CLASSIFYING EQUIVALENCE RELATIONS IN THE ERSHOV HIERARCHY

NIKOLAY BAZHENOV, MANAT MUSTAFA, LUCA SAN MAURO, ANDREA SORBI, AND MARS YAMALEEV

Abstract. Computably enumerable equivalence relations (ceers) received a lot of attention in the literature. The standard tool to classify ceers is provided by the computable reducibility $\leq_c$. This gives rise to a rich degree-structure. In this paper, we lift the study of $c$-degrees to the $\Delta^0_2$ case. In doing so, we rely on the Ershov hierarchy. For any notation $a$ for a non-zero computable ordinal, we prove several algebraic properties of the degree-structure induced by $\leq_c$ on the $\Sigma^0_a \setminus \Pi^0_a$ equivalence relations. A special focus of our work is on the (non)existence of infima and suprema of $c$-degrees.

1. Introduction

Computable reducibility is a longstanding notion that allows classifying equivalence relations on natural numbers according to their complexity.

Definition 1.1. Let $R, S$ be equivalence relations with domain $\omega$. $R$ is computably reducible to $S$, denoted $R \leq_c S$, if there is a total computable function $f$ such that, for all $x, y \in \omega$,

$$xRy \iff f(x) S f(y).$$

We write $f : R \leq_c S$ to denote that $f$ is a computable function that reduces $R$ to $S$; $c$-degrees are introduced in the standard way.

The history of computable reducibility has many roots, being often rediscovered and explored in connection with different fields. Its study dates back to the fundamental work of Ershov in the theory of numberings, where the reducibility is introduced in a category-theoretic fashion (see Ershov’s monograph [11] in Russian, or [12] for an English survey). In the 1980s, computable reducibility proved to be a fruitful tool for calibrating the complexity of provable equivalence of formal systems and scholars focused mostly on the $\Sigma^0_1$ case (see, e.g., [26, 19, 5]). Following Gao and Gerdes [17], we adopt the acronym “ceers” to refer to computably enumerable equivalence relations.

Key words and phrases. Computability theory, Ershov hierarchy, $\Delta^0_2$ equivalence relations, computably enumerable equivalence relations.

Bazhenov, Mustafa, and Yamaleev were supported by Nazarbayev University Faculty Development Competitive Research Grants N090118FD5342. San Mauro was supported by the Austrian Science Fund FWF, project M 2461. Sorbi is a member of INDAM-GNSAGA and his research was supported by the PSR program of the University of Siena.
relations. The interested reader can consult Andrews, Badaev, and Sorbi [1]
for a nice and up-to-date survey on ceers, with a special focus on universal ceers, i.e., ceers to which all other ceers are computably reducible. The degree of universal ceers is by now significantly explored: for instance, in [2] the authors proved that all uniformly effectively inseparable ceers are universal. A complementary line of research aims at providing concrete examples of universal ceers. To this end, Nies and Sorbi [21] constructed a finitely presented group whose word problem is a universal ceer.

Far from being limited to ceers, computable reducibility has been also applied to equivalence relations of much higher complexity. Fokina, Friedman, Harizanov, Knight, McCoy, and Montalbán [15] showed that all \( \Sigma_1^1 \) equivalence relations are computably reducible to the isomorphism relations on several classes of computable structures (e.g., graphs, trees, torsion abelian groups, fields of characteristic 0 or \( p \), linear orderings). This study was fueled by the observation that computable reducibility represents a nice effective counterpart of Borel reducibility, i.e., a key notion of modern descriptive set theory (see [16]). The analogy between Borel and computable reducibility has been explored, for instance, by Coskey, Hamkins, and Miller [7], that investigated equivalence relations on c.e. sets mirroring classical combinatorial equivalence relations of fundamental importance for Borel theory.

Additional motivation for dealing with computable reducibility comes from the study of c.e. presentations of structures, as is shown for instance in [13, 18] (for a nice survey about c.e. structures, see [23]).

The goal of the present paper is to contribute to this vast (yet somehow unsystematic) research program by making use of computable reducibility to initiate a throughout classification of the complexity of \( \Delta_0^0 \) equivalence relations. In this endeavour, we follow and extend the work of Andrews and Sorbi [3], that provides a very extensive analysis of the degree structure induced by computable reducibility on ceers. Ng and Yu [20] broadened the perspective by discussing some structural aspects of the \( c \)-degrees of \( n \)-c.e., \( \omega \)-c.e., and \( \Pi_2^0 \)-equivalence relations. We similarly rely on the Ershov hierarchy to pursue our analysis.

Although our motivation is rather abstract (and to some extent corresponds to the desire of exporting the guiding questions of classical degree theory to the case of equivalence relations), our object of study shall not be regarded as too much artificial. The following example might convince the reader that \( \Delta_0^0 \) equivalence relations occur quite naturally.

Consider the following \( \Pi_2^0 \) equivalence relation \( R \):

\[
i R j \iff \text{card}(W_i) = \text{card}(W_j).
\]

Then one can define a “bounded” version of \( R \):

\[
\langle i, s \rangle R^b \langle j, t \rangle \text{ if and only if } \text{card}(W_i \cap \{0, 1, \ldots, s\}) = \text{card}(W_j \cap \{0, 1, \ldots, t\}).
\]

It is not hard to show that the relation \( R^b \) is \( \omega \)-c.e. Furthermore, the relation \( R^b \) admits an interpretation via algebraic structures: One can interpret a
number \( \langle i, s \rangle \) as the index of a finite linear ordering. Indeed, define the ordering \( \mathcal{L}_{i,s} \) as follows. The domain of \( \mathcal{L}_{i,s} \) is equal to \( W_i \cap \{0,1,\ldots,s\} \), and the ordering on the domain is induced by the standard ordering of natural numbers. Notice that here we assume that \( \mathcal{L}_{i,s} \) may be empty.

The list \( (\mathcal{L}_{i,s})_{i,s \in \omega} \) gives an enumeration of all finite linear orderings, up to permutations of the domains. It is easy to see that

\[
\langle i, s \rangle R^b \langle j, t \rangle \Leftrightarrow \mathcal{L}_{i,s} \cong \mathcal{L}_{j,t},
\]

thus the relation \( R^b \) can be treated as (one of the possible formalizations of) the relation of isomorphism on the class of finite linear orderings.

