Abstract

Background: Cervical compressive myelopathy (CCM) is caused by chronic spinal cord compression due to spondylosis, a degenerative disc disease, and ossification of the ligaments. Tip-toe walking Yoshimura (twy) mice are reported to be an ideal animal model for CCM-related neuronal dysfunction, because they develop spontaneous spinal cord compression without any artificial manipulation. Previous histological studies showed that neurons are lost due to apoptosis in CCM, but the mechanism underlying this neurodegeneration was not fully elucidated. The purpose of this study was to investigate the pathophysiology of CCM by evaluating the global gene expression of the compressed spinal cord and comparing the transcriptome analysis with the physical and histological findings in twy mice.

Methods: Twenty-week-old twy mice were divided into two groups according to the magnetic resonance imaging (MRI) findings: a severe compression (S) group and a mild compression (M) group. The transcriptome was analyzed by microarray and RT-PCR. The cellular pathophysiology was examined by immunohistological analysis and immuno-electron microscopy. Motor function was assessed by Rotarod treadmill latency and stride-length tests.

Results: Severe cervical calcification caused spinal canal stenosis and low functional capacity in twy mice. The microarray analysis revealed 215 genes that showed significantly different expression levels between the S and the M groups. Pathway analysis revealed that genes expressed at higher levels in the S group were enriched for terms related to the regulation of inflammation in the compressed spinal cord. M1 macrophage-dominant inflammation was present in the S group, and cysteine-rich protein 61 (Cyr61), an inducer of M1 macrophages, was markedly upregulated in these spinal cords. Furthermore, C1q, which initiates the classical complement cascade, was more upregulated in the S group than in the M group. The confocal and electron microscopy observations indicated that classically activated microglia/macrophages had migrated to the compressed spinal cord and eliminated synaptic terminals.

Conclusions: We revealed the detailed pathophysiology of the inflammatory response in an animal model of chronic spinal cord compression. Our findings suggest that complement-mediated synapse elimination is a central mechanism underlying the neurodegeneration in CCM.

Background
Cervical compressive myelopathy (CCM) is caused by chronic spinal cord compression due to spondylosis, a degenerative disease of the cervical discs, and ossification of the posterior longitudinal ligaments or yellow ligaments [1,2]. The symptoms appear mainly in the elderly, and include slowly progressive clumsiness and paresthesia in the hands, gait disturbance, and tetraplegia. Human histological studies revealed degeneration of the anterior horns, cavity formation, and demyelination in the severely compressed spinal cord [3,4]. Reports on the surgical outcomes of these patients demonstrate that increased spinal cord stiffness is associated with a worse postoperative recovery [5,6]. Although severe spinal cord compression is known to cause irreversible neurological damage, it is unclear how these pathological changes occur.

Tip-toe walking Yoshimura (twy) mice, which develop progressive spinal cord dysfunction secondary to extradural calcified deposits at the C2/3 ligaments, are reported to be a good in vivo model for the pathological changes related to CCM [7-9]. Because this mouse develops spinal cord compression spontaneously, there are individual differences in the severity of spinal cord compression [10]. Previous histological studies have shown that neurons are lost due to apoptosis in twy mice [11-13], but the exact mechanism of the neurodegeneration has not been fully elucidated. The purpose of this study was to investigate the pathophysiology of CCM by evaluating the global gene expression of the compressed spinal cord and comparing the transcriptome analysis with physical and histological findings in twy mice.

Methods
Animal model
The twy mice were obtained from a breeding colony of the Central Institute for Experimental Animals (Kawasaki, Japan). The mutant twy mice were maintained by brother-sister matings of heterozygotes at the Central Research Institute [11,14]. The twy mice harbor an autosomal recessive mutation in the nucleotide pyrophosphatase (NPPS) gene [7]. The mice were housed in groups under a 12-hour light/dark cycle, with access to food and water ad libitum. All experiments were performed in accordance with the Guidelines for the Care and Use of Laboratory Animals of Keio University School of Medicine and the Central Institute for Experimental Animals.

