Simulations of the Temperature Dependence of the Charge Transfer Inefficiency in a High-Speed CCD

André Sopczak, Khaled Bekhouche, Chris Bowdery, Chris Damerell, Gavin Davies, Lakhdar Dehimi, Tim Greenshaw, Michal Koziel, Konstantin Stefanov, James Walder, Tim Woolliscroft, and Steve Worm

Abstract—Results of detailed simulations of the charge transfer inefficiency of a prototype serial readout CCD chip are reported. The effect of radiation damage on the chip operating in a particle detector at high frequency at a future accelerator is studied, specifically the creation of two electron trap levels, 0.17 eV and 0.44 eV below the bottom of the conduction band. Good agreement is found between simulations using the ISE-TCAD DESSIS program and an analytical model for the former level but not for the latter. Optimum operation is predicted to be at about 250 K where the effects of the traps is minimal; this being approximately independent of readout frequency in the range 7–50 MHz. This work has been carried out within the Linear Collider Flavour Identification (LCFI) collaboration in the context of the International Linear Collider (ILC) project.

Index Terms—Charge coupled devices, position sensitive detectors, radiation damage, semiconductor detectors: characterization, silicon.

I. INTRODUCTION

A TICLE physicists worldwide are working on the design of a high energy collider of electrons and positrons (the International Linear Collider or ILC) which could be operational sometime around 2019. Any experiment exploiting the ILC will require a high performance vertex detector to detect and measure short-lived particles, yet be tolerant to radiation damage for its anticipated lifetime. One candidate is a set of concentric cylinders of Charge-Coupled Devices (CCDs), read out at a frequency of around 50 MHz.

It is known that CCDs suffer from both surface and bulk radiation damage. However, when considering charge transfer losses in buried channel devices only bulk traps are important. These defects create energy levels between the conduction and valence band, hence electrons may be captured by these new levels. These electrons are also emitted back to the conduction band after a certain time.

It is usual to define a Charge Transfer Inefficiency (CTI), which is the fractional loss of charge after transfer across one pixel. An initial charge $Q_0$ after being transported across $m$ pixels is reduced to $Q_m = Q_0 (1 - \text{CTI})^m$. For CCD devices containing many pixels, CTI values around $10^{-5}$ are not negligible.

The CTI value depends on many parameters, some related to the trap characteristics such as: trap energy level, capture cross-section, and trap concentration (density). Operating conditions also affect the CTI as there is a strong temperature dependence on the trap emission rate and also a variation of the CTI with the readout frequency. Other factors are also relevant, for example the mean occupancy ratio of pixels (1% for a 50 MHz readout is assumed here), which influences the fraction of filled traps in the CCD transport region.

Previous studies have been reported in [1]–[5], [25]–[28]. The novel features of this work are detailed 2-D simulations using real device geometry without approximations for the charge storage volume and transport.

II. SIMULATIONS

The UK Linear Collider Flavour Identification (LCFI) collaboration [6], [7], [29] has been studying a serial readout device produced by e2V Technologies, with a manufacturer’s designation ‘CCDS8’. It is a 2.1 Mpixel, three-phase buried-channel CCD with 12 μm square pixels.

Simulations of a simplified model of this device have been performed with the ISE-TCAD package (version 7.5), particularly the DESSIS program (Device Simulation for Smart Integrated Systems). It contains an input gate and an output gate, a substrate contact and nine further gates (numbered 1 to 9) which form the pixels. Each pixel consists of 3 gates but only one pixel is important for this study—gates 5, 6 and 7. The simulation is essentially two dimensional and assumes a 1 μm device thickness (width) for calculating densities. Thus the model is equivalent to a thin slice of one column of CCD58 with rectangular pixels 12 μm long by 1 μm wide. The overall length and depth are 44 μm and 20 μm respectively (Fig. 1).