1.1. **Organization of the paper.** In Section 2, we set up the stage by offering some disanalogies between the degree-structure of c.eers and that of \( \Delta^0_2 \) equivalence relations. We also prove that infinitely many levels of the Ershov hierarchy contain minimal \( c \)-degrees. In Section 3, we focus on dark degrees, i.e., \( c \)-degrees not being above the identity on \( \omega \): we show that all levels of the Ershov hierarchy, with the exception of \( \Pi_1 \), contain dark equivalence relations. Section 4 and Section 5 are devoted to the existence of infima and suprema of \( c \)-degrees of \( \Delta^0_2 \)-equivalence relations: we introduce the notion of mutual darkness and prove that, if \( R, S \in \Sigma_a^{-1} \setminus \Pi_a^{-1} \) are mutually dark, then \( R, S \) have no infimum in \( \Sigma_a^{-1} \setminus \Pi_a^{-1} \) and no supremum in \( \Delta^0_2 \). It follows that none of the degree-structures considered in this paper is neither upper- nor a lower-semilattice.

1.2. **Notation and terminology.** All our equivalence relations have domain \( \omega \). Given a number \( n \), we denote by \([x]_R\) its \( R \)-equivalence class. We say that \( R \) is infinite if \( R \) has infinitely many equivalence classes (otherwise, it is of course finite). The following basic equivalence relations will appear many times:

- \( \text{Id}_n \) is the computable equivalence relation consisting of \( n \) equivalence classes, i.e.,
  
  \[
  x \text{Id}_n y \Leftrightarrow x \equiv y \text{ (mod } n),
  \]
  
  for all \( x, y \in \omega \).

- \( \text{Id} \) is the identity on \( \omega \), i.e., \( x \text{Id} y \) if and only if \( x = y \).

The following definition is due to Gao and Gerdes [17] (but analogous ways of coding sets of numbers by equivalence relations occur frequently in the literature, see for instance the definition of a set-induced \( c \)-degree in [20]).

**Definition 1.2.** An equivalence relation \( R \) is **\( n \)-dimensional** if there are pairwise disjoint sets \( A_0, \ldots, A_{n-1} \subseteq \omega \) such that

\[
x Ry \Leftrightarrow x = y \lor (\exists i)(x, y \in A_i).
\]

We denote such \( R \) by \( R_{A_0,\ldots,A_{n-1}} \).

An equivalence relation \( R \) is **essentially \( n \)-dimensional** if it has exactly \( n \) noncomputable equivalence class.
The next definition appears in [3] and reflects a fundamental distinction in how much information one can effectively extract from a given equivalence relation $R$.

**Definition 1.3.** An equivalence relation $R$ is *light* if $\text{Id} \leq_c R$; it is *dark* if it is not light and has infinitely many equivalence classes.

It is often convenient to think of a given light equivalence relation $R$ in terms of some computable listing of pairwise nonequivalent numbers witnessing its lightness. More formally, a *transversal* of an equivalence relation $R$ with infinitely many $R$-classes is an infinite set $A$ such that $r \neq s$ for all distinct $r, s \in A$. It is immediate to see that $R$ is light if and only if it has a c.e. transversal.

Our computability theoretic notions are standard, see for instance [25]. The basic notions regarding the Ershov hierarchy can be found in [8, 9, 10], see also [4]: in particular, recall the following.

**Definition 1.4.** Let $a$ be a notation for a computable ordinal. A set $A \subseteq \omega$ of numbers is said to be $\Sigma_a^{-1}$ (or $A \in \Sigma_a^{-1}$) if there are computable functions $f(z, t)$ and $\gamma(z, t)$ such that, for all $z$,

1. $A(z) = \lim_t f(z, t)$, with $f(z, 0) = 0$;
2. $\gamma(z, 0) = a$, and
   a. $\gamma(z, t + 1) \leq \gamma(z, t) \leq a$;
   b. $f(z, t + 1) \neq f(z, t) \Rightarrow \gamma(z, t + 1) \neq \gamma(z, t)$.
3. for every $s$ there is at most one $x$ such that $f(x, s + 1) \neq f(x, s)$.

Item 3. usually is not required in the literature, but it is clear that it can be safely assumed without loss of generality: it implies that for every $s$ we have $f(x, s) = 0$ for cofinitely many $x$. We call the partial function $\gamma$ the *mind–change function* for $A$, relatively to $f$.

A $\Sigma_a^{-1}$-approximating pair to a $\Sigma_a^{-1}$-set $A$, is a pair $\langle f, \gamma \rangle$, where $f$ and $\gamma$ are computable functions satisfying 1., 2., and 3. above, for $A$. As is known (see, e.g., [24, 22] for more details), one can effectively list all approximations $\langle f_e, \gamma_e \rangle$ to $\Sigma_a^{-1}$-sets. Thus we can refer to the listing $(E_e)_{e \in \omega}$ of the $\Sigma_a^{-1}$-sets, where $E_e$ is the set of which $\langle f_e, \gamma_e \rangle$ is a $\Sigma_a^{-1}$-approximating pair.

Dually, we say that a set $A$ is $\Pi_a^{-1}$, if $\overline{A} \in \Sigma_a^{-1}$, or equivalently there is a $\Pi_a^{-1}$-approximating pair $\langle f, \gamma \rangle$, i.e. a pair as above but starting with $f(z, 0) = 1$. If $X \in \{\Sigma_a^{-1} : a \in O\} \cup \{\Pi_a^{-1} : a \in O\}$ let us call $X^d = \{\overline{A} : A \in X\}$ the dual class of $X$.

We say that a set $A$ is *properly* $X$ if $A \in X \setminus X^d$.

Since any finite ordinal has only one notation, one usually writes $\Sigma_n^{-1}$ instead of $\Sigma_a^{-1}$, if $a$ is the notation of $n \in \omega$. In analogy with the terminology used for sets, we say that $R$ is a $n$-ceer if $R \in \Sigma_n^{-1}$.
2. A FIRST COMPARISON WITH CEERS

At first sight, one might expect that the structural properties of the \( c \)-degrees of ceers are reflected smoothly on the upper levels of the Ershov hierarchy. In this section we show that the parallel is much more delicate.

2.1. Equivalence relations with finitely many classes. Recall that any ceer with finitely many classes is computable. Surely, this is not the case for relations in the Ershov hierarchy:

**Lemma 2.1.** For every non-zero natural number \( n \), there is a \( \Pi_2^{-1} \) equivalence relation \( R \) such that \( R \) is noncomputable and has finitely many equivalence classes.