Magnetic resonance imaging
Magnetic resonance imaging (MRI) was performed on the mice at 6, 15, and 20 weeks of age using a 7.0-Tesla magnet (BioSpec 70/16; Bruker BioSpin, Ettlingen, Germany) with a cryogenic quadrature RF surface probe (CryoProbe; Bruker BioSpin AG, Fällanden, Switzerland) to improve the sensitivity [15-18]. The MRI was performed under general anesthesia induced by the intramuscular injection of ketamine (50 mg/kg; Sankyo, Tokyo, Japan) and xylazine (5 mg/kg; Bayer, Leverkusen, Germany) and maintained by isoflurane (Foren; Abbott, Tokyo, Japan). The animal’s pulse, arterial oxygen saturation, and rectal temperature were monitored during the MRI. The scanning parameters were as follows: Sagittal T2-weighted images (RARE, eTE/TR: 37.5/2000 ms), axial T2-weighted images (RARE, eTE/TR: 21.5 ms/1200 ms). To examine the extent of spinal cord compression due to extradural calcified deposits, the transverse areas of the calcification and spinal canal were measured on the axial T2-weighted images of the twy mice, and the canal stenosis ratio was calculated as reported previously [10].

Behavioral analyses
The motor function of 20-week-old twy mice was evaluated using a Rotarod treadmill apparatus (Muromachi Kikai Co., Ltd., Tokyo, Japan) and the DigiGait Image Analysis System (Mouse Specifics, Quincy, MA, USA). In the Rotarod treadmill test, the time (latency) that each mouse spent on the rod as it rotated at 10 rpm in a 2-min session, was monitored [19]. Three trials were conducted, and the average number of seconds was recorded. In the footprint analysis using the Digigait system, the stride length of the fore and hindlimb was measured as long as the twy mouse could walk with consistent weight-supported forelimb steps, on a treadmill set at a speed of 8 cm/s.

Gene expression analysis
After the in vivo MRI analysis, the twy mice were anesthetized and transcardially perfused with heparinized saline (5 U/ml). Dissected segments of the cervical spinal cords were rapidly frozen and placed in TRIZol (Invitrogen, CA, USA). The total RNA was isolated using an RNeasy Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer’s instructions. For the microarray analysis, Cyanine-3 (Cy3)-labeled cRNA was prepared from 100 ng of RNA using the One-Color Low RNA Input Liner Amplification kit (Agilent, CA, USA), followed by RNAeasy column purification (Qiagen). Cy3-labeled cRNA (1.5 μg) was fragmented at 60°C for 30 minutes in a reaction volume of 50 μl containing the Fragmentation Buffer and Blocking Agent included in the kit (Agilent). On completion of the fragmentation reaction, 50 μl of the HI-RPM Hybridization Buffer (Agilent) was added to the fragmentation mixture, and the samples were hybridized to Agilent SurePrint G3 Mouse GE 8 x 60 K Microarrays (G4852A, Agilent) for 17 hours at 65°C in a rotating Agilent hybridization oven. After hybridization, the microarrays were washed for 1 minute at room temperature with GE Wash Buffer 1 (Agilent) and for 1 minute with 37°C GE Wash Buffer 2 (Agilent),

Figure 1 (See legend on next page.)
then dried immediately by a brief centrifugation. Immediately after being washed, the slides were scanned on a DNA Microarray Scanner (G2565CA, Agilent) using the one color scan setting for 8 × 60 K array slides. The scanned images were analyzed with the Feature Extraction Software v10.7.3.1 (Agilent) using default parameters to obtain background-subtracted and spatially detrended Processed Signal intensities.

