{2+}$]$_{n}$ rose very rapidly without any important change in [Ca$^{2+}$]$_{m}$. [Ca$^{2+}$]$_{m}$ started increasing together with [Ca$^{2+}$]$_{n}$ (phase 2). In the following 70 s (phase 3), [Ca$^{2+}$]$_{m}$ fell slowly despite the rapid return of [Ca$^{2+}$]$_{n}$ to its resting value. Finally, [Ca$^{2+}$]$_{m}$ progressively and slowly decreased (phase 4) to its resting levels.

We cannot exclude that the measured rise in the extranuclear fluorescence probably reflects a combination of cytosolic and mitochondrial Ca$^{2+}$ signals. However, neither the peak nor the recovery of the [Ca$^{2+}$]$_{m}$ signal appeared to be contaminated by the [Ca$^{2+}$]$_{ cyt}$ signal that peaked and returned to basal level far more quickly than [Ca$^{2+}$]$_{m}$ (see below for time courses of [Ca$^{2+}$]$_{ cyt}$ and [Ca$^{2+}$]$_{m}$). In addition, the flat morphology of astrocytes in culture.
(Sheppard et al., 1997; Simpson et al., 1998) allowed the resolution and selection of individual mitochondria for image analysis.

**Mitochondrial Depolarization Prevents Mitochondrial Ca\(^{2+}\) Uptake and Slows Cytosolic Ca\(^{2+}\) Clearance**

Mitochondrial calcium uptake depends on $\Delta\psi_m$ and dissipation of the potential provides the easiest way to examine the consequences of $[\text{Ca}^{2+}]_m$ accumulation for cell Ca\(^{2+}\) signaling. To this end, we chose to use the mitochondrial protonophore p-trifluoromethoxy-phenylhydrazine (FCCP), a mitochondrial uncoupler that dissipates the proton gradient across the inner mitochondrial membrane, hence abolishing the $\Delta\psi_m$. Under such conditions, activation of the mitochondrial ATPase in reverse mode may lead to the rapid consumption of ATP (Leyssens et al., 1996). Therefore, FCCP (1 $\mu$M) was always applied in combination with 2.5 $\mu$M oligomycin, to inhibit mitochondrial consumption of cellular ATP.

The time series shown in Fig. 4 a, and more particularly the corresponding surface plot (Fig. 4 c) and line image (Fig. 4 d), illustrate the changes in $[\text{Ca}^{2+}]_\text{nuc}$ and $[\text{Ca}^{2+}]_\text{cyt}$ upon FCCP application, followed by 100 $\mu$M ATP. FCCP initially induced a transient rise in $[\text{Ca}^{2+}]_\text{cyt}$ localized to the perinuclear (Fig. 4, a and b, p; Fig. 4 c and d, arrows) and the cytosolic (Fig. 4, a and b, c; Fig. 4 c and d, arrows) regions, most likely reflecting Ca\(^{2+}\) release from mitochondria that was only followed later by a rise in $[\text{Ca}^{2+}]_\text{nuc}$ (Fig. 4, a and b, n; Fig. 4, c and d, asterisk). In the experiment illustrated in Fig. 4 b, the FCCP-induced change in rhod-2 fluorescence was $\sim$1.2-fold. The mean increase in rhod-2 signal in response to FCCP application was $1.76 \pm 0.43$ ($n = 29$) fold (see also below).

Subsequent application of ATP elicited a diffuse, transient rise in nuclear and cytosolic rhod-2 fluorescence (Fig. 4 a), without any apparent mitochondrial rhod-2 signal, demonstrating the effective inhibition of Ca\(^{2+}\) uptake in deenergized mitochondria. The relative change in the nuclear Ca\(^{2+}\) signal appeared far bigger than that in the cytosol (Fig. 4). This apparent nuclear amplification is likely to occur because of an underestimation of $[\text{Ca}^{2+}]_\text{cyt}$ changes resulting from the creation of a pool of indicator seques-
tered in mitochondria that was insensitive to changes in $[\text{Ca}^{2+}]_{\text{cyt}}$ after the dissipation of $D_{c_{m}}$ by FCCP (Mohanna et al., 1994).

Collapse of $D_{c_{m}}$ by FCCP did not significantly alter the peak amplitude of the ATP-induced $[\text{Ca}^{2+}]_{n}$ transient (Fig. 4 b, control cells, peak $= 1.75 \pm 0.36, n = 57$; FCCP-treated cells, peak $= 1.63 \pm 0.33, n = 38$; $P = 0.11$, t test) or the time required to reach half the peak amplitude of $[\text{Ca}^{2+}]_{n}$ (control cells, $t_{1/2} = 1.95 \pm 1.1$ s, $n = 26$; FCCP-treated cells, $t_{1/2} = 1.93 \pm 0.95$ s, $n = 38$; $P = 0.93$, t test). However, the decay phase of the $[\text{Ca}^{2+}]_{n}$ was significantly longer in the presence of FCCP (control cells, $t = 4.84 \pm 1.75$ s, $n = 41$; FCCP-treated cells, $t = 8.92 \pm 2.89$ s, $n = 44$; $P < 0.0001$, Mann-Whitney U test). This result strongly suggests that mitochondrial $\text{Ca}^{2+}$ buffering plays a substantial role in hastening the restoration of $[\text{Ca}^{2+}]_{n}$ and, hence, $[\text{Ca}^{2+}]_{\text{cyt}}$ to basal levels. The $[\text{Ca}^{2+}]_{\text{cyt}}$ transient had a very similar time course to that of the $[\text{Ca}^{2+}]_{n}$ (Fig. 4 b), strengthening the assumption that changes in $[\text{Ca}^{2+}]_{n}$ are a true index of changes in $[\text{Ca}^{2+}]_{\text{cyt}}$.

