(Dated: August 18, 2022)

We demonstrate that superconductors with broken inversion symmetry support a family of stable, spatially localized configurations of the self-knotted magnetic field. These solutions, that we term “toroflux”, are the superconducting counterparts of the Chandrasekhar-Kendall states (spheromaks) that appear in highly conducting, force-free astrophysical and nuclear-fusion plasmas. The superconducting torofluxes are solutions of superconducting models, in the presence of a parity breaking Lifshitz invariant associated with the $O$ point group symmetry. We demonstrate that a magnetic dipole or a ferromagnetic inclusion in the bulk of a noncentrosymmetric superconductor source finite-energy toroflux solutions.

I. INTRODUCTION

Ordinary type-2 superconductors expel weak magnetic fields due to the Meissner effect, while at elevated fields the magnetic flux penetrates in the form of a lattice or a liquid of Abrikosov vortices, see e.g. [1]. Moreover, quantum or thermal fluctuations can induce closed loops of such quantum vortices. Because of the vortex string tension, these loops are unstable, and eventually decay. Thus, apart from certain cases demonstrated in multicomponent systems that allow different topology [2] bulk superconductors do no feature stable, localized configurations of the magnetic field (in three dimensions). In this paper, we demonstrate that bulk noncentrosymmetric superconductors feature a new a new class of localized, impurity-induced, configurations of a knotted magnetic field. We coin these solutions “toroflux”, since the geometry of their current and flux lines resemble a popular toroflux toy [3].

Noncentrosymmetric superconductors, that is superconductors whose crystal lattices lack inversion symmetry, have attracted significant attention from both theoretical [4–9] and experimental [10–14] communities. A key property of a noncentrosymmetric crystal is that it cannot be superimposed on its spatially inverted image with the help of spatial translations. The crystal thus breaks explicitly the parity inversion group. Since the superconducting order parameter captures the parity breaking properties of the underlying ionic lattice, the noncentrosymmetric superconductors constitute a class of exotic systems that spontaneously breaks a continuous symmetry, in a parity violating medium (see, e.g. , Refs. [15–17] for detailed reviews). Ginzburg-Landau free energies of noncentrosymmetric superconductors include contributions that are linear in the magnetic field and in the gradients of the superconducting order parameter: $\propto k_{ij} B_i \text{Im}(\psi^* D_j \psi)$. Here $D$ is the gauge derivative of the order parameter $\psi$, and $k_{ij}$ are coefficients which depends on the crystal symmetry. In this work, we consider a particular class of noncentrosymmetric superconductors with chiral octahedral $O$ symmetry.

Parity-breaking superconducting systems feature several distinctive properties: they generate unusual magneto-electric transport phenomena, exhibit a correlation between supercurrents and electron spin polarizations, lead to the emergence of helical states, and host, in the background of the magnetic field, the vortex lattices with exotic spatial structure [15–18]. Notably, vortices in these superconducting materials can exhibit an inversion of the magnetic field at a certain distance from the vortex core [19, 20]. This property leads to nonmonotonic inter-vortex forces and thus to the formation of vortex-vortex bound states, vortex clusters, and nontrivial bound states at the boundary of the sample [19, 20]. The parity breaking in noncentrosymmetric superconductors can also modify the Josephson effect with an unconventional, phase-shifted relation for the Josephson current [21, 22]. Linked by a uniaxial ferromagnet, the unconventional Josephson junction was suggested to serve as an element of a qubit with a simple and presumably robust architecture [23].

The toroflux solutions that we find in this paper, are the counterparts of the Chandrasekhar-Kendall states [24], in the context of noncentrosymmetric superconductors. The Chandrasekhar-Kendall states are the divergence-free eigenvectors of the curl operator that determine the minimum-energy equilibrium configurations in magnetohydrodynamics of highly conducting plasmas. These states appear in various physical contexts, ranging from astrophysical plasmas [24] to the nuclear fusion theory [25]. In the latter case, the Chandrasekhar-Kendall eigenvectors are also known as Taylor states [25], which represent the relaxed minimum energy states of a plasma in a spheromak device (i.e., inside a spherical shell that confines the plasma) [26, 27]. The principal difference between the toroflux state in parity-broken superconductors and a the Chandrasekhar-Kendall state in a conducting plasma, is that the toroflux are strongly localized config-
urations. The spatial localization of both the magnetic field and the supercurrent of the toroflux originates from the Meissner effect.

Our torofluxes are eigenstates of the London equations for a noncentrosymmetric superconducting material. Labelled by their orbital \(0 < l < \infty\) and magnetic \((-l \leq m \leq +l)\) quantum numbers, there are infinitely many \((l, m)\) toroflux modes, for a given value of the parity breaking parameter. All of the toroflux modes have an intrinsic divergence at the origin, and therefore they require a regularization at the core of the solutions. We demonstrate that each divergent mode is regularized by (pointlike) magnetic multipole sources. The case of a pointlike magnetic dipole is of particular physical relevance, as it corresponds to magnetic impurities inside a noncentrosymmetric superconductor. We argue that such magnetic impurities systematically induce an \((l, m) = (1, 0)\) toroflux mode.

The superconducting toroflux solutions found in this paper share some similarities with knotted field configurations that appear in many areas of physics, including particle physics [28], condensed matter [2, 29–31], and the classical field theory [32, 33]. Knotted electromagnetic field configurations were also suggested to play a role in the chirally imbalanced quark-gluon plasmas [34–38].

The paper is organized as follows. In Section II, we introduce the Ginzburg-Landau theory for parity breaking superconductor and derive the corresponding classical equations in the London limit. In Section III, we express the London equation in terms of a force-free field and discuss localized solutions for the magnetic field and electric currents, using the basis of vector spherical harmonics. There, we also determine the energy and helicity densities for the infinite tower of toroflux states. We further demonstrate that in the London limit, the total energy of the solution diverges in its core. Next, in Section IV, we show that a ferromagnetic inclusion regularizes the singular behavior of the solution, serving, at the same time, as a source for a finite-energy superconducting toroflux. Finally, in Section V investigate the case where the inclusion is a ferromagnetic dipole. There, we explicitly construct the toroflux solutions sourced by such an impurity. We discuss their properties and, in particular, the influence of the parity breaking parameter on the structure, energy, and helicity of the toroflux solutions. Our conclusions are presented in the last section.

II. THEORETICAL FRAMEWORK

A. Parity-broken formulation

We consider a class of isotropic noncentrosymmetric superconductors that are invariant under spatial rotations while possessing, at the same time, an explicitly broken discrete group of spatial inversions. The macroscopic physics of these materials may be described within the Ginzburg-Landau theory supplemented with the Lifshitz term of the simplest form \(j \cdot B\) which directly couples the magnetic field \(B\) to a current \(j\) expressed via the superconducting order parameter \(\psi\) (for a review, see Refs. [15, 39]). This particular structure of the Lifshitz term describes a class of the noncentrosymmetric superconductors with a \(O\) point group symmetry such as, for example, \(\text{Li}_2\text{Pt}_3\text{B}\) [12, 40], \(\text{Mo}_3\text{Al}_2\text{C}\) [41, 42], and \(\text{PtSbS}\) [43].

In the vicinity of the superconducting critical temperature, the density \(F\) of the Ginzburg-Landau free energy \(F = \int d^3x F\) we can written as follows:

\[
F = \frac{B^2}{8\pi} + \frac{k}{2} \sum_{a=\pm} |\mathbf{D}_a \psi|^2 + \beta (|\psi|^2 - \psi_0^2)^2, \tag{1a}
\]

where \(\mathbf{D}_\pm := \nabla - ie\mathbf{A} + ie\mathbf{x}_\pm \mathbf{B}\). \(\tag{1b}\)

The single-component order parameter \(\psi = |\psi|e^{i\phi}\) stands for the density of Cooper pairs. The gauge derivative \(\mathbf{D}\) couples the scalar field \(\psi\) to the vector potential \(\mathbf{A}\) and the magnetic field \(\mathbf{B}\). The coefficients of the Ginzburg-Landau model (1), including the parity-breaking couplings \(\chi_{\pm} = \chi \pm \nu\), can be expressed in terms of the parameters of the microscopic model [20]. Throughout the paper, we use the units \(\hbar = c = 1\).