For the clustering analysis, the normalized data were narrowed down by the cut-off values of each expression signal (>50) and fold change (>1.5) for the signal of severely compressed spinal cords versus the signal of mildly compressed spinal cords. The heat map was visualized by Gene Spring GX12 (Agilent). Pathway enrichment analysis was performed for the genes that showed differences on the microarray. RT-PCR was performed on an ABI 7900HT (Applied Biosystems, CA, USA) with TaqMan probes (Applied Biosystems).

Histological analysis
Twy mice were anesthetized and transcardially perfused with 4% paraformaldehyde in 0.1 M PBS. The spinal cord and spinal canal were removed and immersed in Decalcifying Solution B (Dako, Glostrup, Denmark) for three days. These samples were then embedded in OCT compound (Sakura Finetechnical Co., Ltd., Tokyo, Japan) and sectioned in the axial plane at 20 μm on a cryostat (Leica CM3050 S, Wetzlar, Germany). The spinal cords and spinal canals were histologically evaluated by Hematoxylin-eosin (HE) staining and immunohistochemistry. The tissue sections were stained with the following primary antibodies:
Figure 3

(See legend on next page.)
anti-Iba-1 (rabbit IgG, 1:200, Wako, Osaka, Japan), anti-CD86 (rat IgG, 1:200, Abcam, Cambridge, UK), anti-arginase-1 (goat IgG, 1:200, Santa Cruz Biotechnology, CA, USA), anti-Cyr61 (rabbit IgG, 1:200, Santa Cruz Biotechnology), anti-C1q (goat IgG, 1:200, Santa Cruz Biotechnology), and anti-PSD95 (mouse IgG2a, 1:200, Millipore, MA, USA). The samples were examined with an inverted fluorescence microscope (BZ 9000; Keyence Co., Osaka, Japan) and an LSM 700 confocal laser-scanning microscope (Carl Zeiss, Munich, Germany). To quantify the HE-stained and C1q-immunostained sections, images obtained with the BZ9000 microscope were analyzed using Keyence Analysis Software (Keyence Co.). Constant threshold values were maintained for all the analyses. HE-stained images were taken at C2/3 (the lesion epicenter) in axial sections at ×20 magnification to measure the transverse area of the spinal cord. The CD86/Iba1-, Arg-1/Iba1-, and Cyr61-stained images were automatically captured at the compressed spinal cord area in axial sections at ×200 magnification, and the CD86/Iba1- and Arg-1/Iba1-positive cells per field of view in compressed spinal cords were quantified.

Immuno-electron microscopy
Cryosections of severely compressed twy mouse spinal cord (20 μm) were incubated with 5% block ace (DS Pharma Biomedical., Osaka, Japan), 0.1% Saponin in 0.1 M phosphate buffer for 1 h. Sections were immuno-stained with a primary rabbit anti-Iba antibody (1:100 Wako) for 72 h, and nanogold-conjugated anti-rabbit secondary antibody (1:100 Invitrogen) for 24 h at 4°C. After fixation in 2.5% glutaraldehyde, the nanogold signals were enhanced with the HQ-Silver kit (Nanoprobes Inc.) for 10 minutes. The samples were post-fixed with 0.5% osmium tetroxide, dehydrated through ethanol, acetone, and QY1, and embedded in Epon. Ultrathin (80 nm) sagittal spinal cord sections were stained with uranyl acetate and lead citrate for 10 and 12 minutes, respectively. The sections were examined under a transmission electron microscope (JEOL model 1230) and photographed using a Digital Micrograph 3.3 (Gatan Inc., CA, USA).

Statistical analysis
All values are presented as the mean ± standard error of the mean (s.e.m.). An unpaired two-tailed Student’s t-test was used for the comparisons. A P-value of <0.05 was considered significant.
was used to determine the significance of differences in the behavioral, transcriptome, histological findings of each group. For all statistical analyses, significance was defined as $P < 0.05$. GraphPad Prism software (version 5.0d) was used for the analyses (GraphPad Software, Inc., CA, USA).