**In Resting Conditions, Mitochondria may Contain Substantial $\text{Ca}^{2+}$ Loads**

Dissipation of $\Delta\psi_{m}$ by FCCP reverses the activity of the $\text{Ca}^{2+}$ uniporter, which becomes a $\text{Ca}^{2+}$ efflux pathway (Kröner, 1992). We applied 1 $\mu$M FCCP to resting astrocytes dual-loaded with rhod-2 and fura-2, in the presence of 2.5 $\mu$g/ml oligomycin. Data are illustrated in Fig. 5. Short application of FCCP induced a steep rise in $[\text{Ca}^{2+}]_{n}$ monitored by rhod-2 (solid circle) that returned to basal level within a minute (mean peak amplitude $= 1.76 \pm 0.43$, $n = 29$).

We were concerned that the change in the rhod-2 signal might reflect some form of redistribution of dye and dequench (i.e., as seen with TMRE, although this is not expected on theoretical grounds; see below) rather than a true reflection of changing $[\text{Ca}^{2+}]_{n}$. We have recorded rhod-2 fluorescence simultaneously with a second widely used $\text{Ca}^{2+}$-sensitive fluorescent indicator, fura-2. FCCP caused a rise in fura-2 ratio (open circle, mean peak amplifi-
Mitochondrial Modulation of Ca$^{2+}$ Waves in Astrocytes

Rhod-2/AM and fura-2/AM. The Ca$^{2+}$ changes in mitochondrial depolarization is an accurate reflection of the rise in rhod-2 signal upon the presence of oligomycin. Qualitatively, similar results were observed under these conditions (data not shown). Thereafter, these data suggest that the rise in rhod-2 signal upon mitochondrial depolarization is an accurate reflection of changes in [Ca$^{2+}$]$_{cyt}$ and that Ca$^{2+}$ is released from mitochondria in these resting astrocytes.

Characteristics of [Ca$^{2+}$]$_{cyt}$ Waves Induced by Chemical or Mechanical Stimulation in Rat Cortical Astrocytes

To investigate the spatio-temporal organization of the [Ca$^{2+}$]$_{cyt}$ changes in astrocytes, we examined Ca$^{2+}$ waves in fluo-3–loaded astrocytes at higher time resolution (~7–14 Hz). Single-cell stimulation was performed either chemically by pressure application from a micropipette filled with ATP (20 μM) or mechanically with a micromanipulator-driven glass micropipette filled with the recording saline. We chose an ATP concentration of 20 μM to temporally resolve the Ca$^{2+}$ wave as stimulation with 100 μM induced a rapid wave that could not be resolved (data not shown).

After either chemical or mechanical stimulation, a wave of [Ca$^{2+}$]$_{cyt}$ was routinely observed throughout the stimulated cell, usually spreading in directions away from the point of stimulation. Fig. 6 a shows some sample images from a sequence to illustrate the propagation of an intracellular [Ca$^{2+}$]$_{cyt}$ wave after ATP application. The time course of propagation was defined by selecting a line along the wave path on the image series. The intensity profile for the line for each frame was plotted as a two-dimensional line image (the post hoc equivalent of a line scan on a confocal system) as shown in Fig. 6 c. The wave propagation is seen as a gradual increase of the fluorescent signal across the cell from one side to the opposite side as a function of time. The wave velocity was readily measured simply as the slope of distance with time across the cytosol (Fig. 6 c).

The mean value for the velocity of the [Ca$^{2+}$]$_{cyt}$ wave was 21.6 ± 11.5 μm/s (Table I, n = 133) and 24.4 ± 10.7 μm/s (Table I, n = 129) under chemical and mechanical stimulation, respectively. These velocities were not significantly different, suggesting that once initiated, the waves were propagated by the same mechanism. The mean rate given by all these data was 22.9 ± 11.2 μm/s (Table I, n = 262). The time course of the amplitude changes in [Ca$^{2+}$]$_{cyt}$ signal for six regions of the cell during the propagation of the wave as a function of time is shown in Fig. 6 b. The peak amplitude of the wave was sustained throughout the rest of the experiment.