**Proof.** Consider a set \( X \in \Sigma_n^{-1} \setminus \Pi_n^{-1} \) and define the relation

\[
F_X := \{(x, y) : x, y \in X \text{ or } x, y \in \overline{X}\}.
\]

It is straightforward to check that \( F_X \) is a noncomputable equivalence relation with two equivalence classes and is in \( \Pi_2^{-1} \).

Relations of the form (1) already allow us to demonstrate some simple differences concerning elementary theories:

**Proposition 2.2.** Suppose that \( X \in \Pi_a^{-1} \cup \{a \mid |a| \geq 2\} \cup \{\Sigma_a^{-1} : |a| \geq 3\} \). Then the structure of \( X \)-equivalence relations is elementarily equivalent to neither ceers nor co-ceers.

**Proof.** Fix a c.e. set \( W \) such that deg\(_m\)(\( W \)) is a minimal \( m \)-degree. Note that \( \text{Id}_2 \triangleleft_c F_W \). Suppose that \( E \) is an equivalence relation such that \( \text{Id}_2 \leq_c E \leq_c F_W \). Then \( E \) is equal to \( F_V \) for some c.e. set \( V \) and the minimality of \( \text{deg}_m(W) \) implies that either \( V \) is computable or \( V \equiv_m W \). Thus, we have \( E \equiv_c \text{Id}_2 \) or \( E \equiv_c F_W \).

Hence, the desired elementary difference can be witnessed by the following argument:

1. The \((c\)-degree of the\) relation \( \text{Id}_1 \) is the least element under computable reducibility (in ceers, co-ceers, and \( \mathcal{X} \)).
2. \( \text{Id}_2 \) is the unique minimal \( c \)-degree over \( \text{Id}_1 \) (in ceers, co-ceers, and \( \mathcal{X} \)).
3. Inside \( \mathcal{X} \), one can find two incomparable elements \( x_0 \) and \( x_1 \) (namely, the \( c \)-degrees of \( \text{Id}_3 \) and \( F_W \)) such that \( \text{Id}_2 < x_i \) and \( \neg \exists z (\text{Id}_2 < z < x_i) \). Note that this property fails for ceers and co-ceers.

\[ \square \]

2.2. Finite minimality. We move now to equivalence relations with infinitely many equivalence classes.

Notice that in the context of ceers, explored in [3], equivalence relations with finitely many classes are computable, whereas this is not so in higher levels of the Ershov hierarchy as witnessed by the two-classes equivalence relations of the form \( F_X \) introduced in the proof of Lemma 2.1. This suggests
the following notion of minimality (called finite minimality) when we work in the Ershov hierarchy.

**Definition 2.3.** An equivalence relation $R$ is **finitely minimal** if $S \preceq_c R$ implies that $S$ has only finitely many equivalence classes.

Observe also that if $R$ is light and $R \preceq_c \text{Id}$, then $R$ is not finitely minimal.

The previous definition does perfect justice to the notion of minimality for dark equivalence relations, as it is easy to see (see [3] where the property is stated for ceers, but it clearly holds of all equivalence relations) that if $E$ is dark, $R \preceq_c E$ and $R$ has infinitely many equivalence classes, then $R$ is dark as well. So a finitely minimal dark equivalence relation is exactly a minimal dark equivalence relation, i.e. a dark equivalence relation for which there is no dark equivalence relation strictly below it.

One of the tools that will be useful to us is the **collapse technique**, extensively used for ceers in [3]. If $R$ is an equivalence relation and $x \sim_R y$, then the **collapse** $R_{\text{coll}(x,y)}$ (denoted by $R_{/\{x,y\}}$ in [3]) is defined as

$$R_{\text{coll}(x,y)} := R \cup \{(u,v) : u,v \in [x]_R \cup [y]_R\}.$$ 

We illustrate the technique by obtaining the next two results about finite minimality.

**Lemma 2.4.** Suppose that $R$ is dark with a computable class. Then $R$ cannot be finitely minimal.

*Proof.* Suppose that classes $[a]_R$ and $[b]_R$ are distinct, and $[b]_R$ is computable. Consider the collapse $S := R_{\text{coll}(a,b)}$. Then (by essentially the same argument as in the proof of [3, Lemma 2.6]) $S$ is reducible to $R$ by the function

$$f(x) = \begin{cases} x, & \text{if } x \notin [b]_R, \\ a, & \text{otherwise.} \end{cases}$$

Assume that $g: R \preceq_c S$. Consider the map $h := f \circ g$ and the $h$-orbit of $b$, i.e. the set

$$\text{orb}_h(b) = \{h^k(b) : k \in \omega\}.$$ 

It is easy to see that $h: R \preceq_c R$. We claim that the orbit $\text{orb}_h(b)$ consists of pairwise non-$R$-equivalent elements: indeed, if $h^k(b) R h^l(b)$ for $k < l$, then we have $b R h^{l-k}(b)$, and $\text{range}(f) \cap [b]_R \neq \emptyset$, which contradicts the choice of the map $f$. Hence, $\text{orb}_h(b)$ is an infinite c.e. transversal of $R$, and we obtain a contradiction with the darkness of $R$. Therefore, we deduce that $S <_c R$ and $R$ is not finitely minimal. \qed

Now we show that there are infinitely many levels of the Ershov hierarchy which contain finitely minimal, dark equivalence relations properly belonging to the level:

**Theorem 2.5.** Suppose that $a \in \mathcal{O}$ and $|a|_\mathcal{O} \geq 1$. Then there exists a finitely minimal, dark equivalence relation $R \in \Delta^0_2 \setminus \Sigma^{-1}_a$. 
Proof. In the proof of [3, Thm. 3.3], Andrews and Sorbi constructed infinitely many pairwise incomparable, finitely minimal, dark ceers $S_l$, $l \in \omega$, with the following property: for any $e$ and $l$, if the c.e. set $W_e$ intersects infinitely many $S_l$-classes, then it intersects every $S_l$-class. We choose only one such a ceeer $S := S_0$. As explained in the introduction, fix a $\Sigma^{-1}_a$ list $(E_e)_{e \in \omega}$ of all $\Sigma^{-1}_a$ sets $(E_e)_{e \in \omega}$. We build a $\Delta^0_2$ equivalence relation $R$ with the following properties:

- $R \supseteq S$, and
- $R \neq E_e$, for every $e \in \omega$.