Parameters of interest are the readout frequency, up to 50 MHz, and the operating temperature between 120 K and 300 K although simulations have been done up to 500 K. The CTI value depends on many parameters, some related to the trap characteristics such as: trap energy level, capture cross-section, and trap concentration (density). Operating conditions also affect the CTI as there is a strong temperature dependence on the trap emission rate and also a variation of the CTI with the readout frequency. Other factors are also relevant, for example the mean occupancy ratio of pixels (1% for a 50 MHz readout is assumed here), which influences the fraction of filled traps in the CCD transport region.

Previous studies have been reported in [1]–[5], [25]–[28]. The novel features of this work are detailed 2-D simulations using real device geometry without approximations for the charge storage volume and transport.

These separate the area under study from the input drain and output diffusion junctions.
The signal charge used in the simulation is chosen to be similar to the charge generated by a minimum ionising particle (MIP), amounting to about 1620 electron-hole pairs for CCD58. DESSIS has a directive for generating heavy ions and this is exploited to create the charges. The heavy ion is made to travel in a downwards direction starting at 1.2 \( \mu \text{m} \) below gate 2 at 1 \( \mu \text{s} \) before charge transfer begins. This provides ample time for the electrons to be drawn upwards to the transport channel which is 0.25 \( \mu \text{m} \) beneath the gate electrodes.

### A. Calculating CTI

Charge Transfer Inefficiency is a measure of the fractional loss of charge from a signal packet as it is transferred over a pixel, or three gates. After DESSIS has simulated the transfer process, a 2-D integration of the trapped charge density distribution is performed independently to give a total charge under each gate.

The CTI for transfer over one gate is equivalent to

\[
\text{CTI} = \frac{e_T - e_B}{e_S}
\]

where:
- \( e_S \) = number of electrons in the signal packet,
- \( e_B \) = number of background trapped electrons prior to signal packet transfer,
- \( e_T \) = number of trapped electrons under the gate, after signal transfer across gate.

In this way the CTI is normalised for each gate. The determinations of the trapped charge take place for gate \( n \) when the charge packet just arrives at gate \( n+1 \). If the determination were made only when the packet has cleared all three gates of the pixel, trapped charge may have leaked out of the traps.

2This number has to be divided by 12 because the charge is assumed to be distributed over the whole pixel but the model has only 1/12th of the true pixel volume.

3Since some of this leaked charge might rejoin the signal packet now under the next gate, this procedure may slightly overestimate the CTI.

The total CTI (per pixel) is determined from gates 5, 6 and 7, hence

\[
\text{CTI} = \sum_{n=5}^{7} \frac{e_T - e_B}{e_S} \quad (2)
\]

where \( n \) is the gate number. The background charge is taken as the trapped charge under gate 1 because this gate is unaffected by the signal transport when the charge has just passed gates 5, 6 or 7.

### B. 0.17 eV and 0.44 eV Traps

This CTI study, at nominal clock voltage, focuses only on the bulk traps with energies 0.17 eV and 0.44 eV below the bottom of the conduction band. These will be referred to simply as the
0.17 eV and 0.44 eV traps. An incident particle with sufficient energy is able to displace an atom from its lattice point leading eventually to a stable defect. These defects manifest themselves as energy levels between the conduction and valence band, in this case the energy levels 0.17 eV and 0.44 eV; hence electrons may be captured by these levels. The 0.17 eV trap is an oxygen vacancy defect, referred to as an A-centre defect. The 0.44 eV trap is a phosphorus-vacancy defect—an E-centre defect—that is a result of the silicon being doped with phosphorus and a vacancy manifesting from the displacement of a silicon atom bonded with the phosphorus atom [2], [25].

In order to determine the trap densities for use in simulations, a literature search on possible ILC radiation backgrounds and trap induction rates in silicon was undertaken. The main expected background arises from $e^+e^-$ pairs with an average energy of 10 MeV and from neutrons (knocked out of nuclei by synchrotron radiation).

Table I shows results of background simulations of $e^+e^-$ pairs generation for three proposed vertex detector designs (from three ILC detector concepts).