Results

High-resolution MRI was performed when the mice were 6, 15, and 20 weeks old, as reported previously (Figure 1A) [10]. In the twy mice, spinal cord compression progressed at the C2/3 level due to ligamentous calcification. Twenty twy mice were divided into two groups according to the MRI findings: a severe compression group ($n = 8$, S group) and a mild compression group ($n = 8$, M group). The canal stenosis ratio was higher than 45% in the S group (average, 57.1%) and less than 25% in the M group (average, 11.1%) (Figure 1B and 1C). The other four twy mice were excluded from the analysis because they had moderate compression and could not be assigned to either group. The body weight was significantly lower in the S group than the M group (Figure 1D), and both the Rotarod treadmill latency and stride length were significantly decreased in the S group compared to the M group (Figure 1E and 1F). Consistent with the MRI findings, the spinal cord area of axial sections in the S group was significantly smaller than in the M group (Figure 1G and 1H).

To investigate the pathophysiology of the compressed spinal cord in detail, microarray analysis was performed for the S and M groups (Figure 2), as previously described [20]. This analysis revealed that the expression levels of 215 genes were significantly different between the S group and the M group; 205 genes showed increased expression in the S group, and 10 showed decreased expression. Pathway analysis revealed that the genes expressed at higher levels in the S group were enriched for terms related to macrophage markers, Toll-like receptor (TLR) signaling, and chemokine signaling, which regulate inflammation and gliosis in the injured spinal cord [21]. Furthermore, genes related to prostaglandin synthesis and regulation and to oxidative damage, which suggest ischemia of the compressed spinal cord [22], were upregulated in the S group. On the other hand, Neurogenin-2, which mainly regulates the differentiation of dopaminergic neurons (‘dopaminergic neurogenesis’) [23], was downregulated in the S group. Autophagy and apoptosis pathway components were also upregulated in the S group, consistent with previous reports [11,24].

To evaluate the macrophage phenotype in the two groups, cervical spinal cord samples were subjected to

![Graph](image.png)

**Figure 5** Upregulation of the complement classical pathway in the severely compressed spinal cord. RT-PCR and histological analyses. The mRNAs encoding TNFα and CD86, markers of the M1 phenotype, were significantly increased in the S group compared to the M group (Figure 3A), whereas there was no significant difference in the mRNAs for arginase1 or CD163, which indicate the M2 phenotype (Figure 3B). Histological analyses also showed that the number of double-positive cells for CD86 and Iba1, a microglia/macrophage marker, per field of view (FOV) (1 FOV = 100 × 100 μm²) was significantly higher in the S than in the M group (Figure 3C and 3D), whereas there was no significant difference in the number of Iba1/arginase1-positive cells (Figure 3E and 3F).

M1 macrophages are recruited by chemotaxis in response to cysteine-rich protein 61 (Cyr61) [25], which is induced by mechanical stress [26,27]. We therefore examined the gene expression of Cyr61 in the cervical spinal cord of the S and M groups. Cyr61 was significantly upregulated in the S compared to the M group (Figure 4A), and Cyr61-positive cells were located at the compressed area and colocalized extensively with reactive astrocytes (Figure 4B and 4C).

To examine the mechanism of the neurodegeneration associated with inflammation in the chronically compressed spinal cord, we focused on the complement activation classical pathway (Figure 2). Previous reports suggested that at the early stage of neurodegenerative diseases and normal aging, C1q plays an important role in the pathophysiological process that leads to synapse loss and ultimately to neuronal death [28-31]. Our microarray analysis showed that the C1qa, C1qb, and C1qc expression levels were significantly higher in the S than the M group (Figure 5A). The area of punctate C1q staining was also significantly greater in the S than the M group (Figure 5B and 5C). Interestingly, many of the C1q-positive puncta that were close to microglia/macrophages in the compressed spinal cord were associated with synaptic puncta identified by double immunostaining with synaptic markers such as PSD-95 (Figure 6A). To confirm
that there was direct contact between the microglia/macrophages and synaptic structures, immune-electron microscopic examination was performed. Consistent with the confocal imaging, this analysis showed that the microglia/macrophages made direct contact with both presynaptic and postsynaptic structures (Figure 6B). These observations indicated that classically activated microglia/macrophages had migrated to the compressed spinal cord and eliminated synaptic terminals.