The construction proceeds in a straightforward $\mathbf{0}'$-effective manner. We choose a $\mathbf{0}'$-effective list $\{x_e\}_{e \in \omega}$ which enumerates representatives of all $S$-classes, without repetitions (i.e. $x_i \neq x_j$ for $i \neq j$). We start with $R[0] = S$, i.e. $S$ is the approximation $R[0]$ of $R$ at stage 0.

Consider stage $k$. If $x_{2k} \notin x_{2k+1}$, then $R[k+1]$ is equal to the collapse $R[k] \text{coll}(x_{2k}, x_{2k+1})$. Otherwise, $R[k+1] = R[k]$.

As per usual, set $R = \bigcup_{k \in \omega} R[k]$. First notice that $R$ is $\Delta^0_2$: to see if $x \in R$ use oracle $\mathbf{0}'$ to search for the unique $h,k$ such that $x \in S_h$ and $y \in S_k$, and then check if $x_h = x_k$ or $x_h$ and $x_k$ have been collapsed at stage $\text{max}(h,k)$. Finally, it is not hard to show that $R$ has infinitely many classes, and $R \notin \Sigma^{-1}_a$.

Assume now that $f: \text{Id} \leq_c R$. Since $R \supseteq S$, the map $f$ is also a reduction from $\text{Id}$ to $S$, which contradicts the darkness of $S$. Thus, $R$ is also dark.

Suppose that $g: Q \leq_c R$ and $Q$ has infinitely many classes. Since $Q$ contains infinitely many classes, the set $W := \text{range}(g)$ is a c.e. set which intersects infinitely many $R$-classes. Recall that $R \supseteq S$, hence, $W$ intersects infinitely many $S$-classes. The choice of the ceeer $S$ implies that $W$ intersects every $S$-class.

Now we build a map $h$ as follows: Fix an effective approximation $\{S[t]\}_{t \in \omega}$ of the ceeer $S$ and for a number $x$, define $h(x)$ to be the first seen $y$ such that $g(y) \in S[x]$ more formally,

$$
\begin{align*}
t(x) &:= \mu t[(\exists y < t)(x,y) \in S[t]], \\
h(x) &:= \mu y[(x,y) \in S[t(x)]].
\end{align*}
$$

Since $\text{range}(g)$ intersects every $S$-class, $h$ is a total computable function. We show that $h: R \leq_c Q$. Note that for any $x,y \in \omega$, we have $x \in S \iff gh(x)$, and the following conditions are equivalent:

$$
R \equiv_c Q \iff g(h(x)) \iff x \in R \iff y.
$$

Thus, we have $Q \equiv_c R$, and $R$ is finitely minimal. Theorem 2.5 is proved. □

Note that in the relation $R$ from the theorem above, every $R$-class is a c.e. set. Thus, $R$ has the following curious property: If $Q \leq_c R$ and $Q$ has only finitely many classes, then $Q \equiv_c \text{Id}_n$ for some $n \in \omega$. 

2.3. Failure of Inversion Lemma. A fundamental technique when studying ceers is provided by the following result: see for instance [3, Lemma 1.1].

Lemma 2.6 (Inversion Lemma). Suppose that $R,S$ are ceers and $R \leq_c S$ via $f$. If $f$ hits all the equivalence classes of $S$ (i.e. $\text{range}(f)$ intersects with every $S$-class), then $S \leq_c R$.

The Inversion Lemma does not hold, in general, for the Ershov hierarchy. In fact, it fails already for 2-ceers:

Lemma 2.7. There is an equivalence relation $R \in \Sigma_2^{-1} \setminus \Sigma_1^{-1}$ such that $\text{Id} \leq_c R$ via a function $f$ which is surjective on the equivalence classes of $R$.

Proof. Fix a noncomputable c.e. set $X$. Split $\omega$ into four computable parts: $A = \{a_0, a_1, a_2, \ldots\}$, $B = \{b_0, b_1, b_2, \ldots\}$, $C = \{c_0, c_1, c_2, \ldots\}$, and $D = \{d_0, d_1, d_2, \ldots\}$.

The relation $R$ is given by its equivalence classes: for every $i \in \omega$,

- If $i \notin X$, then $R$ contains disjoint classes $\{a_i, c_i\}$ and $\{b_i, d_i\}$.
- If $i \in X$, then there are $R$-classes $\{a_i, d_i\}$ and $\{b_i, c_i\}$.

It is clear that $R$ is not a ceer, and the function

$$f(2i) = a_i, \quad f(2i + 1) = b_i,$$

gives a reduction from $\text{Id}$ to $R$, hitting all the $R$-classes. Furthermore, $R$ is a 2-ceer, since after separating two classes in the approximation of $R$ (due to some $i$ being enumerated in $X$), we never merge them again. \qed

Lemma 2.8. For any dark $\Delta_2^0$ equivalence relation $R$, there are a dark equivalence relation $R \leq_c S$ and a reduction $f : R \leq_c S$ such that $f$ hits all the $S$-classes.

Proof. Fix a dark ceer $Q$. Choose a $0'$-effective list $\{r_i\}_{i \in \omega}$ of representatives of all $R$-classes, without repetitions. Similarly, choose a $0'$-effective list $\{q_i\}_{i \in \omega}$ for representatives of $Q$-classes.

The construction is given in a $0'$-computable way. At stage $0$, set $S[0] := R \uplus Q$. At stage $e + 1$, if $\varphi_e(2r_e) \downarrow \varphi_e(2q_e + 1) \downarrow$, then set $S[e + 1] := S[e]_{\text{coll}(2r_e, 2q_e + 1)}$. Otherwise, define $S[e + 1] := S[e]_{\text{coll}(0, 2q_e + 1)}$.

It is not hard to show that the constructed $S$ is $\Delta_2^0$, and $S \leq_c R$. Moreover, the function $f : x \mapsto 2x$ gives a reduction of $R$ to $S$, hitting all the $S$-classes.

Assume that $g : \text{Id} \leq_c S$. Then either range$(g)$ contains infinitely many even numbers and $R$ cannot be dark, or range$(g)$ contains infinitely many odd numbers and $Q$ cannot be dark. In any case, this leads to a contradiction, thus, $S$ is dark. \qed

3. Dark equivalence relations in the Ershov Hierarchy

In this section, we show that the phenomenon of darkness is rather pervasive: with the exception of the co-ceers, dark degrees exist properly at each level of the Ershov hierarchy. In the construction of these degrees we
also develop some strategies that will be helpful in further sections, when the focus will be on the existence of infima and suprema of \(c\)-degrees.