### Table I. Inhibition of Mitochondrial Function Increases the Mean Ca$^{2+}$ Wave Velocities in Chemically and Mechanically Stimulated Astrocytes

regions of propagation although the rate of rise tended to decrease with propagation of the wave. Similar results were found for mechanically induced Ca\(^{2+}\) waves (data not shown). The \([\text{Ca}^{2+}]_{\text{cyt}}\) at this sustained level (~1.8-fold increase from resting values) remained within the measurable range. Indeed, saturation of the fluo-3 signal by application of 20 \(\mu\text{M}\) ionomycin showed a fluorescence enhancement of 5.7 \(\pm\) 3.3-fold \((n = 77)\) in comparison to resting \([\text{Ca}^{2+}]_{\text{cyt}}\). Determination of the diffusion rate of Ca\(^{2+}\) across the nucleus of ATP-stimulated cells showed a significantly higher rate than the Ca\(^{2+}\) wave velocity calculated over the cytosol (Table I, 34.6 \(\pm\) 26.7 \(\mu\text{m/s,}\) \(n = 27,\) Mann-Whitney U test, \(P < 0.05\)) corresponding to a 60% increase.

**Cytosolic Calcium Waves Are Followed by Waves of Mitochondrial Depolarization**

We asked about the consequences of mitochondrial calcium uptake, for mitochondrial function and, as described below, for calcium signaling. Upon chemical and mechanical stimulation, waves of \([\text{Ca}^{2+}]_{\text{m}}\) propagating across single astrocytes could be observed (Fig. 2, ATP challenge). However, the features of a \([\text{Ca}^{2+}]_{\text{m}}\) wave front were hard to characterize given the spatially irregular punctate rhod-2 signal. In addition, the rhod-2 signal arising from the cytosol obscured the initial rising phase of the \([\text{Ca}^{2+}]_{\text{m}}\) characteristics. To overcome this problem, we followed changes in \(\Delta\psi_{\text{m}}\), as influx of Ca\(^{2+}\) into mitochondria induces a small transient mitochondrial depolarization (Duchen, 1992; Loew et al., 1994; Duchen et al., 1998; Peuchen et al., 1996b). Indeed, monitoring changes in \(\Delta\psi_{\text{m}}\) tends to amplify the response to mitochondrial calcium uptake and provides a sensitive index of a small calcium flux during mitochondrial Ca\(^{2+}\) uptake (Duchen et al., 1998).

To follow changes in \(\Delta\psi_{\text{m}}\), astrocytes were loaded with the potentiometric dye TMRE that selectively accumulates in mitochondria. The concentration of TMRE into polarized mitochondria causes autoquenching of TMRE fluorescence that is relieved by mitochondrial depolarization.

**Figure 6.** Characteristics of the propagating \([\text{Ca}^{2+}]_{\text{cyt}}\) wave in ATP-stimulated astrocytes. (a) Time series of images showing the propagation of an intracellular Ca\(^{2+}\) wave across a fluo-3-loaded cortical astrocyte upon ATP challenge (20 \(\mu\text{M}\)). (b) Plots of six consecutive areas across the cytoplasm of an astrocyte (at positions 1-6 shown in image inset) following the wave path. Note the sequential and sustained increase in fluorescence in the different regions. (c) Line image to illustrate the propagating wave using data obtained by selecting a line along the axis of the cell (see image inset in b). The asterisk indicates the position of the nucleus. The arrow in b and c signals ATP application.
tion. Therefore, TMRE dequench is associated with a rise in fluorescence. Induction of a Ca\(^{2+}\) wave with a brief deformation of the plasma membrane initiated a wave of mitochondrial depolarization spreading from the stimulation point across the cell seen clearly in the confocal image series shown in Fig. 7a. A line image (Fig. 7c) constructed from a similar image series but obtained using the fast readout CCD camera (Fig. 7b) clearly showed the initiation sites of the propagating wave as mitochondria (the bright lines on the line image), whereas TMRE diffused slowly into the nucleus (asterisk). Determination of the wave velocity gave a mean value of 9.7 ± 4.2 μm/s (n = 89). Fig. 7b illustrates the changes in Δψ\(_m\) recorded in six regions of the cell as a function of time. The peak amplitude of the transient mitochondrial depolarization was sustained over long distances throughout the regions of wave propagation (Fig. 7b). Indeed, roughly the same peak amplitude of Δψ\(_m\) signals was seen at the cytosolic stimulation point 1 and the more distal point 6, suggesting again the regenerative nature of the propagating wave. In addition, the rate of rise tended to decrease with propagation of the wave, strikingly mirroring the gradual decrease of the rate of rise of the \([Ca^{2+}]_{cyt}\) wave. Thus, the propagation of the Ca\(^{2+}\) wave causes a wave of mitochondrial depolarization in its wake.