The physical length scales of the theory, namely the coherence length \(\xi\) and the London penetration depth \(\lambda_L\), are determined by the coefficients of the Ginzburg-Landau model as

\[
\lambda_L = \lambda_0 \sqrt{1 + \chi_+^2 + \chi_-^2} / 2\lambda_0^2, \quad \text{where} \quad \lambda_0^2 = \frac{1}{8\pi k e^2 \psi_0^2}, \tag{2a}
\]

\[
\xi^2 = \frac{k}{2\beta \psi_0^2}, \tag{2b}
\]

respectively. The Ginzburg-Landau parameter is the ratio \(\kappa = \lambda_L / \xi\). Note that in noncentrosymmetric superconductors, an externally applied magnetic field does not decay in a simple monotonic way; for a detailed discussion how a counterpart of the London’s penetration length is defined in such a case see, e.g. Refs. [19, 20].

The variation of the free energy (1) with respect to the field \(\psi^*\) yields the Ginzburg-Landau equation for the superconducting condensate

\[
k \sum_{a=\pm} \mathbf{D}_a \mathbf{D}_a \psi = 2\beta (|\psi|^2 - \psi_0^2) \psi, \tag{3}\]

while the variation with respect to the vector potential \(\mathbf{A}\) determines the Ampère-Maxwell equation

\[
\nabla \times \left( \frac{\mathbf{B}}{4\pi} + k e \sum_{a=\pm} \chi_a \mathbf{J}_a \right) = k e \sum_{a=\pm} \mathbf{J}_a, \tag{4}
\]

where \(\mathbf{J}_a = \text{Im}(\psi^* \mathbf{D}_a \psi)\).

The structure of the magnetic field lines can be conveniently characterized by the magnetic helicity:

\[
\mathcal{H} = \int \mathbf{A} \cdot \mathbf{B}, \tag{5}
\]
It can indeed serve as a measure the entanglement of the magnetic field lines in knotted configurations of the magnetic field [44]. The magnetic helicity is widely used in ordinary electrically conducting plasmas described by ideal magnetohydrodynamics, where it is a conserved quantity modulo reconnections of the magnetic field lines [27].

B. London-limit

The kinetic term of the free energy (1), can be expanded into a sum of gauge-invariant terms:

$$\frac{1}{2} \sum_{a=\pm} |D_a \psi|^2 = |D \psi|^2 + \chi j \cdot B + e^2 (\chi^2 + \nu^2) |\psi|^2 B^2,$$

where $D := \nabla - ieA$, and $j = 2e|\psi|^2(\nabla \varphi - eA)$. (6)

In the London limit (i.e., $\kappa \to \infty$), the superconducting density is a spatially uniform quantity, $|\psi| = \psi_0$, and the free energy reads as follows [45]:

$$F_L = k\lambda_L^2 e^2 \psi_0^2 \{ B^2 + \hat{j}^2 + 2\Gamma \hat{j} \cdot B \},$$

where $\hat{j} = \frac{j}{2k\lambda_L^2 e^2 \psi_0^2}$, and $\Gamma = \frac{\chi}{\lambda_L}$, and $0 \leq \Gamma \leq 1$.

Importantly, the dimensionless parameter $\Gamma$ quantifies the importance of the parity breaking. At $\Gamma = 0$, the material is thus centrosymmetric. The second London equation that relates the magnetic field $B$ and the current (6) $j = 2e\psi_0^2(\nabla \varphi - eA)$ takes the following form:

$$B = \Phi_0 v - \nabla \times \hat{j}.$$ (8)

Here $v = \frac{1}{2\pi} \nabla \times \nabla \varphi$ is the density of vortex field that accounts for the phase singularities, and $\Phi_0 = 2\pi/e$ is the superconducting flux quantum. In the dimensionless units used here $\tilde{x} = x/\lambda_L$ and $\nabla = \lambda_L \nabla$, the Ampère-Maxwell equation (4) reads as:

$$\nabla \times H = \nabla \times (B - 4\pi M) = \hat{J},$$ (9)

where $H = B + \Gamma \hat{j}$, $\hat{j} = \hat{j} + \Gamma B$, and $M = -\frac{\Gamma \hat{j}}{4\pi}$, are, respectively, the (dimensionless) magnetic field, the total current, and the magnetization.

Introducing the complex quantity $\eta = \Gamma + i\sqrt{1-\Gamma^2}$, the free energy density (7) in the London limit can further be rewritten as

$$\tilde{F}_L := \frac{F_L}{k\lambda_L^2 e^2 \psi_0^2} = (B + \eta \hat{j})(B + \eta^* \hat{j}).$$ (10)

The constant density approximation, together with the expression for the magnetic field (8), thus yields the dimensionless free energy:

$$\tilde{F}_L = (\mathcal{L}^* \hat{j} - \Phi_0 v) \cdot (\mathcal{L} \hat{j} - \Phi_0 v).$$ (11)

Here, for a shorthand notation, we introduce the operator $\mathcal{L} \hat{j} = \nabla \times \hat{j} - \eta \hat{j}$. The London equation for the current $\hat{j}$, obtained as the Euler-Lagrange equation by varying the free energy (11) with respect to $\hat{j}$, reads as

$$\mathcal{L} \mathcal{L}^* \hat{j} = \Phi_0 \text{Re} [\mathcal{L}^* v].$$ (12)

Note that, the source field $v$ is not a regular function but a distribution which is zero almost everywhere, except for a set of phase singularities identified with positions of vortices. Since we are interested in vortex free configurations, the source term associated with the vortex fields is, from now on, set to zero $v = 0$.

As we demonstrate below, the London equation (12) can be seen as a complex, force-free equation whose solution corresponds to the eigenfunctions of the curl operator with complex eigenvalues. The general axisymmetric eigenfunctions of the curl operator can, for example, be found by using the Chandrasekhar-Kendall toroidal-poloidal decomposition [24, 46]. Below, we will express the solutions differently, using the basis of vector spherical harmonics.

III. LOCALIZED FORCE-FREE SOLUTIONS

We are interested in finding the spatially localized solutions of the London equation (12). This equation can be simplified by introducing a complex, force-free vector field $Q$ that satisfies the force-free equation:

$$\mathcal{L}Q = 0.$$ (13)

Hence, in the absence of a source term, the London equation implies that

$$\mathcal{L}^* \hat{j} = i \text{Im}(\eta)Q,$$

where $Q$ obeys the force-free equation (13). The definition (14) relates the physical magnetic fields and the electric current to the force-free field $Q$ as:

$$\hat{j} = \text{Re}Q,$$

$$J = \sqrt{1-\Gamma^2} \text{Im}(\eta)Q,$$

$$B = -\text{Re}(\eta Q),$$

$$H = \sqrt{1-\Gamma^2} \text{Im}(Q).$$ (15a-b)