**Proposition 3.1.** There are no dark co-ceers.

**Proof.** Suppose that \( R \in \Pi^0_1 \). If \( R \) has finitely many equivalence classes, then it is trivially not dark. Hence, assume there exist infinitely many \( R \)-classes. We prove that \( R \) is light by inductively building the following c.e. transversal of \( R \): Let \( x_0 = 0 \) and let \( x_{i+1} \) be any number \( z \) such that, for all \( j \leq i \), \((x_j, z) \notin R\). Such a \( z \) must exist (otherwise, there would be only finitely many \( R \)-classes) and, since \( R \) is co-c.e. will be found effectively. \( □ \)

**Theorem 3.2.** If \( X = \Sigma^{-1}_a \) with \(|a|_o \geq 1\) then there is a dark equivalence relation having only finite equivalence classes, and properly lying in \( X \).

**Remark 3.3.** Theorem 3.2 can be obtained as a corollary of Theorem 4.6. For the sake of exposition, being the proof of Theorem 4.6 more complicated, we shall provide a proof of Theorem 3.2 nonetheless. This might help the reader to familiarize, in a simpler context, with the techniques required for Theorem 4.6, and in fact exploited also in the proof of Theorem 5.5.

**Proof of Theorem 3.2.** Let us start with the case \( X = \Sigma^{-1}_a \) with \(|a|_o \geq 1\). We want to build an equivalence relation \( R \) satisfying the following requirements, for every \( e \in \omega \):

- \( F_e \): \([e]_R \) is finite,
- \( P_e \): \( W_e \) is not an infinite transversal for \( R \),
- \( Q_e \): \( A \neq E_e \),

where \((E_e)_{e \in \omega}\) is a listing of the \( \Pi^{-1}_a \) sets as explained in the introduction, with \( \langle f, \gamma \rangle \) a \( \Pi^{-1}_a \)-approximation to \( E_e \).

Let us define the **priority ordering** of the requirements as

\[
F_0 < Q_0 < P_0 < \cdots < F_e < Q_e < P_e < \cdots .
\]

We build computable functions \( f(x, s) \) and \( \gamma(x, s) \) so that the pair \( \langle f, \gamma \rangle \) is a \( \Sigma^{-1}_a \)-approximating pair to a \( \Sigma^{-1}_a \)-equivalence relation \( R \) defined as

\[
x R y \iff \lim_{s} f(\langle x, y \rangle, s) = 1,
\]

satisfying the given requirements.

**Strategies for the requirements and their interactions.** The strategy for \( F_e \) requires that no lower priority requirement adds any element to \([e]_R\), which is eventually finite because only higher priority requirements may contribute with their actions to add elements to \([e]_R\) (we will see every requirement may act only finitely many times).

For the \( Q \)-requirement \( Q_e \) we appoint as witness a pair

\((x_e, y_e) \in 2\omega \times (2\omega + 1)\).
Each time we see $W_e$ enumerate a pair of distinct numbers $u,v$, both even or both odd. When found, it simply $R$-collapses $u,v$ (if not already collapsed): this ensures that $W_e$ is not a transversal for $R$. Notice that if $W_e$ is infinite then by the Pigeon Hole Principle it either contains infinitely many even numbers or infinitely many odd numbers. We will see by Lemma 3.4 that by the Pigeon Hole Principle it either contains infinitely many even numbers or infinitely many odd numbers. We will see by Lemma 3.4 that $P_e$ will not be restrained by $\Sigma^1_0$-ness from $R$-collapsing two even numbers or two odd numbers, since the construction will ensure that a necessary condition, at any stage, for which we may have $f(\langle x, y \rangle) = 0$ but already $\gamma(\langle x, y \rangle) = 1$ is that $x,y$ have different parity.

As $f_e(\langle x_e, y_e \rangle, 0) = 1$ (and $\gamma_e(\langle x_e, y_e \rangle, 0) = a$), the construction starts up with having $(x_e, y_e)$ not in $R$, i.e. $f(\langle x_e, y_e \rangle, 0) = 0$, and $\gamma(\langle x_e, y_e \rangle, 0) = a$. Every time we see $f_e(\langle x_e, y_e \rangle, s+1) \neq f_e(\langle x_e, y_e \rangle, s)$, we change accordingly $f(\langle x_e, y_e \rangle, s+1)$ as to have

$$f(\langle x_e, y_e \rangle, s+1) \neq f_e(\langle x_e, y_e \rangle, s+1),$$

and we define

$$\gamma(\langle x_e, y_e \rangle, s+1) := \gamma_e(\langle x_e, y_e \rangle, s+1).$$

In this way $Q_e$ is able to diagonalize against $E_e$ at the witness $(x_e, y_e)$, consistently with $R$ being in $\Sigma^1_0$.

**The construction.** The construction is in stages: at stage $s$ we define the approximation $R[s]$ to $R$, and the approximations to the various parameters $(x_e, y_e)$. We will often omit to mention the stage to which a given parameter is referred, if this is clear from the context. Unless otherwise specified, at each stage each parameter keeps the same value as at the previous stage. To initialize a $Q$-requirement at stage $s$ means to cancel at that stage the current value of its witness. A pair $(x_e, y_e)$ is an active witness for $Q_e$ at stage $s$ if the pair has been appointed as a witness for $Q_e$ at some previous stage and never canceled thereafter. We say that a requirement $P_e$ is inactive at the end of stage $s$ if there are already distinct numbers $u,v \in W_e$ such that $u \not\vDash R \vdash v$ at the end of stage $s$; it is active otherwise.

A requirement $T$ requires attention at stage $s+1$ if either

1. $T$ is initialized; or
2. one of the following holds, for some $e$:
   (a) $T = P_e$, $P_e$ is active at the end of $s$, and at the current stage there is a distinct pair of numbers $u,v \in W_e$ both even or both odd, and such that $u,v$ are bigger than all numbers in the union of all current equivalence classes of numbers $i \leq x_e + y_e$;
   (b) $T = Q_e$ and $f(\langle x_e, y_e \rangle, s) = f_e(\langle x_e, y_e \rangle, s+1)$, where $(x_e, y_e)$ is the witness of $T$ at the end of stage $s$. 