Choosing the scenario with the highest expected background, that is the LDC concept, where the innermost layer of the vertex detector would be located 14 mm from the interaction point, one can estimate an $e^+e^-$ flux around 3.5 hits/cm²/bunch crossing which gives a fluence of $0.5 \times 10^{12}$ e/cm²/year. In the case of neutrons, from two independent studies, the fluence was estimated to be $10^{10}$ n/cm²/year [11] and $1.6 \times 10^{10}$ n/cm²/year [12].

Based on the literature [13]–[21], the trap densities introduced by 1 MeV neutrons and 10 MeV electrons have been estimated with two established assumptions: the electron trap density is a linear function of dose, and the dose is a linear function of fluence. A summary is given in Table II.

The actual trap concentrations and electron capture cross-sections used in the simulations are shown in Table III.

### Partially Filled Traps

Each electron trap in the semiconductor material can either be empty (holding no electron) or full (holding one electron). In order to simulate the normal operating conditions of CCD58, partial trap filling was employed in the simulation (which means that some traps are full and some are empty) because the device will transfer many charge packets during continuous operation.

In order to reflect this, even though only the transfer of a single charge packet was simulated, the following procedure was followed in all cases. During an initial 98 ns waiting period so that 1 clocking is started. During this period some of the traps become filled. The 0.44 eV trap is therefore employed in the simulation (which means full traps at clocking frequencies 7, 25 and 50 MHz).

### III. Simulation Results

The CTI dependence on temperature and readout frequency was explored.

#### A. 0.17 eV Traps

Fig. 3 shows the CTI for simulations with partially filled 0.17 eV traps at different frequencies for temperatures between 123 K and 260 K, with a nominal clock voltage of 7 V.

A peak structure can be seen. For 50 MHz, the peak is at 150 K with a CTI of $27 \times 10^{-5}$. The peak CTI is in the region between 145 K and 150 K for a 25 MHz clock frequency and

**Table I**

| Scenarios | Simulator | SiD | LDC | GLD |
|-----------|-----------|-----|-----|-----|
| CAIN/Jupiter | 2.9 | 3.5 | 0.5 |
| GuineaPig | 2.3 | 3.0 | 2.0 |

**Table II**

| Particle type | $0.17\,\text{eV}$ (cm$^{-3}$) | $0.44\,\text{eV}$ (cm$^{-3}$) |
|---------------|-------------------------------|-------------------------------|
| $10\,\text{MeV}\,e^-$ | $3.0 \times 10^{11}$ | $3.0 \times 10^{10}$ |
| $1\,\text{MeV}\,\text{n}$ | $(4.5...7.1) \times 10^8$ | $(0.7...1.1) \times 10^{10}$ |
| total | $3.0 \times 10^{11}$ | $4.1 \times 10^{10}$ |

**Table III**

| $E_1 - E_2$ (eV) | Type | $C$ (cm$^{-3}$) | $\sigma$ (cm$^2$) |
|------------------|------|----------------|-------------------|
| 0.17             | Acceptor | $1 \times 10^{11}$ | $1 \times 10^{-14}$ |
| 0.44             | Acceptor | $1 \times 10^{11}$ | $3 \times 10^{-15}$ |

---

4This waiting time corresponds to the mean time between the arrival of charge packets from a 1% mean pixel occupancy with a 50 MHz readout frequency and to lower values for lower frequencies.

---

**Fig. 3.** CTI values against temperature for simulations with 0.17 eV partially filled traps at clocking frequencies 7, 25 and 50 MHz.
with a value of about $43 \times 10^{-5}$. This is about 1.6 times bigger than the charge transfer inefficiency at 50 MHz. The peak CTI for 7 MHz occurs at about 142 K, with a maximum value of about $81 \times 10^{-5}$, an increase from the peak CTI at 50 MHz ($27 \times 10^{-5}$) by a factor of about 3 and an increase from the peak CTI at 25 MHz ($43 \times 10^{-5}$) by a factor of nearly 2. Thus CTI increases as frequency decreases. For higher readout frequency there is less time to trap the charge, thus the CTI is reduced. At high temperatures the emission time is so short that trapped charges rejoin the passing signal.