It is convenient to represent the solutions $Q$ of the force-free equation (13) in the basis of the vector spherical harmonics $Z_{lm} = (Y_{lm}, \Psi_{lm}, \Phi_{lm})$:

$$Q(\hat{r}) = \sum_{\substack{l=0 \atop m=-l}}^{\infty} \sum_{m=-l}^{l+1} \left( \sum_{\mathbf{z}} Q_{lm}(r) Z_{lm}(\mathbf{z}) \right),$$ (16)

where the harmonics $Z_{lm}$ and the corresponding radial functions $Q_{lm}(r)$ are labeled by the integer-valued quantum number of the angular momentum $l = 0, 1, 2, \ldots$ and its projection on the $z$-axis, $m = m_z \in \mathbb{Z}$ with $-l \leq m \leq l$. The angular coordinates are encoded in the unit vector $\hat{r} = r/r$. The vector spherical harmonics are defined, in the parametrization of Ref. [47], via their scalar counterpart $Y_{lm}(\hat{r})$ as:

$$Y_{lm}(\hat{r}) = Y_{lm}(\mathbf{r}) \hat{r},$$ (17a)
Given the decomposition (16), the force-free equation (13) yields a set of differential equations whose solutions, that are bounded at infinity are (see details in the Appendix A):

\[ Q^\Phi_{lm} = c_{lm} h^{(1)}_{l}(\eta r), \quad Q^Y_{lm} = -c_{lm} \frac{l(l+1)}{\eta r} h^{(1)}_{l}(\eta r), \]
\[ Q^\Psi_{lm} = -c_{lm} \left( \frac{l+1}{\eta r} h^{(1)}_{l}(\eta r) - h^{(1)}_{l+1}(\eta r) \right). \] (18)

Here \( c_{lm} \) is an arbitrary complex constant, and \( h^{(1)}_{l}(z) \) is the spherical Hankel function of the first kind. Using the relations between the physical fields and the force-free field (15), the total London free energy (11) can be written in the basis of the vector spherical harmonics as:

\[ \tilde{F} = (1 - \Gamma^2) \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \int_{0}^{\infty} r^2 dr \int_{\Omega} w^Z_{lm} |Q^Z_{lm}|^2, \] (19)

where \( w^Y_{lm} = 1 \) and \( w^\Phi_{lm} = w^\Psi_{lm} = l(l+1) \). Here, the angular degrees of freedom have been integrated out using the orthogonality properties of the spherical harmonics (see Appendix D). Note that the dimensionless energy (19) is related to the total free-energy as \( F = \kappa \lambda^2 e^2 v^2 \tilde{F} \).

According to the definitions of the free energy (7), in the absence of phase gradients, the gauge field \( A \) is related to the dimensionless current \( j \) as \( A = -\lambda L j \). Thus, the dimensionless helicity (5) reads as: \( \mathcal{H} \equiv \mathcal{H}/\lambda L = -\int \mathbf{j} \cdot \mathbf{B} \). Here again, given the relations (15) between the physical fields and the force-free field \( \mathcal{Q} \), the dimensionless helicity takes the following form:

\[ \mathcal{H} = \int \text{Re}(\mathcal{Q}) \cdot \text{Re}(\eta \mathcal{Q}) = \sum_{l,m} \int r^2 dr \mathcal{H}_{lm} \], (20)

where \( \mathcal{H}_{lm} = \sum_{Z} w^Z_{lm} \left\{ \text{Re}(\eta Q^Z_{lm}) \text{Re}(Q^Z_{lm}) \text{ if } m \text{ even}, \right. \left. \text{Im}(\eta Q^Z_{lm}) \text{Im}(Q^Z_{lm}) \text{ if } m \text{ odd} \right\} \).

At small radius \( r \), all the components of the force-free field (18) are divergent:

\[ Q^\Phi_{lm} \sim r^{-(l+2)}, \quad Q^Y_{lm} \sim r^{-(l+2)}, \quad Q^\Psi_{lm} \sim r^{-(l+1)}. \] (21)

Therefore, all the toroflux modes, in the London limit, have an intrinsic divergence at the origin. For example, the divergence of the \( l = 1 \) solution behaves as a point-like magnetic dipole which, in realistic circumstances, can be regularized by the size of a ferromagnetic (spherical) inclusion that represents a physical dipole. The same statement can also be applied to the other, quadrupole \((l = 2)\) and higher modes. Below we consider a general case of a magnetized inclusion which naturally regularizes the divergence of the toroflux modes (21).

IV. MAGNETIZED INCLUSION

In order to account for the divergences of the force-free field, it is instructive to consider the case of a magnetized (spherical) inclusion in the bulk of the noncentrosymmetric material. The Maxwell equations that determine the magnetic field inside the inclusion are:

\[ \nabla \times \mathbf{H} = 0, \quad \nabla \cdot \mathbf{B} = 0, \quad \text{where } \mathbf{B} = \mathbf{H} + 4\pi \mathbf{M}. \] (22)

The magnetic field \( \mathbf{B} \) and the magnetization \( \mathbf{M} \) are decomposed onto the vector spherical harmonics, similarly to the force-free field \( \mathcal{Q} \) (16). The fields of the magnetized spherical inclusion are constructed following the standard textbook calculations, see e.g. [48] (for a detailed derivation, see the Appendix B). The general solutions are constrained by the requirement that the magnetic field should be a real-valued quantity, while the magnetic fields \( \mathbf{B} \) and \( \mathbf{H} \) inside the magnetized spherical inclusion of radius \( r_0 \) satisfy the following relations:

\[ \tilde{H}^Y_{lm} = \tilde{H}^\Phi_{lm} = -\frac{4\pi l M^Y_{lm}}{2l + 1} \left( \frac{r}{r_0} \right)^{l-1}, \quad \tilde{H}^\Psi_{lm} = 0, \] (23a)
\[ \tilde{B}^Z_{lm} = \tilde{H}^Z_{lm} + 4\pi M^Z_{lm}, \quad \text{with } \mathbf{Z} = \mathbf{Y}, \mathbf{\Psi}, \mathbf{\Phi}. \] (23b)

The continuity conditions for the current and the magnetic fields at the interface between a magnetized inclusion inside a superconducting medium read as:

\[ 0 = \mathbf{J} \cdot \mathbf{n}_{12} \bigg|_{r=r_0}, \] (24a)
\[ 0 = \mathbf{n}_{12} \cdot (\mathbf{B}_2 - \mathbf{B}_1) \bigg|_{r=r_0}, \] (24b)
\[ \mathbf{J}_S = \mathbf{n}_{12} \times (\mathbf{H}_2 - \mathbf{H}_1) \bigg|_{r=r_0}. \] (24c)

Here, \( \mathbf{n}_{12} \) is the normal vector from medium 1 (the magnetized inclusion) to the medium 2 (the parity-breaking superconductor) and \( \mathbf{J}_S \) is the surface current density which is localized at the interface. The first equation in (24) represents the requirement of the absence of a flow of \( \mathbf{J} \) through the interface between the superconductor and the magnetized inclusion [39]. Using the representation (16) of the solution in the basis of vector spherical harmonics, and given that \( Y_{lm} \) is the only vector harmonic that has a radial component, we represent the first two equations in Eq. (24) as:

\[ \mathbf{J} \cdot \mathbf{n}_{12} \bigg|_{r=r_0} = \sqrt{1 - T^2} \sum_{l,m} \text{Im}(\eta Q^Y_{lm} Y_{lm}) = 0, \] (25a)
\[ (\mathbf{B} - \tilde{\mathbf{B}}) \bigg|_{r=r_0} = -\sum_{l,m} \text{Re}(\eta Q^Y_{lm} + \tilde{B}^Y_{lm}) Y_{lm} = 0. \] (25b)

Note that the intrinsic degrees of freedom of the solutions of these equations always allows to reconstruct the real-valued magnetic field (23) inside the inclusion. In other words, it is always possible to find the field \( \tilde{\mathbf{B}} \) such that
Im $\mathbf{B} = 0$. Hence, the interface conditions (25), for a given $(l, m)$ mode, boil down to
\[
\eta Q_{lm}^Y + B_{lm}^Y |_{r=r_0} = 0.
\] (26)