**Mitochondria Modulate the Kinetics of Cytosolic Ca\(^{2+}\) Wave Propagation**

To determine the impact of mitochondrial Ca\(^{2+}\) uptake

---

**Figure 7.** Propagation of a wave of mitochondrial depolarization induced by mechanical stimulation in astrocytes. (a) Images selected from a time series of confocal images showing the propagation of a wave of mitochondrial depolarization across a TMRE-loaded cortical astrocyte elicited by mechanical stimulation. (b) Plot of six consecutive box areas across another cell (see image inset), following the wave path. Note the sequential and sustained increase in fluorescence in the different regions. (c) Line image of a line trace obtained by drawing a line across the length of the cell (b, image inset). The asterisk marks the position of the nucleus. The arrows in a indicate the progression of the wave. In b and c, the arrow signals mechanical stimulation of the cell.
on the spatio-temporal characteristics of calcium signaling, fluo-3–loaded astrocytes were treated either with 2.5 μg/ml antimycin A1 or with 10 μM rotenone (an inhibitor of mitochondrial respiratory complex I), both in association with 2.5 μg/ml oligomycin. This protocol induced a complete collapse of ΔΨm (assessed with TMRE, data not shown), preventing any subsequent Ca2+ uptake into mitochondria. Whatever the mitochondrial inhibitor used, mechanical or chemical stimulation elicited a typical [Ca2+]cyt wave spreading away from the stimulation point, very similar to control cells in terms of pattern and regenerative nature of the propagation. Fig. 8 shows a typical example of Ca2+ waves spreading across an astrocyte upon ATP challenge either in control conditions (a) or after treatment with antimycin A1/oligomycin (b). The differentiated line image (corresponding to a time series of iteratively subtracted images, only showing changes occurring between consecutive frames) given in the lower part of each frame showed the wavefront propagating through the cell. It is clear that the Ca2+ wave traveled faster in the antimycin-treated cells (Fig. 8 b).

Determination of the wave velocity in antimycin-treated cells showed a mean value of 35.6 ± 23 μm/s (n = 121) in response to ATP application and 31.1 ± 10.5 μm/s (n = 66) to mechanical stimulation (Table I). These values were not significantly different and the pooled data gave an average Ca2+ wave rate in antimycin-treated cells of 34 ± 19.6 μm/s (n = 187). Rotenone-treated cells exhibited a Ca2+ wave rate of 40.4 ± 28.6 μm/s (n = 50) to ATP challenge and of 30.6 ± 12.4 μm/s (n = 35) to mechanical stimulation (Table I). The averaged Ca2+ wave rate was 36.4 ± 23.7 μm/s (n = 85), remarkably similar to the diffusion rate of Ca2+ through the mitochondrion-free nucleus (see above). This corresponds to a significant 48% and 58% increase (P < 0.0001, Mann-Whitney U test) of the [Ca2+]cyt wave velocity in antimycin- and rotenone-treated astrocytes, respectively. Statistical analysis of the Ca2+ wave velocities from antimycin- and rotenone-treated cells revealed no significant difference. These results clearly demonstrate that mitochondrial calcium uptake exerts a negative feedback action upon the kinetics of Ca2+ wave propagation in astrocytes.

Discussion
In the present study, we have addressed several related questions: (a) Do mitochondria take up Ca2+ during physiological Ca2+ signaling in adult rat cortical astrocytes? (b) If so, what are the temporal characteristics of the mitochondrial response? (c) What are the consequences for mitochondrial potential and (d) what are the consequences for the spatio-temporal characteristics of the Ca2+ signal? Our data show that mitochondria in these cells take up Ca2+ during physiological Ca2+ signaling, that they tend to retain that Ca2+ for prolonged periods of time, and that the uptake not only shapes [Ca2+]cyt signals but also

![Figure 8. Inhibition of [Ca2+]m uptake increases the velocity of [Ca2+]cyt waves in astrocytes. exerts a negative feedback on the rate of propagation of Ca\textsuperscript{2+} waves, by acting as high capacity fixed Ca\textsuperscript{2+} buffers.

Evidence for [Ca\textsuperscript{2+}]\textsubscript{cyt} Uptake in Adult Rat Cortical Astrocytes

Little information is available about the functional consequences of [Ca\textsuperscript{2+}]\textsubscript{cyt} accumulation with respect to [Ca\textsuperscript{2+}]\textsubscript{cyt} handling in glial cells. Stimulation of IP3-mediated ER Ca\textsuperscript{2+} release by ATP in astrocytes routinely induced a simultaneous rise in [Ca\textsuperscript{2+}]\textsubscript{cyt}, and in [Ca\textsuperscript{2+}]\textsubscript{cyt}. However, these signals exhibited quite distinct temporal features: the [Ca\textsuperscript{2+}]\textsubscript{cyt} transient recovered within 1 min. In contrast, the mitochondrial response rose 1.6-fold more slowly than the nuclear signal, and full recovery took several minutes. A longer time of recovery to basal level for [Ca\textsuperscript{2+}]\textsubscript{cyt} than for [Ca\textsuperscript{2+}]\textsubscript{cyt} also has been described in the glial cell line RBA-1 (Jou et al., 1996), in oligodendrocytes (Simpson and Russel, 1998), in hepatocytes (Hajnoczky et al., 1995), in myocytes (Trollinger et al., 1997; Zhou et al., 1998), and in adrenal chromaffin cells (Herrington et al., 1996), although the specific rates varied widely between these different cell types.