Discussion
In the present study, we showed that severe chronic progressive spinal cord compression in *twy* mice caused more body weight loss and neurological deficits in motor function than milder spinal cord progression. Furthermore, M1 macrophage-dominant inflammation was present in mice with a severely compressed spinal cord. In agreement, Cyr61, an inducer of M1 macrophages, was also markedly upregulated in these spinal cords. Furthermore, immunostaining and electron microscopic analyses indicated that the inflammatory C1q complement cascade eliminated synapse formation, resulting in neurodegeneration.

Macrophages are typically divided into classically activated (M1) and alternatively activated (M2) macrophages [32]. M1 macrophages, activated via TLRs, produce pro-inflammatory cytokines and oxidative metabolites [33]. Here we found that the M1 macrophage and TLR signals were activated in the chronically compressed spinal cord. These results were consistent with the distribution of M1 macrophages in traumatic spinal cord injury that continues even during the chronic phase [34,35]. The shift to M1 macrophages, which have deleterious and cytotoxic effects [36], may represent the main pathology of the neurodegeneration that accompanies chronic spinal cord compression.

Although the extracellular matrix has been classically viewed as an inert scaffold, recent studies have revealed that it influences diverse aspects of cellular behavior and function [37]. Cyr61 is a matricellular protein that is highly expressed at sites of inflammation, where its ability to regulate gene expression in macrophages plays an important role [25,38]. In addition, various mechanical stresses induce Cyr61 expression in cartilage/bone tissues and periodontal ligaments [26,39]. Our present data indicated that Cyr61 is significantly upregulated in the chronically, severely compressed spinal cord and colocalizes extensively with reactive astrocytes. These findings suggest that Cyr61 engages in a distinct intracellular signaling cascade in microglia/macrophages and promotes M1 macrophage recruitment in the compressed spinal cord.

Microglia/macrophages were recently identified as the phagocytes responsible for eliminating tagged synapses, via classical complement signaling [40], and the complement cascade is strongly induced in the brain tissues of patients with various neurodegenerative diseases [41]. Interestingly, in a mouse model of glaucoma, a relatively common neurodegenerative disease related to high intraocular pressure, the classical complement pathway is upregulated long before retinal ganglion cell death occurs [28]. Yet another study suggested that initiation of the classical complement pathway via C1q is detrimental to recovery after spinal cord injury [42]. The present microarray and immunohistochemical analyses showed that the classical complement pathway via C1q was significantly upregulated in the severely compressed spinal cord. Our findings raise the intriguing possibility that C1q may also be involved in synapse elimination in the chronically compressed spinal cord. Future studies should examine whether the inhibition of C1q in animal models of chronic spinal cord compression hinders the associated neurodegenerative changes.

Previous studies on the surgical outcomes of CCM patients demonstrated that the postoperative recovery was poor in those with severe canal stenosis, because irreversible changes had occurred in the spinal cord [5]. Recent studies have revealed that neural stem cell therapy can be an effective treatment for previously incurable nervous system disorders, such as spinal cord injury [43-47]. Therefore, an appropriate stem cell treatment for CCM should be examined in future studies.

To our knowledge, these data are the first to document the detailed pathophysiology of the inflammatory response in an animal model of chronic spinal cord compression. The clinical implications are noteworthy, because manipulation of the classical complement cascade in the chronically compressed spinal cord could be a strategy for minimizing synapse loss and secondary neurodegeneration due to inflammation. We believe that our findings are valuable for future research on the alterations taking place in the inflammatory environment in CCM.