Finally, the use of the explicit form of the solutions for the radial functions (18) and the expressions for the fields inside the spherical inclusion (23), provides us with the matching conditions that fixes the coefficients $c_{lm}$ as:
\[
c_{lm} = \frac{4\pi r_0 M_{lm}^Y(r_0)}{l(2l + 1)h_l^{(1)}(\eta r_0)} \quad \text{for} \quad l > 0.
\] (27)

V. TOROFUX INDUCED BY A DIPOLE

Consider now the particular case of a spherical impurity of the radius $r_0$, with the magnetic dipole moment $\mathbf{M}$ directed along the axis $\hat{z}$. In spherical coordinates, the magnetic moment of the impurity reads as follows:
\[
\hat{M} = M_0 \hat{z} = M_0 \left( \hat{r} \cos \theta - \hat{\theta} \sin \theta \right) = \sqrt{\frac{4\pi}{3}} M_0 (Y_{10} + \Psi_{10}) .
\] (28)

The continuity conditions (27) fix the only nonzero coefficient $c_{10}$ of the force-free field $\mathcal{Q}$ (16):
\[
c_{10} = \frac{r_0 M_0}{h_1^{(1)}(\eta r_0)} \left( \frac{4\pi}{3} \right)^{3/2}.
\] (29)

The behaviour of the Hankel functions for small arguments imply that:
\[
c_{10} = i \sqrt{\frac{4\pi}{3}} \left( \frac{4\pi r_0^3}{3} \right) M_0 \eta^2, \quad \text{when} \quad r_0 \to 0.
\] (30)

Thus, for a point-like dipole with the magnetic moment $M_0^d = \frac{4\pi}{3} r_0^3 M_0$, the coefficient is uniquely determined as
\[
c_{10} = \sqrt{\frac{4\pi}{3}} \eta^2 M_0^d.
\] (31)

The related force-free field $\mathcal{Q}$ corresponds to the $(l, m) = (1, 0)$ harmonics:
\[
\mathcal{Q}_{10} = -M_0^d \eta r \left[ (1 - i\eta r) \left( 2 \cos \theta \hat{r} + \eta r \sin \theta \hat{\theta} \right) + \left( 1 - i\eta r(1 - i\eta r) \right) \sin \theta \hat{\theta} \right],
\] (32)

where we used the explicit form of spherical Hankel functions of the first kind (18) in order to express the solution in the closed form. An alternative derivation via the Chandrasekhar-Kendall method is briefly outlined in Appendix C.

The physical fields can be reconstructed from the force-free field (32) by using the relations (15) (see the Appendix B3 for the explicit expressions for $\mathbf{H}$ and $\mathbf{J}$). The complex parameter $\eta$ depends on the parity breaking parameter $0 \leq \Gamma \leq 1$ as $\eta = \Gamma + i\sqrt{1 - \Gamma^2}$. Thus all the fields are exponentially localised as $e^{-r\sqrt{1-\Gamma^2}}$. Hence, the size of the torofluxes, $L_{\text{tot}} = \frac{\lambda_L}{\sqrt{1-\Gamma^2}}$ (33), is determined by the London penetration length $\lambda_L$ and the dimensionless parity breaking coupling $\Gamma$ defined in Eq. (7). In the limit of the maximal parity violation, $\Gamma \to 1$, the size of the toroflux diverges.

A. Knotted nature of the toroflux

The physical fields $\mathbf{H}$ and $\mathbf{J}$ associated with the force-free field $\mathcal{Q}_{10}$ induced by a magnetic dipole (32) are displayed in the Fig. 1, for the value of the parity-breaking parameter $\Gamma = 0.5$. This figure illustrates that a magnetic dipole impurity induces, in a noncentrosymmetric superconductor, the knotted lines of both the magnetic field and the electric current. These toroidal, axially symmetric, nested structures, resemble in many aspects the standard Chandrasekhar-Kendall states \[24\]. The alternative derivation of our solutions, presented in the Appendix C, highlights the proximity of the toroflux and the Chandrasekhar-Kendall states. The torofluxes are basically the spatially localized analogues of the Chandrasekhar-Kendall states. Note that since the magnetic lines of the toroflux are closed, the total flux through any cross-section of the solution vanishes identically.

The London penetration depth determines the overall length scale the toroflux without affecting the geometry of its internal structure. On the contrary, the strength of the noncentrosymmetry strongly affects the overall structure of the toroflux. The latter feature is illustrated in the Fig. 2, which shows the streamlines of the magnetic field $\mathbf{H}$ and the electric current $\mathbf{J}$ as well as their Poincaré sections of the torofluxes for moderate ($\Gamma = 0.15$), intermediate ($\Gamma = 0.5$), and high ($\Gamma = 0.95$) values of the parity-breaking parameter $\Gamma$.

At small parity breaking ($\Gamma = 0.15$), the magnetic field lines resembles that of a magnetic dipole. They are attached to the magnetized inclusion and slightly twisted around the axis of the dipole (and the chirality of twist depends on the sign of $\Gamma$). Accordingly, the current flows around the dipole and covers various tori. When the noncentrosymmetry becomes more important ($\Gamma = 0.5$), the toroflux features nested tori of the magnetic lines, in addition to the twisted structure near the dipole. This property can be seen, in particular, in the $\mathbf{H}_{z=0}$ Poincaré section in Fig. 2. Interestingly, the chirality of the extra nested tori is reversed compared to set of field lines that are attached to the dipole. Upon
Figure 1. A toroflux solution induced by a magnetic dipole for the parity breaking parameter $\Gamma = 0.5$. The left panel displays the streamlines of the magnetic field $\mathbf{H}$, while the right panel shows the streamlines of the total electric current $\mathbf{J}$. These quantities are related to the other to the Ampère-Maxwell equation (9). The sphere in the center shows the position of the magnetized inclusion (the magnetic dipole).

increase of the parity breaking, additional sets of nested tori appear, as can be seen field the $\mathbf{H}|_{x=0}$ Poincaré section in Fig. 2 for $\Gamma = 0.95$. The fact that the number of tori with opposite chirality increases as the parity breaking becomes stronger is qualitatively similar to the effect of the magnetic-field inversion observed near vortices at large $\Gamma$ reported in Refs. [19, 20].

B. Energy and helicity of the toroflux

The dimensionless energy (19) of the toroflux solution (32) induced by a magnetic dipole depends on the parity breaking parameter $\Gamma$ as:

\[
\tilde{F}(\Gamma, r_0) = \frac{2(M_0^d)^2}{r_0^3} e^{-2r_0\sqrt{1-\Gamma^2}} \left[ (1 + 2r_0^2)(1 - \Gamma^2) + 2(1 - \Gamma^2 + r_0^2)r_0\sqrt{1-\Gamma^2} \right].
\]

The exponential prefactor contains the ratio of the inclusion radius $r_0$ with the size (33) of the toroflux, which is the consequence of the Meissner effect.

The Figure 3 shows the toroflux energy (34) as a function of the parity-breaking parameter $\Gamma$. The toroflux energy monotonically decreases as the parity breaking parameter $\Gamma$, and it is maximal in the centrosymmetric limit, $\Gamma \to 0$. As the non-linear corrections are small for small inclusions, the helicity is almost a linear function of $\Gamma$. The leading contribution to the helicity at the small radius $r_0$ reads explicitly as follows:

\[
\frac{H(\Gamma, r_0)}{2(M_0^d)^2} = \frac{2\Gamma(1 + r_0^2(\Gamma^2 + 1))}{r_0^3} - 2 \left( \Gamma^5 + 4\Gamma^3 - 3\Gamma \right) + \frac{8\Gamma^5 + 12\Gamma^3 - 17\Gamma}{3\sqrt{1-\Gamma^2}} + O(r_0^3).
\]

As previously stated, the magnetic helicity, which is associated with the topological properties of the magnetic field lines, serves as the measure of the entanglement of knotted lines of the magnetic field $\mathbf{B}$.