These observations differ strikingly from results obtained with aequorin targeted to mitochondria in HEIa cells (Rizzuto et al., 1992). This discrepancy could result from the use of different cell types, different methodologies, different temperatures, the relative inaccuracy of aequorin at [Ca\textsuperscript{2+}] values below 300-400 nM (K\textsubscript{d} for Ca\textsuperscript{2+} = 1 \mu M), or alteration of the apparent kinetics of the [Ca\textsuperscript{2+}]\textsubscript{cyt} signal by rhod-2 given its relatively high affinity to Ca\textsuperscript{2+} compared with the low affinity aequorin. The mitochondrial model elaborated by Magnus and K eizer (1998) also predicts a delay between increases in [Ca\textsuperscript{2+}]\textsubscript{cyt} and [Ca\textsuperscript{2+}]\textsubscript{cyt}. This delay may result from the positive cooperativity of uniporter activation by extramitochondrial Ca\textsuperscript{2+} (Hill coefficient \sim 2) (Gunter and Pfeffe r, 1990). Mitochondria start accumulating cytosolic Ca\textsuperscript{2+} from [Ca\textsuperscript{2+}]\textsubscript{cyt} \sim 500 nM but do not saturate readily (Gun ter, 1994). Rates of [Ca\textsuperscript{2+}]\textsubscript{cyt} increase after intracellular Ca\textsuperscript{2+} mobilization have been demonstrated to be more than one order of magnitude faster than that predicted on the basis of the amplitude of the mean rise in [Ca\textsuperscript{2+}]\textsubscript{cyt} (Rizzuto et al., 1993). This has been explained by proposing that mitochondria closely exposed to Ca\textsuperscript{2+} release sites would be exposed to local concentrations of Ca\textsuperscript{2+} much higher than those measured in the bulk of the cytoplasm (Rizzuto et al., 1993, 1998). Such a close localization of mitochondria to IP3 receptors recently has been observed in rat astrocytes in culture (Simpson et al., 1998), and is also suggested by the appearance of transient mitochondrial depolarizations due to focal calcium release from the sarcoplasmic reticulum in cardiac myocytes (Duchen et al., 1998).

Depolarization of the mitochondrial potential with FCCP completely prevented [Ca\textsuperscript{2+}]\textsubscript{cyt} loading after a challenge with ATP. In addition, the rate of decay of the [Ca\textsuperscript{2+}]\textsubscript{cyt} signal was significantly slowed, suggesting that mitochondrial Ca\textsuperscript{2+} uptake plays a significant role in the clearance of [Ca\textsuperscript{2+}]\textsubscript{cyt} loads in these cells. The effects of the mitochondrial uncoupler on Ca\textsuperscript{2+} clearance were almost certainly not attributable to ATP depletion, as the mitochondrial ATPase was inhibited throughout by oligomycin to minimize mitochondrial consumption of cellular ATP. In contrast to our results, FCCP exposure did not influence the kinetic parameters of the depolarization-triggered [Ca\textsuperscript{2+}]\textsubscript{cyt} transient in oligodendrocytes (Kirischuk et al., 1995b), suggesting that [Ca\textsuperscript{2+}]\textsubscript{cyt} accumulation does not play an important role in shaping Ca\textsuperscript{2+} signals in oligodendroglia. It seems likely that differences in such contributions of mitochondria to calcium signaling may vary simply as a function of the relative mitochondrial density or intracellular location in different cell types.

The [Ca\textsuperscript{2+}]\textsubscript{cyt} signal in the astrocytes after ATP stimulation recovered with a monoexponential time course. In a number of cell types, [Ca\textsuperscript{2+}]\textsubscript{cyt} decay characteristically follows a biphasic sequence in which a fast initial decay is followed by a much slower secondary decay that appears to be maintained by the reequilibration of [Ca\textsuperscript{2+}]\textsubscript{cyt} by the mitochondrial Na\textsuperscript{+}/Ca\textsuperscript{2+} exchange (rat gonadotropes, H ehl et al., 1996; sensory neurons, Thayer and Miller, 1990). The absence of such a plateau phase in the astrocyte model seems consistent with the very prolonged retention of Ca\textsuperscript{2+} in the mitochondria of these cells. This may reflect a low [Na\textsuperscript{+}] content of astrocytes and the absence of Na\textsuperscript{+} influx during this form of stimulation (in contrast to depolarization-induced transients in the excitable sensory neurons, gonadotropes, and chromaffin cells). Indeed, while the accumulated [Ca\textsuperscript{2+}]\textsubscript{cyt} is clearly released back into the cytosol, this occurs at such a low rate that it does not cause a significant change in [Ca\textsuperscript{2+}]\textsubscript{cyt}. Therefore, the [Ca\textsuperscript{2+}]\textsubscript{cyt} signal in these cells.

We noted that depolarization of the mitochondrial potential routinely released Ca\textsuperscript{2+} into the cytosol within quiescent cells, suggesting that mitochondria in this preparation were often Ca\textsuperscript{2+}-loaded at rest. Given the very prolonged time course of [Ca\textsuperscript{2+}]\textsubscript{cyt} reequilibration, perhaps this is not very surprising as only occasional spontaneous activity would keep the mitochondria primed with a significant Ca\textsuperscript{2+} content. A substantial Ca\textsuperscript{2+} pool has been found in mitochondria of oligodendrocytes under resting conditions (Kirischuk et al., 1995a,b), in contrast to the very modest [Ca\textsuperscript{2+}]\textsubscript{cyt} content in neurons (Werth and Thayer, 1994), T lymphocytes (H oth et al., 1997), rat gonadotropes (H ehl et al., 1996), and rat chromaffin cells (Herrington et al., 1996).