Stage 0. Initialize all $Q$-requirements; no $P$-requirement is inactive; define $R[0] := \emptyset$, and consequently $f(x, 0) := 0$ and $\gamma(x, 0) := a$ for all $x$. (Notice that we do not define here $R[0] := \text{Id}$, as would be perhaps more appropriate since we are defining an equivalence relation which is bound to be reflexive, because we want to accompany the definition of $R$ with an accompanying $\Sigma_0^{-1}$-approximating pair $\langle f, \gamma \rangle$ to $R$ so that $f$ must start with $f(x, 0) = 0$, for every $x$.)

Stage 1. Define $R[1] := \text{Id}$, and $f(\langle x, x \rangle, 1) := 1$ and $\gamma(\langle x, x \rangle, 1) := 1$, leaving untouched the other values of both $f$ and $\gamma$. (Recall that $|1|\emptyset = 0$. Notice that for every $s \geq 1$, we will have $x R[s] x$, so there will never be need to redefine $\gamma(\langle x, x \rangle, s)$.) Therefore we can say that the construction essentially starts (with $R := \text{Id}$) at stage 1 instead of 0.

Stage $s + 1 \geq 2$. Consider the highest priority requirement $T$ that requires attention. (Notice that there is always such a requirement since at each stage almost all $Q$-requirements are initialized). Action:

1. If $T$ is initialized, then $T = Q_e$ for some $e$: choose a new fresh witness $(x_e, y_e)$ for $T$, i.e. $x_e = 2i$ and $y_e = 2i + 1$, where $i$ is bigger than all numbers $T$-equivalent to numbers so far used in the construction (so we can also assume that $e \leq x_e + y_e$). Notice that because of (3) in the definition of a $\Pi_0^{-1}$-approximation, we may as well suppose that still $f_e(\langle x_e, y_e \rangle, s + 1) = 1$, $f(\langle x_e, y_e \rangle, s) = 0$, and $\gamma_e(\langle x_e, y_e \rangle, s + 1) = \gamma(\langle x_e, y_e \rangle, s) = a$.

2. Otherwise:
   a. if $T = P_e$ then pick the least pair $u, v$ as in the definition of requiring attention; define $f(\langle u, v \rangle, s + 1) := 1$ and $\gamma(\langle u, v \rangle, s + 1) := 1$; for any other $R$-collapse $x R y$ induced at this stage by the $R$-collapse of $u, v$ define $f(\langle x, y \rangle, s + 1) := 1$ and $\gamma(\langle x, y \rangle, s + 1) := 1$; declare $P_e$ inactive (and thus it will remain inactive forever unless later re-initialized);
   b. if $T = Q_e$ then define $f(\langle x_e, y_e \rangle, s + 1) \neq f_e(\langle x_e, y_e \rangle, s + 1)$ and $\gamma(\langle x_e, y_e \rangle, s + 1) := \gamma_e(\langle x_e, y_e \rangle, s + 1)$, so that we diagonalize $R$ against $E_e$.

This is the end of the stage. Initialize all lower priority $Q$-requirements. Define $R[s + 1]$ to be the equivalence relation having $f(\langle x, s + 1 \rangle)$ as characteristic function, i.e. (as is easily seen) the equivalence relation generated by the set of pairs provided by $R[s]$ plus or minus the pairs enumerated in or extracted from $R$ at $s + 1$.

The verification. An easy inductive argument shows that for every requirement $T$ there is a least stage $t_T$ such that no $T'$ of higher priority than $T$, nor $T$ itself, requires attention or acts at any $s \geq t_T$. Indeed suppose that this is true of every $T'$ of higher priority than $T$. Then there is a least stage $t$ such that no such $T'$ requires attention after $t$. So either $T = P_e$ and thus $T$ may act at most once after $t$; or $T = Q_e$ and thus $T$ may require
attention a first time to appoint the final value of its witness \((x_e, y_e)\) (this value will never be canceled, because \(T\) will never be re-initialized again, as no higher priority \(T'\) will ever act again), and subsequently finitely many times in response to the finitely many changes of \(f_e(x_e, y_e, s)\). In any case this shows that \(t_T\) exists.

**Lemma 3.4.** For every \(e,s\), if \((x_e, y_e)\) is still an active witness for \(P_e\) at \(s\), then at that stage \([x_e]_R \cup [y_e]_R = \{x_e, y_e\}\), each equivalence class among \([x_e]_R\) and \([y_e]\) being a singleton if and only if \(f_e(x_e, y_e, s) = 1\). Moreover, if distinct \(u,v\) have the same parity then \(f(u,v)\) may change at most once from value 0 to 1 in response to some \(P\)-requirement which becomes inactive.

**Proof.** Suppose that \((x_e, y_e)\) is active at \(s\), and let \(t \leq s\) be the stage at which this witness has been appointed for \(Q_e\). Then the restraint imposed by \(Q_e\) (reflected in the fact that lower priority \(P\)-requirements may not modify the equivalence classes of numbers \(i \leq x_e + y_e\) and thus may not modify the equivalence classes of \(x_e, y_e\)) prohibits any modification of the equivalence classes of \(x_e, y_e\) done by any lower priority requirement. Such a modification can only be performed by a higher priority requirement \(P_t\), but if such a requirement has acted after \(t\), then the witness \((x_e, y_e)\) has been re-initialized and thus canceled.

The latter claim about the number of changes of \(f(u,v)\) if \(u,v\) are distinct and have the same parity follows from the fact that by the first part of this lemma the value \(f(u,v)\) is not changed by any \(Q\)-requirement, so if the value \(f(u,v,1) = 0\) is later changed from 0 to 1 then this is due to a \(P\)-requirement, which becomes inactive, and by choice of \(u,v\) and the first part of this lemma this change is never revoked by any higher priority \(Q\)-requirement.

This enables us to show also that \(T\) is in the end satisfied. This is evident if \(T = F_e\) as after \(t_Q_e\) no \(P\)-requirement can add numbers to \([e]_R\) since \(e \leq x_e + y_e\). Notice that this shows that each \(R\)-equivalence class is finite.

It is also evident if \(T = Q_e\) as \(T\) is by Lemma 3.4 the only requirement which is entitled to move its final witness \((x_e, y_e)\) in or out of \(R\).