VI. CONCLUSION

We demonstrated that noncentrosymmetric superconductors with broken inversion symmetry host a new family of stable configurations with self-knotted magnetic field lines. These states, which we call toroflux, are superconducting counterparts of the Chandrasekhar-Kendall states that play an important role in highly conducting, force-free plasmas relevant to astrophysical research and applications in nuclear fusion [24, 25]. The Meissner ef-
Figure 2. The structure of the streamlines of the magnetic field $H$ and the electric current $J$, of the toroflux solution induced by a magnetic dipole, for the values of the parity-breaking parameter $\Gamma = 0.15$, 0.5, and 0.95. The line on the top row shows the streamlines of $H$, and the two next rows are the Poincaré sections of the streamlines of $H$ on the $x = 0$ and $z = 0$ planes, respectively. Similarly, the block of the three bottom rows indicates the structure of the current $J$. The central sphere depicts the spherical magnetic dipole inclusion. The relative sizes of the torofuxes can be seen from the vector basis.
fect forces the spatial localization of the toroflux solutions, thus making them different from the conventional Chandrasekhar-Kendall states.

The size of the toroflux is determined by the London penetration length $\lambda_L$ and the dimensionless parity breaking parameter $0 \leq \Gamma \leq 1$, as $L_{\text{tor}} = \lambda_L / \sqrt{1-\Gamma^2}$. In the limit of the maximal parity violation, $\Gamma \to 1$, the size of the toroflux diverges.

The knotted nature of the toroflux states is rooted in the parity breaking magnetoelectric effect that generates the supercurrent along the magnetic field lines. The supercurrent also produces the magnetic field, thus linking the magnetic field lines of the toroflux. In the absence of the parity breaking, the magnetic helicity of the solution vanishes, indicating that the knottedness disappears. The broken parity in a noncentrosymmetric superconductor plays a crucial role in the existence of the toroflux states.

The torofluxes constitute an infinitely high tower of solutions labeled by orbital $0 \leq l < \infty$ and magnetic quantum numbers. Although the energy of any $(l, m)$-toroflux diverges at its core in the London limit, one could argue that toroflux energy should be finite beyond this limit (similarly to the energy density of the Abrikosov vortices, which is divergent in the London limit if a core cutoff is neglected and finite otherwise). Detailed investigation of this question, however, goes beyond the scope of the current work.

We show that a finite-sized ferromagnetic inclusion with an $(l, m)$-multipole moment regularizes the divergences and thus induces an $(l, m)$-toroflux with finite energy. The most physically relevant case we discussed here in detail is the case of a magnetic dipole inclusion $(l, m) = (1, 0)$. Note that in all generality, our solutions are regularized by any finite size magnetized inclusion with a nonvanishing $(l, m)$-multipole moment.

These findings open up a possibility to extract new information about noncentrosymmetric superconductors from muon spin rotation probes. A muon spin rotation probe allows to obtain the statistics of the magnetic field distribution in a superconductor. Our study suggests that doping a noncentrosymmetric superconductor with magnetic impurities will result into toroflux: helical localized configurations of the magnetic field. The distribution of magnetic field polarization’s that we obtain for toroflux solutions is principally different from a dipole field configuration of a magnetic impurity in a conventional superconductor. It potentially allows to extract the parameters $\kappa_\pm$ from the statistics of the polarization of magnetic field sensed by muons.

**Appendix A: Detailed derivation of a general solution via vector spherical harmonics**

We derive a general solution of the force-free equation \( \mathcal{L} \mathcal{Q} = 0 \) using the basis of the spherical vector harmonics [47], which provides a convenient separation of the radial and angular variables. The force-free field \( \mathcal{Q} \), as well as the other fields, are thus decomposed as follows:

\[
\mathcal{Q}(r) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} Q^Z_{lm}(r) Z_{lm}(\hat{r}) \ . \quad (A1)
\]

Here \( Z_{lm}(\hat{r}) = (Y_{lm}, \Psi_{lm}, \Phi_{lm}) \) are the three orthogonal vector spherical harmonics, defined as [47]

\[
\begin{align*}
Y_{lm}(\hat{r}) &= Y_{lm}(\hat{r})\hat{r} , \\
\Psi_{lm}(\hat{r}) &= r \nabla Y_{lm}(\hat{r}) , \\
\Phi_{lm}(\hat{r}) &= r \times \nabla Y_{lm}(\hat{r}) ,
\end{align*} \quad (A2a)
\]

where \( Y_{lm}(\hat{r}) \) are the scalar spherical harmonics which depend on on the angular coordinates encoded in the unit vector \( \hat{r} \equiv \mathbf{r}/r \). See the Appendix D, for details on the definitions and properties of the vector spherical harmonics.

Given the decomposition (A1), the force-free vector equation \( \mathcal{L} \mathcal{Q} = 0 \) determines a system of three differential equations:

\[
\begin{align*}
- \frac{l(l+1)}{r^2} Q^\Phi_{lm} - \eta Q^Y_{lm} &= 0 , \\
- \frac{1}{r} \frac{d}{dr} (r Q^\Psi_{lm}) - \eta Q^\Phi_{lm} &= 0 , \\
\frac{1}{r} \frac{d}{dr} (r Q^\Psi_{lm}) - \frac{1}{r} Q^Y_{lm} - \eta Q^\Phi_{lm} &= 0 ,
\end{align*} \quad (A3a)
\]

which, combined together, yields:

\[
\begin{align*}
Q^Y_{lm} &= - \frac{l(l+1)}{\eta r} Q^\Phi_{lm} , \\
Q^\Psi_{lm} &= - \frac{1}{\eta r} \frac{d}{dr} (r Q^\Phi_{lm}) , \\
\left[ \frac{l}{r^2} \frac{d}{dr} \left( r^2 \frac{d}{dr} \right) - \frac{l(l+1)}{r^2} + \eta^2 \right] Q^\Phi_{lm} &= 0 . 
\end{align*} \quad (A4a)
\]

The equation (A4b) on \( Q^\Phi_{lm} \) is the spherical Bessel equation whose general solution is the superposition of two spherical Hankel functions

\[
Q^\Phi_{lm} = c_{lm} h^{(1)}_l(\eta r) + d_{lm} h^{(2)}_l(\eta r) . \quad (A5)
\]

Here, \( h^{(1)}_l \) and \( h^{(2)}_l \) are respectively the Hankel functions of the first and second kind.

**1. Hankel functions**

The spherical Hankel functions are expressed via the spherical Bessel functions as [49]

\[
h^{(1)}_l(z) = j_l(z) + iy_l(z) , \quad h^{(2)}_l(z) = j_l(z) - iy_l(z) , \quad (A6)
\]

where, in turn, the spherical Bessel functions are related to the Bessel functions of half-integer order:

\[
j_l(z) = \sqrt{\frac{2}{\pi z}} J_{l+1/2}(z) , \quad y_l(z) = \sqrt{\frac{2}{\pi z}} Y_{l+1/2}(z) , \quad (A7)
\]

with \( J_l \) and \( Y_l \) being respectively the Bessel functions of the first and second kind. Note that for a non-negative rank \( l \), the spherical Hankel function of the first kind can be expressed in a closed form,

\[
h^{(1)}_l(z) = (-i)^l \frac{1}{\pi} \frac{\pi^2}{(2l)!} \sum_{p=0}^{l} (-i2z)^{-p} (l+p)! \frac{(l+1)^l}{p(l-p)!} , \quad (A8)
\]

and the Hankel function of the second kind can be obtained in a similar way using the definition in Eq. (A6).