In astrocytes, mitochondria seem to contribute to cytosolic Ca\textsuperscript{2+} clearance during the [Ca\textsuperscript{2+}]\textsubscript{cyt} decay only but not in the fast rising phase of the [Ca\textsuperscript{2+}]\textsubscript{cyt} transient. In addition, dissipation of \Delta \psi \textsubscript{m} by FCCP did not appreciably affect the peak amplitude of the ATP-induced [Ca\textsuperscript{2+}]\textsubscript{cyt} response. These results are similar to those described in adrenal chromaffin cells (Babcok et al., 1997), T lymphocytes (H oth et al., 1997), rat gonadotropes (H ehl et al., 1996), and HEIa cells (Rizzuto et al., 1992). Simpson et al. (1998) found that FCCP pretreatment caused variable effects on the norepinephrine-evoked [Ca\textsuperscript{2+}]\textsubscript{cyt} responses in astrocytes, ranging from complete block of the response to minor effects. In contrast, we consistently found no significant alteration in the amplitude of the Ca\textsuperscript{2+} peak induced by ATP in FCCP (+ oligomycin)-treated astrocytes. This disparity could be partly explained by the absence of oligomycin in most of their experiments, leading to ATP rundown in the course of the norepinephrine stimulation.
Mitochondria Exert a Negative Feedback on the Propagation of Intracellular Ca\(^{2+}\) Waves in Astrocytes

Stimulation of astrocytes triggers an increase in [Ca\(^{2+}\)]\(_{cyt}\) that can propagate as a wave through the cytoplasm of individual cells and through astrocytic networks (Cornell-Bell et al., 1990; V erkhatorsky et al., 1998). Thus, we were interested in determining the role of mitochondria upon the spatio-temporal characteristics of these Ca\(^{2+}\) waves. Both mechanical and chemical stimuli were used to trigger Ca\(^{2+}\) waves. In addition to triggering Ca\(^{2+}\) influx, mechanical stimulation recently has been shown to activate phospholipase C in astrocytes (V enance et al., 1997). The propagation velocities of these Ca\(^{2+}\) waves were nearly identical regardless of the initiating stimulus (pooled control rate = 22.9 \(\pm\) 11.2 \(\mu\)m/s, \(n = 262\)), suggesting that once initiated, the waves were propagated by the same mechanism. This range of Ca\(^{2+}\) wave velocities correlates well with those found in hippocampal astrocytes (Cornell-Bell et al., 1990) and retinal astrocytes (Newman and Z ahls, 1997).

The amplitude of the Ca\(^{2+}\) signal from the wave initiation site could be maintained or could even increase during spread across the cell, strongly suggesting that the wave propagates as an actively regenerative process and not simple long-range passive diffusion following release from a point source. The propagating [Ca\(^{2+}\)]\(_{cyt}\) wave was associated with a propagating wave of mitochondrial depolarization that traveled at around 10 \(\mu\)m/s following mechanical stimulation. Thus, during the propagation of an intracellular [Ca\(^{2+}\)]\(_{cyt}\) wave, mitochondria take up Ca\(^{2+}\) as the wave travels across the cell. The discrepancy between the velocity of the [Ca\(^{2+}\)]\(_{cyt}\) wave and of the wave of mitochondrial depolarization probably reflects fundamental differences in the behavior of the fluorescent dyes fluo-3 and TMRE. Whereas fluo-3 fluorescence rises immediately upon Ca\(^{2+}\) binding, the increase in TMRE fluorescence occurs after mitochondrial depolarization results from dye egress from mitochondria, dequench of fluorescence and then diffusion of dye through the cytosol, inevitably underestimating the rate of progression of the wave of mitochondrial depolarization. Furthermore, the change in \(\Delta m\)\(_{mit}\) reflects the rate of Ca\(^{2+}\) flux, which tends to be slower at the distal end of the cell (Fig. 8) compared with the origin of the wave front. Nevertheless, the appearance of a wave of mitochondrial depolarization clearly demonstrates that mitochondria take up Ca\(^{2+}\) as a [Ca\(^{2+}\)]\(_{cyt}\) wave travels across the cell.

To determine whether mitochondria play a functional role in the propagation of the Ca\(^{2+}\) wave in astrocytes, mitochondrial Ca\(^{2+}\) uptake was prevented by dissipation of the mitochondrial potential using antimycin A or rotenone (each in association with oligomycin). The Ca\(^{2+}\) waves presented the same regenerative pattern of propagation as in the control cells, but the wave velocity increased substantially. Thus, mitochondrial Ca\(^{2+}\) uptake appears to slow the rate of propagation of the cytosolic signal. Taken together, these results suggest that functional mitochondria exert a negative feedback on the propagation of intracellular Ca\(^{2+}\) waves in adult rat cortical astrocytes.