### B. 0.44 eV Traps

Simulations were also carried out with partially filled 0.44 eV traps at temperatures ranging from 250 K to 500 K. This is because previous studies [5], [27], [28] on 0.44 eV traps have shown that these traps cause only a negligible CTI at temperatures lower than 250 K due to the long emission time and thus traps remain fully filled at lower temperatures. The results are depicted in Fig. 4.

The peak CTI is higher for lower frequencies with little temperature dependence of the peak position.

### C. 0.17 eV and 0.44 eV Traps Together

The logarithmic scale plot (Fig. 5) of the simulation results at the different frequencies and trap energies clearly identifies an optimal operating temperature of about 250 K.

### IV. COMPARISONS WITH AN ANALYTICAL MODEL

The motivation for introducing an analytical model is to understand the underlying physics through making comparisons with the DESSIS simulations. This might then allow predictions of CTI for other CCD geometries without requiring a full simulation.

#### A. Capture and Emission Time Constants

The charge transfer inefficiency is modeled by a differential equation in terms of the different time constants and temperature dependence of the electron capture and emission processes. In the electron capture process, electrons are captured from the signal packet and each captured electron fills a trap. This occurs at a rate determined by a capture time constant $\tau_c$. The electron emission process is described by the emission of captured electrons from filled traps back to the conduction band, and into a second signal packet at the emission rate determined by an emission time constant $\tau_e$.

Following the treatment by Kim [22], [30], based on earlier work by Shockley, Read and Hall [23], [31], a defect at an energy $E_s$ below the bottom of the conduction band, $E_C$, has time constants

$$\tau_c = \frac{1}{\sigma_e \chi_e \nu_e N_e}$$

$$\tau_e = \frac{1}{\sigma_e \chi_e \nu_e N_e} \exp\left(\frac{E_s - E_k}{k_B T}\right)$$

where:
- $\sigma_e$ = electron capture cross-section,
- $\chi_e$ = entropy change factor by electron emission,
- $\nu_e$ = electron thermal velocity,
- $N_e$ = density of states in the conduction band,
- $k_B$ = Boltzmann’s constant,
- $T$ = absolute temperature,
- $n_s$ = density of signal charge packet.

It is assumed that $\chi_e = 1$.

At low temperatures, the emission time constant $\tau_e$ can be very large and of the order of seconds. The charge shift time for one gate, $t_{sh} = 1/(3f)$, where $f$ is the readout frequency, is of the order of nanoseconds. A larger $\tau_e$ means that a trap remains filled for much longer than the charge shift time. Further trapping of signal electrons is not possible and, consequently, CTI is small at low temperatures. A peak occurs between low and high temperatures because the CTI is also small at high temperatures. This manifests itself because, at high temperatures, the emission time constant decreases to become comparable to the charge shift time so trapped electrons rejoin their signal packet.
V. Conclusions and Outlook

The Charge Transfer Inefficiency (CTI) of a CCD device has been studied with a full simulation (ISE-TCAD DESSIS) and compared with an analytical model.

Partially filled traps from the 0.17 eV and 0.44 eV trap levels have been implemented in the full simulation and variations of the CTI with respect to temperature and frequency have been analyzed. The results confirm the dependence of CTI with the readout frequency. At low temperatures (<250 K) the 0.17 eV traps dominate the CTI, whereas the 0.44 eV traps dominate at higher temperatures.

Good agreement between simulations and an Analytical Model has been found for 0.17 eV traps but not for 0.44 eV traps. This shows the limitations of the model with respect to the full simulation.

The optimum operating temperature for CCD58 in a high radiation environment is found to be about 250 K for clock frequencies in the range 7 to 50 MHz. However, CCD58 is not really suited to high-speed readout, and attempts to make laboratory measurements have given inconsistent results. So in order to meet the demanding readout requirements for a vertex detector at the ILC, interest has now moved to an alternative CCD design with Column-Parallel (CP) and 2-phase readout. Our prototype CP-CCD has recently operated at 45 MHz. Thus, our involvement with serial readout devices will probably now cease but the experience gained with DESSIS and building analytical models will transfer to our studies of CP-CCDs.