**2. Asymptotics**

For large \( |z| \), when \( -\pi < \arg z < \pi \), the spherical Hankel functions have the following asymptotic behaviour at the large argument [49]:

\[
\begin{align*}
h^{(1)}_l(z) &\sim \frac{2\pi}{z} \exp \left[ i \left( z - \frac{l+1}{2} \pi \right) \right] , \\
h^{(2)}_l(z) &\sim \frac{2\pi}{z} \exp \left[ -i \left( z - \frac{l+1}{2} \pi \right) \right] ,
\end{align*} \quad (A9a)
\]

By definition, \( \eta = \Gamma + i\sqrt{1-\Gamma^2} \) with \( \Gamma \in [0,1] \), so that \( 0 < \arg(\eta r) < \pi \) and thus

\[
\begin{align*}
h^{(1)}_l(\eta r) &\sim \frac{2\pi}{\eta r} (-i)^l+1 e^{it} e^{-\sqrt{1-\Gamma^2} r} , \\
h^{(2)}_l(\eta r) &\sim \frac{2\pi}{\eta r} (-i)^{l+1} e^{-it} e^{\sqrt{1-\Gamma^2} r} .
\end{align*} \quad (A10a)
\]

Hence, the second spherical Hankel functions diverges at large \( r \). It follows that for the solutions (A5) to be bounded at infinity, we must have \( \ell_{lm} = 0 \), and thus

\[
Q_{lm} = c_{lm} h^{(1)}_l(\eta r) . \quad (A11)
\]
Finally, given the defining relations \((A4a)\), the asymptotically finite components of the force-free field, associated with the different vector spherical harmonics are

\[
Q_{lm}^\Phi = c_{lm} h_i^{(1)}(\eta r), \quad Q_{lm}^\Psi = c_{lm} \frac{l(l+1)}{\eta r} h_i^{(1)}(\eta r),
\]

\[
Q_{lm}^\Psi = -c_{lm} \left( \frac{l+1}{\eta r} h_i^{(1)}(\eta r) - h_i^{(1)}(\eta r) \right), \quad (A12)
\]

where \(c_{lm}\) is an arbitrary complex constant.

### 3. Behaviour at small \(r\)

At small \(z\), the spherical Hankel function behave as \([49]\)

\[
h_i^{(1)}(z) = -\frac{z^{l+1/2}}{\sqrt{\pi} \Gamma(l+1/2)} . \quad (A13)
\]

It follows that the leading contributions of the different components of the force-free field at small \(r\) are

\[
Q_{lm}^Y = c_{lm} \frac{i2^l l(l+1) \Gamma(l+1/2)}{\sqrt{\pi} \eta^{l+2} r^{l+2}}, \quad \quad (A14a)
\]

\[
Q_{lm}^\Psi = c_{lm} \frac{i2^l l(l+1/2)}{\sqrt{\pi} \eta^{l+2} r^{l+2}}, \quad \quad (A14b)
\]

\[
Q_{lm}^\Phi = -c_{lm} \frac{i2^l (l+1/2)}{\sqrt{\pi} \eta^{l+2} r^{l+2}} . \quad (A14c)
\]

Thus, at small radius \(r\), all the components of the force-free field diverge as

\[
Q_{lm}^\Phi \sim r^{-(l+2)}, \quad Q_{lm}^Y \sim r^{-(l+2)}, \quad Q_{lm}^\Psi \sim r^{-(l+1)}. \quad (A15)
\]

It follows that all of the toroflux modes have an intrinsic divergence at the origin, and, therefore, they require a regularization, or a cut-off, at the core of the solutions. We demonstrate in the next section that such a regularization can consistently be done.

### Appendix B: Magnetized spherical inclusion

Here, we consider the case of a magnetized inclusion in the bulk of the noncentrosymmetric medium. For simplicity, we study a spherical inclusion of radius \(r_0\), as it is schematically illustrated in Fig. 4. Inside a magnetized medium, the consistent magnetostatics equations are

\[
\nabla \times \mathbf{H} = 0, \quad \nabla \cdot \mathbf{B} = 0 \quad \text{where} \quad \mathbf{B} = \mathbf{H} + 4\pi \mathbf{M} . \quad (B1)
\]

The fields of the magnetized spherical inclusion are constructed following the standard textbook calculations, see e.g. \([48]\). To this end, we introduce the magnetic scalar potential \(\omega_M\) which describe the magnetic field

\[
H = -\nabla \omega_M , \quad \text{and decompose the magnetic potential over the (scalar) spherical harmonics. It follows that}
\]

\[
\mathbf{H} = -\nabla \omega_M , \quad \text{and decompose the magnetic potential over the (scalar) spherical harmonics. It follows that}
\]

\[
\omega_{lm} = \begin{cases} c_{lm} r^l & \text{if } r < r_0 \\ \frac{d\omega_{lm}^\text{in}}{dr} & \text{if } r > r_0 \end{cases} . \quad (B3)
\]

Hereafter, the symbol \(\cdot\) marks the quantities inside the spherical inclusion.

The continuity of the magnetic potential at the boundary \(r = r_0\) implies that \(\omega_{lm}^\text{in} = \omega_{lm}^\text{out}\). The normal derivative of the magnetic potential is discontinuous across the interface. Therefore, the relation \(\nabla \cdot (\mathbf{H} + 4\pi \mathbf{M}) = 0\) implies that, at \(r = r_0\),

\[
\frac{d\omega_{lm}^\text{in}}{dr} - \frac{d\omega_{lm}^\text{out}}{dr} = 4\pi \tilde{M}_{lm}^\text{Y} \Rightarrow \tilde{c}_{lm} = \frac{4\pi \tilde{M}_{lm}^\text{Y}}{(2l+1)} . \quad (B4)
\]

Here, \(\tilde{M}_{lm}^\text{Y}\) is the \(Y\)-component of the magnetization \(\tilde{M}\), decomposed over the vector spherical harmonics analogously to \((16)\). Hence, the magnetic fields inside the magnetized spherical inclusion are

\[
\hat{H}_{lm}^Y = \tilde{H}_{lm}^Y = -4\pi \tilde{M}_{lm}^\text{Y} \left( r \right) / r_0^{l+1} , \quad \hat{H}_{lm}^\Phi = 0 \quad (B5a)
\]

\[
\hat{B}_{lm}^Z = \tilde{H}_{lm}^Z + 4\pi \tilde{M}_{lm}^Z , \quad \text{with} \quad Z = Y, \Phi, \Phi . \quad (B5b)
\]

![Figure 4. Schematic representation of a spherical magnetized medium (#1) of radius \(r_0\) and the noncentrosymmetric superconducting medium (#2). The unit vector \(\mathbf{n}_{12}\) is the normal vector at the interface between these media.](image-url)
As detailed below, the interface boundary conditions between the magnetized inclusion and the superconductor allow to relate the values of the parameters $c_{lm}$ between both media.

1. Matching conditions at the interface

The continuity conditions for the current and the magnetic fields at the interface between a magnetized inclusion inside a superconducting medium read as:

\begin{equation}
0 = J \cdot n_{12} \big|_{r=r_0}, \tag{B6a}
\end{equation}

\begin{equation}
0 = n_{12} \cdot (B_2 - B_1) \big|_{r=r_0}, \tag{B6b}
\end{equation}

\begin{equation}
J_S = n_{12} \times (H_2 - H_1) \big|_{r=r_0}. \tag{B6c}
\end{equation}

Here, $n_{12}$ is the normal vector from medium 1 (the magnetized inclusion) to the medium 2 (the parity-odd superconductor) and $J_S$ is the surface current density which is localized at the interface, Fig. 4.