What could be the underlying mechanism of the negative feedback control exerted by mitochondria upon the propagating Ca\(^{2+}\) wave? Current models to account for the propagation of Ca\(^{2+}\) signals suggest that IP3 induces a wave by diffusing through the cell, priming IP3 receptors, and releasing Ca\(^{2+}\) as puffs from ER release sites (Finkelbeiner, 1993; V enance et al., 1997; Wang et al., 1997). The rise in [Ca\(^{2+}\)]\(_{cyt}\) generates additional IP3 through the Ca\(^{2+}\)-dependent activation of phospholipase C (B erridge, 1993) providing a positive feedback step, whereas the diffusion of Ca\(^{2+}\) to neighboring IP3 receptors activates increasing numbers of IP3-primed IP3 receptors (Y ao et al., 1995), as type 1 IP3 receptors display a bell-shaped sensitivity to Ca\(^{2+}\) that functions as a coagonist with IP3 to release stored Ca\(^{2+}\) (B ezprozvanny et al., 1991; Finch et al., 1991). The peak sensitivity to Ca\(^{2+}\) lies at \(\sim\)300 nM, whereas at higher concentrations Ca\(^{2+}\) becomes inhibitory. However, type 2 IP3 receptors, lack the Ca\(^{2+}\)-dependent inactivation at high [Ca\(^{2+}\)]\(_{cyt}\) (R amos-Franco et al., 1998). Thus, depending on the type of receptors expressed by a cell, mitochondrial control of local [Ca\(^{2+}\)]\(_{cyt}\) through Ca\(^{2+}\) uptake could result in either a positive or a negative control on the Ca\(^{2+}\) wave propagation. The importance of mitochondria in the regulation of propagating [Ca\(^{2+}\)]\(_{cyt}\) waves was first demonstrated in oocytes of the amphibian X enopus laevis (J ouaville et al., 1995) that express type 1 IP3 receptors (K ume et al., 1993). These authors found that IP3-mediated Ca\(^{2+}\) waves were synchronized and increased in both amplitude and velocity by addition of substrates for mitochondrial respiration. The additional substrate hyperpolarizes the \(\Delta m\)\(_{mit}\), promoting [Ca\(^{2+}\)]\(_{im}\) uptake and slowing IP3 receptor inactivation by reducing the Ca\(^{2+}\) concentration in the immediate vicinity of active IP3 receptors (J ouaville et al., 1995).

In the present study, we found that mitochondria exert a negative control on Ca\(^{2+}\) wave propagation. Rat astrocytes in culture express predominantly type 2 IP3 receptors (Sheppard et al., 1997; B otilier, E., S. Brind, and M. R. Duchen, unpublished observations). In addition, mitochondria in astrocytes are located near IP3 receptors, which correspond to the amplification sites for Ca\(^{2+}\) waves (Sheppard et al., 1997). One possible explanation would be that mitochondria in close proximity to IP3 receptors participate in a local Ca\(^{2+}\) buffering that alters gating kinetics of type 2 IP3 receptor channels. The fall in local [Ca\(^{2+}\)]\(_{cyt}\) would decrease the affinity of the IP3 receptors to IP3, decreasing further IP3-mediated Ca\(^{2+}\) release. Less Ca\(^{2+}\) will be available to feedback onto the Ca\(^{2+}\) releasing IP3 receptors and to diffuse away to stimulate nearby IP3 receptors. This mechanism would completely account for the slowing of the intracellular Ca\(^{2+}\) wave (W ang et al., 1997). In this model, type 2 IP3 receptors will not be inherently self-limiting, because Ca\(^{2+}\) passing through an active type 2 channel cannot negatively feedback and turn the channel off (R amos-Franco et al., 1998). This hypothesis is further supported by the observation that the diffusion rate of Ca\(^{2+}\) across the (mitochondrion-free) nucleus was of the same order of magnitude as the Ca\(^{2+}\) wave velocities in cells in which mitochondrial uptake had been abolished (\(\sim\)34 \(\mu\)m/s). Such differences in the wave rates between nucleus and cytosol have been observed in other cell types (D onnadieu and B ourguignon, 1996; Koopman et al., 1997). This probably reflects the paucity of Ca\(^{2+}\) buffers in the nucleus, and strengthens the concept that mitochondria are predominant cytosolic Ca\(^{2+}\) buffers in astrocytes.

Studying the impact of cytoplasmic Ca\(^{2+}\) buffering on the spatial and temporal characteristics of intercellular
Ca\(^{2+}\) signals in astrocytes, Wang et al. (1997) found that pretreatment with an exogenous Ca\(^{2+}\) chelator such as BAPTA dramatically decreased the Ca\(^{2+}\) wave velocity within individual astrocytes. A corollary to these authors, the positive feedback role of Ca\(^{2+}\) in wave propagation is primarily local, acting at the Ca\(^{2+}\) release sites, while Ca\(^{2+}\) diffusion constitutes an important factor as a rate-limiting step during the initiation and propagation of Ca\(^{2+}\) waves (Lechleiter et al., 1991; Wang and Thompson, 1995; Wang et al., 1997). One major consequence of the presence of an exogenous Ca\(^{2+}\) buffer might be to reduce the peak-free Ca\(^{2+}\) concentration at a puff site, thereby attenuating the regenerative potential of the wave. These authors suggested that the presence of endogenous cytosolic Ca\(^{2+}\) buffers with a relatively low affinity for Ca\(^{2+}\) would permit wave propagation but still restrict this mode of intracellular Ca\(^{2+}\) signaling to a very localized range (Wang et al., 1997). Ca\(^{2+}\) uptake into mitochondria is a low affinity, high capacity process (Gunter, 1994). In addition, a rapid mode of Ca\(^{2+}\) uptake recently has been discovered in liver mitochondria allowing [Ca\(^{2+}\)]\(_{m}\) accumulation for low [Ca\(^{2+}\)]\(_{cyt}\) (Sparagna et al., 1995). Taken together, the data indicate that Ca\(^{2+}\) wave kinetic parameters are controlled tightly by active Ca\(^{2+}\) buffering by mitochondria.