To show that \(T\) is satisfied if \(T = P_e\), assume that \(W_e\) is infinite. Since the witness \((x_e, y_e)\) reaches a limit, and all equivalence classes are finite, it follows that \(W_e\) contains at least two even numbers or two odd numbers bigger than any element in the equivalence class of some \(i \leq x_e + y_e\) so that at some point we are able to \(R\)-collapse such a pair \(u,v\) if \(P_e\) is still active. So if \(W_e\) is infinite then it cannot be a transversal of \(R\).

By Lemma 3.4 it is also clear that \(R \in \Sigma^{-1}_a\), and the pair \(\langle f, \gamma \rangle\) is a \(\Sigma^{-1}_a\)-approximation to \(R\). Indeed on pairs \(u,v\) such that \(u,v\) have the same parity the characteristic functions of \(R\) may change value on \(\langle u, v \rangle\) only once (from 0 to 1). On pairs of different parity the characteristic function may change value more times. Indeed, it can do so on \(u,v\), with say \(u\) even and \(v\) odd for the following reasons. A first possibility is that for instance we already have
z R v due to some $Q$-requirement which has used the pair $(z, v)$ as witness, and some higher priority $P$-requirement $R$-collapses $u$ and $z$ so that we get $u R v$ (or we already have $z R u$ for some odd $z$, and now a higher priority $P$-requirement $R$-collapses $v$ and $z$): but this is compatible with the relation being in $\Sigma_a^{-1}$, as witnessed by $\gamma((u, v), \_)$ which decreases from $a$ to 1. A second possibility is that the characteristic function of $R$ changes on $x u, v y$ if this value is moved by the diagonalizing strategy of some $Q$-requirement $Q$, but then this is done with a number of changes compatible with the relation being in $\Sigma_a^{-1}$, as witnessed by $\gamma((u, v), \_)$ which mimics $\gamma_e((u, v), \_)$.

Finally, we consider the case when $X = \Pi_a^{-1}$ for some notation $a$ with $|a|_0 > 1$. The construction is virtually the same as in the dual case. We start with $R[0] = Id_1$ with consequent definitions of $f$ and $\gamma$: $f(x, 0) := 1$; $\gamma(x, 0) := a$ for every $x$, and $R[1]$ defined as follows:

$$x R[1] y \iff x = y \lor (\exists i)[\{x, y\} = \{2i, 2i + 1\}],$$

with consequent suitable definitions of $f$ and $\gamma$: in particular

$$\gamma((x, y), 1) = \begin{cases} a, & \text{if } x = y \lor (\exists i)[\{x, y\} = \{2i, 2i + 1\}], \\ 2, & \text{otherwise}, \end{cases}$$

where we have used the assumption that $|a|_0 > 1$. The construction now mimics the one for the $\Sigma_a^{-1}$-case, essentially starting from stage 1. The idea is to make the first approximation to $R$ to look very much like $Id$ (as in the proof of Theorem 3.2), except for pairs of the type $(2i, 2i + 1)$ for which we do not want to add an extra initial change which could spoil our possibility of playing the extraction/enumerating game exploited by the diagonalization strategies. This allows a requirement $P_e$ to be able, if it requires attention, to $R$-collapse pairs of numbers of the same parity that have been set as non-$R$-equivalent at stage 1 (when for this purpose we have defined $\gamma$ to be 2 for these pairs).

\[\square\]

4. The problem of the existence of infima

Let us fix a notation $a$ for a non-zero computable ordinal. The following observation is straightforward.

**Fact 4.1.** The poset of degrees of $\Sigma_a^{-1}$-equivalence relations is not a lower-semilattice.

**Proof.** This follows immediately from the fact that the degrees of ceers forms an initial segment of the degrees of $\Sigma_a^{-1}$-equivalence relations, and on the other hand ceers are known not to form a lower-semilattice, see for instance [3].

We will show however that we can find properly $\Sigma_a^{-1}$-equivalence relations with no inf, proving that the $e$-degrees of $\Sigma_a^{-1} \setminus \Pi_a^{-1}$ equivalence relations do not form a lower-semilattice.
Andrews and Sorbi [3] showed that many questions about the degree structure of ceers can be fruitfully tackled by inspecting the interplay between light and dark ceers. By lifting our focus to the class of $\Delta^0_2$ equivalence relations, we need to introduce the following relativized version of Definition 1.3, which stands as a natural companion of the analysis of the complexity of transversals of a given ceer provided in [14].

**Definition 4.2.** Let $R$ be an equivalence relation, and $A$ any set of numbers. $R$ is $A$-dark if $R$ is infinite and has no infinite $A$-transversal, i.e. there is no infinite $A$-c.e. set $W_e^A$ such that for all distinct $u, v \in W_e^A$, one has $u R v$.

Two equivalence relations $R, S$ are mutually dark if $R$ is $S$-dark, and $S$ is $R$-dark.

Notice:

**Proposition 4.3.** If $R, S$ are mutually dark then they are dark.

**Proof.** In fact, if $R$ is such that there is a set $A$ such that $R$ has no infinite $A$-c.e. set as a transversal then $R$ is dark. This follows from the fact that a c.e. set is $A$-c.e. relatively to every oracle $A$. \qed

By Theorem 4.6, we prove that mutually dark equivalence relations exist at all levels of the Ershov hierarchy. But before that, let us offer a nice alternative characterization of mutual darkness. We first need to relativize computable reducibility in an obvious way (as in [14], where the complexity of $d$-computable reductions is considerably explored): Let $d$ be a Turing degree. $R$ is $d$-computationally reducible to $S$, denoted $R \leq_d S$, if there is a total $d$-computable function $f$ such that, for all $x, y \in \omega$,

$$x R y \iff f(x) S f(y).$$

**Definition 4.4.** Define $R|_d S$ if $R, S$ are infinite and $R \leq_{\deg_T(R)} S$ and $S \leq_{\deg_T(S)} R$.

Hence, $R|_d S$ holds if the information of neither of the two equivalence relations is enough by itself to compute a reduction into the other. The next proposition shows that this is the same as asking that $R$ and $S$ are mutually dark.