The first equation in (B6) states that the superconducting current $J$ does not enter the non-superconducting magnetized inclusion [39]. Consequently, the normal component of $J$ vanishes at the interface between these media. Given the decomposition (A1) over the vector spherical harmonics, and since $Y_{lm}$ is the only vector harmonic that has a radial component, the first two relations in Eq. (B6) reduce to:

\begin{equation}
J \cdot n_{12} \big|_{r=r_0} = \sqrt{1 - \Gamma^2} \sum_{l,m} \text{Im}(\eta Q_{lm}^Y Y_{lm}) = 0, \tag{B7a}
\end{equation}

\begin{equation}
(B - \hat{B}) \big|_{r=r_0} = - \sum_{l,m} \text{Re}(\eta Q_{lm}^Y + \tilde{B}_{lm}^Y)Y_{lm} = 0. \tag{B7b}
\end{equation}

Note that there is always the freedom to construct the magnetic field $B$ inside the spherical inclusion, so that it is real. It is thus always possible to construct $\hat{B}$ such that $\text{Im} \hat{B} = 0$. Hence, the conditions (B7) at the interface, for a given mode $(l, m)$, boil down to:

\begin{equation}
\eta Q_{lm}^Y + \tilde{B}_{lm}^Y \big|_{r=r_0} = 0. \tag{B8}
\end{equation}

Finally, we use the explicit form of the radial modes (A12) to fix all the coefficients $c_{lm}$ of the solution:

\begin{equation}
c_{lm} = \frac{r_0 \tilde{B}_{lm}^Y(r_0)}{l(l+1)\eta_l^{(1)}(\eta r_0)}, \quad \text{for } l > 0. \tag{B9}
\end{equation}

Now, given the $(l, m)$ magnetization modes of the magnetized spherical inclusion (B5), the arbitrary coefficient $c_{lm}$ reads as

\begin{equation}
c_{lm} = \frac{4\pi r_0 M_Y_{lm}(r_0)}{l(2l+1)\eta_l^{(1)}(\eta r_0)}, \quad \text{for } l > 0. \tag{B10}
\end{equation}

Thus, we obtain the most general solution for a spherical inclusion with arbitrary magnetization.

2. Ferromagnetic inclusion and magnetic dipole

Consider now the particular case of a spherical inclusion of radius $r_0$, which possesses a magnetic dipole moment $\vec{M}$ directed along the axis $\hat{z}$, and with all higher-order modes vanishing. In spherical coordinates, the magnetic moment reads as

\[ \vec{M} = M_0 \hat{z} = M_0 \left( \hat{r} \cos \theta - \hat{\theta} \sin \theta \right) = \sqrt{\frac{4\pi}{3}} M_0 (Y_{10} + \Psi_{10}). \tag{B11a} \]

Thus, the magnetic fields (B5) inside the inclusion are

\begin{equation}
\hat{H}^Y_{10} = \hat{H}^{\Psi}_{10} = -\left( \frac{4\pi}{3} \right)^{3/2} M_0, \quad \hat{H}^{\Phi}_{10} = 0, \tag{B12a}
\end{equation}

\begin{equation}
\hat{B}^Y_{10} = \hat{B}^{\Psi}_{10} = 2 \left( \frac{4\pi}{3} \right)^{3/2} M_0, \quad \hat{B}^{\Phi}_{10} = 0. \tag{B12b}
\end{equation}

Finally, given the continuity conditions, the free coefficient $c_{10}$ (B10) in this case becomes

\[ c_{10} = \frac{r_0 M_0}{\eta_1^{(1)}(\eta r_0)} \left( \frac{4\pi}{3} \right)^{3/2}. \tag{B13} \]

The behaviour of the Hankel functions for small arguments (A13), implies that

\[ c_{10} = i \sqrt{\frac{4\pi}{3}} \left( \frac{4\pi r_0^3}{3} \right)^{3/2} M_0 \eta^2, \quad \text{when } r_0 \to 0. \tag{B14} \]

Thus, for a point-like dipole with the magnetic moment $M_0 d = \frac{4\pi}{3} r_0^3 M_0$, the coefficient is uniquely determined as

\[ c_{10} = \sqrt{\frac{4\pi}{3}} \eta^2 M_0 d. \tag{B15} \]

3. Explicit forms of the toroflux

Now, given the coefficient (B15), the magnetic field $\hat{H}$ and the current $J$ induced by a magnetic pointlike dipole can be reconstructed from the force-free field $\Phi$ according to (15). The components of the force-free field $\Phi$ corresponding to a given sector of the vector spherical harmonics are defined in terms of the spherical Hankel functions of the first kind (18). These functions can further be expressed in a closed form using the relation (A8). Finally, the vector harmonics of a dipolar source possess the single mode $(l, m) = (1, 0)$ which have the simple form (D12). Thus, in terms of elementary functions, the force-free field $\Phi_{10}$ induced by a magnetic dipole reads as

\begin{equation}
\Phi_{10} = - M_0 \eta r \left[ (1 - i\eta r)(2\cos \theta \hat{r} + i\eta r \sin \theta \hat{\theta}) + (1 - i\eta r(1 - i\eta r)) \sin \theta \hat{\theta} \right]. \tag{B16}
\end{equation}

As a result, given the definition of the physical fields (15) the magnetic field $\hat{H}$ and the current $J$, are respectively:
\[ H = M_0^d e^{-r \sqrt{1 - \Gamma^2}} \left\{ \frac{2 \cos \theta}{r^3} \left[ \left( \sqrt{1 - \Gamma^2} + r \right) \cos \Gamma r - \Gamma \sin \Gamma r \right] \hat{r} \\
+ \frac{\sin \theta}{r^3} \left[ \left( (1 + r^2) \sqrt{1 - \Gamma^2} + r \right) \cos \Gamma r + \Gamma (r^2 - 1) \sin \Gamma r \right] \hat{\theta} \\
+ \frac{\sin \theta}{r^2} \left[ \Gamma r \cos \Gamma r - \left( 1 + r \sqrt{1 - \Gamma^2} \right) \sin \Gamma r \right] \hat{\phi} \right\}, \quad (B17a) \]

\[ J = M_0^d e^{-r \sqrt{1 - \Gamma^2}} \left\{ \frac{2 \cos \theta}{r^3} \left[ \Gamma r \cos \Gamma r - \left( 1 + r \sqrt{1 - \Gamma^2} \right) \sin \Gamma r \right] \hat{r} \\
+ \frac{\sin \theta}{r^3} \left[ \Gamma r \left( 1 + 2 r \sqrt{1 - \Gamma^2} \right) \cos \Gamma r - \left( 1 + r \sqrt{1 - \Gamma^2} + r^2 (1 - 2 \Gamma^2) \right) \sin \Gamma r \right] \hat{\theta} \\
- \frac{\sin \theta}{r^2} \left[ \Gamma \left( 1 + 2 r \sqrt{1 - \Gamma^2} \right) \sin \Gamma r + \left( r (1 - 2 \Gamma^2) + \sqrt{1 - \Gamma^2} \right) \cos \Gamma r \right] \hat{\phi} \right\}. \quad (B17b) \]

**Appendix C: Outline of the Chandrasekhar-Kendall approach for a dipole source**

The above section provides the explicit forms of the to-roflux solutions induced by a dipole. These can alternatively be derived via the Chandrasekhar-Kendall method [24]. Consider a case when we want to find the magnetic field \( B \) that satisfies the following equation:

\[ \mathcal{L}^* B = c \nabla \times \left( \nabla \times M^d \right) + d \nabla \times M^d, \quad (C1) \]

where \( c \) and \( d \) are some real parameters and \( M^d \) is a field that corresponds to an external field induced by a magnetic moment. Then, the magnetic field \( B \) can be solved in terms of the following functions:

\[ B = -\text{Re} (\eta \mathcal{Q}), \quad (C2a) \]

\[ \mathcal{Q} = \nabla \times u + \nabla \times (\nabla \times u) / \eta, \quad (C2b) \]

\[ \Delta u + \eta^2 u = b M^d, \quad b = -i (d + c \eta) / lim \eta. \quad (C2c) \]

where \( u \) is found from solving inhomoogeneous vector Helmholtz equation \( (C2c) \). The set of equations \( (C2) \) can be verified by showing that

\[ \mathcal{L} \mathcal{Q} = -b \nabla \times M^d / \eta, \quad (C3) \]

which subsequently implies Eq. \( (C1) \).