Working on the same cell model, Simpson et al. drew completely opposite conclusions (Simpson and Russell, 1996; Simpson et al., 1998), suggesting that mitochondria located close to IP3 receptors promote Ca\(^{2+}\) wave propagation by preventing Ca\(^{2+}\)-dependent inactivation of the IP3 receptor at high [Ca\(^{2+}\)]\(_{cyt}\). This hypothesis relies on the bell-shaped response of the IP3 receptor to Ca\(^{2+}\), characteristic of type 1 IP3 receptor (Bezprozvanny et al., 1991; Finch et al., 1991). However, they showed that astrocytes essentially possess type 2 IP3 receptors (Sheppard et al., 1997). The fact that mitochondria are located near IP3 receptors does not necessarily mean that they play a positive role in Ca\(^{2+}\) wave propagation. On the contrary, such a close location could represent a highly plastic mechanism whereby the cell could finely tune intracellular Ca\(^{2+}\) wave characteristics, thus modulating this newly discovered form of nonsynaptic long-range signaling in the brain (Cornell-Bell et al., 1990).

Physiological and Pathological Relevance of Mitochondrial Modulation of Ca\(^{2+}\) Wave Kinetics

Under physiological conditions, mitochondrial status could contribute to the modulation of the intercellular propagation of Ca\(^{2+}\) waves within the astrocyte network. Indeed, modulation could simply rely upon supply of mitochondrial respiratory substrates to mitochondria or transient inhibition of mitochondrial respiration, regulating \(\Delta\varphi_{m}\), and modulating mitochondrial Ca\(^{2+}\) uptake. In the astrocyte, functional active mitochondria would permit wave propagation but could restrict the extent of spread of this mode of intercellular Ca\(^{2+}\) signaling. Modulation of such a mitochondrial contribution would allow a differential activation of specific neurons in the brain and may directly participate in information processing in the CNS.

Brain mitochondria have been found to be impaired in some pathologies such as ischemia/reperfusion injury (Sims, 1995) and Parkinson’s disease (Bowling and Beal, 1995). In such conditions, [Ca\(^{2+}\)]\(_{m}\) uptake is impaired and mitochondria will no longer be able to regulate Ca\(^{2+}\) wave spread. One possible consequence might be an increased spread of intercellular Ca\(^{2+}\) waves in the astrocytic networks that might eventually lead to Ca\(^{2+}\) deregulation in the surrounding nervous system. The astrocytic Ca\(^{2+}\) wave may be important for the phenomenon known as Liao’s spreading depression (SD) (Do Carmo and Somjen, 1994): a slow wave of depression of neuronal activity (Liao, 1944). It is accompanied generally by an increase in intracellular Ca\(^{2+}\) concentration (Martins-Ferreira and Ribere, 1995). More recently, a similar, if not identical, phenomenon has been shown to be induced by hypoxia (Somjen et al., 1993). A glial role was suggested in SD since this depression propagates through diverse heterogeneous brain regions with similar velocity (33–100 \(\mu\)m/s). The Ca\(^{2+}\) waves in the astrocytes studied therein, more particularly in those where mitochondrial Ca\(^{2+}\) uptake was prevented, bear similarities to SD such as their high rates of propagation. The fact that hypoxia seems to mimic such a depression may support our hypothesis of negative mitochondrial feedback on Ca\(^{2+}\) wave propagation. In such a condition, mitochondrial function would be disrupted, \(\Delta\varphi_{m}\) dissipated and finally mitochondrial Ca\(^{2+}\) uptake prevented. This would inexorably lead to further spreading of the glial Ca\(^{2+}\) wave, stimulating in passing neuronal networks that normally are not activated by these astrocytes, and may contribute to brain activity disorganization.

In conclusion, we have characterized an important role of mitochondria in glial Ca\(^{2+}\) signaling, i.e., a strong negative feedback control on intracellular Ca\(^{2+}\) wave propagation via their high Ca\(^{2+}\) buffering capacities. Physiological alteration of mitochondrial function would allow the fine tuning of the Ca\(^{2+}\) wave spreading through the astrocyte network, hence modulating their information processing functions (Wang et al., 1997). Besides, in pathological conditions, a mitochondrial dysfunction could contribute to the pathogenesis of numerous CNS disorders such as ischemia and epilepsy.

We thank Miss D.L. Patterson for cell culture, and Mr. J.ake J. acobson, Dr. J ulie K.eelan, and Dr. M. art H. M oj et for critical appraisal of the manuscript and helpful discussion.

We thank the Wel lcom e T rust for financial support. R. R .wa was supported by the Wellcom e 4 Y ear Ph. D. Programme in Neuroscience.

Received for publication 20 November 1998 and in revised form 19 M arch 1999.