In the simplest case of pointlike dipole source \( M^d = M_0^d \hat{z} \delta(r) \), the explicit solution of the Helmholtz equation \( (C2c) \) is:

\[ u = -M_0^d \hat{z} \frac{e^{i \eta r}}{4 \pi r}. \quad (C4) \]

Note, that values of \( c \) and \( b \) depend on boundary conditions that are used between magnetised and superconducting medium. The boundary conditions \( (B8) \) are given by:

\[ (\eta \mathcal{Q} + \hat{B}) \cdot \hat{r} \bigg|_{r=r_0} = 0. \quad (C5) \]

For \( \mathcal{B}(r_0) = 2 M_0^d \hat{z} / r_0^3 \) this results in the constants being \( c = 4 \pi \) and \( d = -4 \pi \text{Re} \eta \) (and thus \( b = 4 \pi \)).

Now, given the values of \( c \) and \( d \) that satisfy the appropriate boundary condition, inserting the solution \( (C4) \) of the Helmholtz equation into the constituting equation \( (C2b) \) yields the very same expression for the force-free field \( \mathcal{Q} \) as the explicit form of equation \( (B16) \).

**Appendix D: Spherical harmonics**

The scalar spherical harmonics are defined as [49]

\[ Y_{lm}(\hat{r}) = (-1)^m \sqrt{\frac{2l + 1}{4 \pi} \frac{l - m}{l + m}} P^m_l(\cos \theta) e^{im \phi}, \quad (D1) \]

where \( P^m_l \) are the associated Legendre polynomials. The spherical harmonics depend on the polar \( \theta \) and azimuthal \( \phi \) angles expressed collectively via the unit vector \( \hat{r} \equiv r / r \). The spherical harmonics satisfy the orthonormality condition:

\[ \int d \Omega Y_{lm}(\hat{r}) Y^*_{lm'}(\hat{r}) = \delta_{ll'} \delta_{mm'}, \quad (D2) \]

where \( Y_{lm} \equiv (-1)^m Y_{l,-m} \) and \( d \Omega = \sin \theta d \theta d \phi \) is the solid-angle element.

Adopting the parametrization of Ref. [47], the vector spherical harmonics are defined via their scalar counterpart in Eq. \( (A2) \). In a given \((l, m)\) sector, the vector spherical harmonics are locally orthogonal to each other at every point of the unit sphere:

\[ Y_{lm}(\hat{r}) \cdot \Phi_{lm}(\hat{r}) = 0, \quad (D3a) \]

\[ Y_{lm}(\hat{r}) \cdot \Psi_{lm}(\hat{r}) = 0, \quad (D3b) \]

\[ \Psi_{lm}(\hat{r}) \cdot \Phi_{lm}(\hat{r}) = 0. \quad (D3c) \]

They also satisfy also the normalization and orthogonality relations:

\[ \int d \Omega Y_{lm}(\hat{r}) \cdot Y^*_{lm'}(\hat{r}) = \delta_{ll'} \delta_{mm'}, \quad (D4a) \]
These relations allow to express the divergence, 
\[ \int d\Omega \Phi_{lm}(\mathbf{r}) \cdot \Phi_{lm'}^{*}(\mathbf{r}) = l(l + 1) \delta_{ll'} \delta_{mm'}, \]  
(D4b) and the curl, 
\[ \nabla \times \mathbf{G} = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \left[ -\frac{l(l+1)}{r} G_{lm}^{\Phi} Y_{lm} - \left( \frac{dG_{lm}^{\Phi}}{dr} + \frac{1}{r} G_{lm}^{\Phi} \right) \Psi_{lm} + \left( -\frac{1}{r} G_{lm}^{\Phi} Y_{lm} \right) \phi_{lm} \right], \]  
(D9) of a generic vector: 
\[ G(r) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \left( \mathbf{z} \cdot \sum_{m=-l}^{l} G_{lm}^{\phi} \Phi_{lm}(\mathbf{r}) \right). \]  
(D10)

1. Differential operators on vector spherical harmonics

The divergence of the vector spherical harmonics is:
\[ \nabla \cdot \left( f(r) Y_{lm} \right) = \left( \frac{df}{dr} + \frac{2}{r} f \right) Y_{lm}, \]  
(D6a)
\[ \nabla \cdot \left( f(r) \Psi_{lm} \right) = -l(l+1) f Y_{lm}, \]  
(D6b)
\[ \nabla \cdot \left( f(r) \Phi_{lm} \right) = 0. \]  
(D6c)

Similarly, the curl of the vector spherical harmonics gives
\[ \nabla \times \left( f(r) Y_{lm} \right) = \frac{1}{r} f \Phi_{lm}, \]  
(D7a)
\[ \nabla \times \left( f(r) \Psi_{lm} \right) = \left( \frac{df}{dr} + \frac{2}{r} f \right) \Phi_{lm}, \]  
(D7b)
\[ \nabla \times \left( f(r) \Phi_{lm} \right) = -l(l+1) \frac{f}{r} Y_{lm} - \left( \frac{df}{dr} + \frac{1}{r} f \right) \Psi_{lm}. \]  
(D7c)

These relations allow to express the divergence, 
\[ \nabla \cdot \mathbf{G} = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \left( \frac{1}{r^2} \frac{d}{dr} \left( r^2 G_{lm}^{\Phi} \right) - \frac{l(l+1)}{r} G_{lm}^{\Phi} \right) Y_{lm}, \]  
(D8)

The basis for \( l = 2 \) vector spherical functions is as follows:
\[ Y_{20} = \frac{1}{4} \sqrt{\frac{5}{\pi}} (3 \cos^2 \theta - 1) \hat{r}, \quad Y_{21} = -\sqrt{\frac{15}{8\pi}} e^{i\phi} \sin \theta \cos \theta \hat{r}, \quad Y_{22} = \frac{1}{4} \sqrt{\frac{15}{2\pi}} e^{2i\phi} \sin^2 \theta \hat{r}, \]  
(D13)
\[ \Psi_{20} = -\frac{3}{2} \sqrt{\frac{5}{\pi}} \sin \theta \cos \theta \hat{\theta}, \quad \Psi_{21} = -\sqrt{\frac{15}{8\pi}} e^{i\phi} \left( \cos 2\theta \hat{\theta} + i \cos \phi \hat{\phi} \right), \quad \Psi_{22} = \sqrt{\frac{15}{8\pi}} e^{2i\phi} \sin \theta \left( \cos \theta \hat{\theta} + i \hat{\phi} \right), \]  
\[ \Phi_{20} = -\frac{3}{2} \sqrt{\frac{5}{\pi}} \sin \theta \cos \theta \hat{\phi}, \quad \Phi_{21} = \sqrt{\frac{15}{8\pi}} e^{i\phi} \left( i \cos \theta \hat{\phi} - \cos 2\theta \hat{\phi} \right), \quad \Phi_{22} = \sqrt{\frac{15}{8\pi}} e^{2i\phi} \sin \theta \left( -i \hat{\theta} + \cos \theta \hat{\phi} \right). \]