**Proposition 4.5.** $R|_d S$ if and only if $R, S$ are mutually dark.

**Proof.** Let $R, S$ be infinite equivalence relations.

Suppose that $R$ is not $S$-dark, and let $g$ be an $S$-computable function which lists an infinite transversal of $R$. We claim in this case that $S \leq_{\deg_T(S)} R$. Indeed, a suitable $S$-computable function reducing $S$ to $R$ can be defined by induction as follows: $f(0) := g(0)$; and

$$f(n + 1) := \begin{cases} f(i), & \text{if } i \leq n \text{ and } i S n + 1, \\ g(n + 1), & \text{if there is no } i \leq n \text{ such that } i S n + 1. \end{cases}$$

In a similar way one can show that if $S$ is not $R$-dark then $R \leq_{\deg_T(R)} S$.\/
Vice versa suppose that $S \leq_{\text{deg}_P(S)} R$, via a function $f \in \text{deg}_P(S)$. As $S$ is infinite, let $g$ be an $S$-computable function listing an infinite transversal for $S$. Then the function $f \circ g$ is $S$-computable and lists an infinite transversal of $R$. Thus $R$ is not $S$-dark. In a similar way, one shows that if $R \leq_{\text{deg}_P(R)} S$ then $S$ is not $R$-dark. □

**Theorem 4.6.** If $\mathcal{X} \in \{\Sigma_a^{-1} : a \in \mathcal{O}, |a|_O \geq 1\} \cup \{\Pi_a^{-1} : a \in \mathcal{O}, |a|_O > 1\}$ then there exist mutually dark equivalence relations having only finite classes and properly lying in $\mathcal{X}$.

**Proof.** Let us start again with the case $\mathcal{X} = \Sigma_a^{-1}$, with $|a|_O \geq 1$. We build equivalence relations $U,V$ satisfying the following requirements, for every $e \in \omega$:

- $F^U_e : [e]_U$ is finite,
- $F^V_e : [e]_V$ is finite,
- $P^U_e : W^U_e$ is not an infinite transversal for $V$,
- $P^V_e : W^V_e$ is not an infinite transversal for $U$,
- $Q^U_e : U \neq E_e$, $Q^V_e : V \neq E_e$.

where $(E_e)_{e \in \omega}$ is a listing of the $\Pi_a^{-1}$-sets, with $\langle f_e, \gamma_e \rangle$ a $\Pi_a^{-1}$-approximation to $E_e$. We build $U,V$ via defining $\Sigma_a^{-1}$-approximating pairs $\langle f^U_e, \gamma^U_e \rangle$ and $\langle f^V_e, \gamma^V_e \rangle$ to $U,V$ respectively.

The priority ordering of the requirements is

$$F^U_0 < F^V_0 < Q^U_0 < P^U_0 < P^V_0 < \cdots$$

$$< F^U_e < F^V_e < Q^U_e < Q^V_e < P^U_e < P^V_e < \cdots .$$

We say that a requirement $R$ has priority position $e$, if $e$ is the position of $R$ in the above ordering: the priority position of $R$ will be denoted by $e_R$.

**Strategies for the requirements and their interactions.** The strategies for the requirements are essentially the same as the ones for the “corresponding” requirements in the proof of Theorem 3.2. The additional complication is due to the fact that we have also sometimes to preserve certain Turing-computations. For this reason we will view the restraint imposed at any stage by a requirement $R$ as two finite binary strings $r_{R,U}$ and $r_{R,U}$: if $S \in \{U,V\}$ the string $r_{R,S}$ extends $r_{R,S}$ (i.e. $r_{R,S} \supseteq r_{R,S}$) which represents the restraint inherited at that stage by the higher priority requirements (the string $r_{R,S}$ is empty if $R$ is the highest priority requirement); in turn, $r_{R,S}$ is a string which lower priority requirements are bound to preserve if $R$ is not re-initialized: this string automatically becomes $r_{R,S} = r_{R,S}'$ where $R'$ is the requirement immediately following $R$ in the priority ordering. The strings $r_{R,S}$ and $r_{R,S}$ depend of course on the stage.
The strategy for $R = F_e^U$ (the one for $F_e^V$ is similar) sets up a restraint requesting that no lower priority requirement change $[e]_U$.

The strategy for $R = Q_e^U$ (the one for $Q_e^V$ is similar) works with a suitable witness $(x_e^U, y_e^U) \in 2\omega \times (2\omega + 1)$ (consisting as in the proof of Theorem 3.2 of numbers of different parity, say of the form $(2i, 2i + 1)$), and sets up a restraint to preserve the $U$-equivalence classes of $x_e^U$ and $y_e^U$.

Let us now consider a $P$-requirement $R = P_e^U$ (the case $R = P_e^V$ is similar). The strategy for $P_e^U$ consists in seeing if we can define $U, V$ so that there are distinct $u, v \in W_e^U$ of the same parity, and $u, v$ can be $V$-collapsed without injuring higher priority restraints.

$Q$-requirements may be initialized as in the proof of Theorem 3.2. A requirement $R$ requires attention at stage $s + 1$ if either

1. $R$ is initialized; or
2. one of the following holds, for some $e \in \omega$ and $S \in \{U, V\}$, where we assume $S = U$, the other case being similar and treated by interchanging the roles of $U$ and $V$:
   (a) $R = P_e^U$, $R$ is active at the end of $s$ (i.e. it is not already the case that at $s + 1$ there are already distinct numbers $u, v$ with $u, v \in W_e^{\rho_{U,R}}$ and $r_{R,V}^{-1}(\langle u, v \rangle) = 1$), and there is a pair $(\sigma, \tau)$ of strings and a pair $(u, v)$ of distinct numbers of the same parity such that:
      (i) $r_{R,U} \subseteq \sigma \subset \mathcal{C}_U[s]$ (the characteristic function of $U[s]$), $u, v \in W_e^\sigma$;
      (ii) $r_{R,V} \subseteq \tau \subset \mathcal{C}_V[s]_{\mathcal{C}_V[u,v]}$, and $V[s]_{\mathcal{C}_V[u,v]}$ and $V[s]$ give the same equivalence classes relatively to all $i < e_R$ (this is for the sake of not modifying the equivalence classes of any such $i$, so that $F_i^S$ is not injured), and finally $V[s]_{\mathcal{C}_V[u,v]}$ and $V[s]$ give the same equivalence classes relatively to all currently defined $x_i^V, y_i^V$, with $i < e_R$ (this is for the sake of not modifying the equivalence classes of any such $x_i^V, y_i^V$, so that the restraint imposed by $Q_i^V$ is not injured).
   (b) $R = Q_e^U$ and $f^U(\langle x_e^U, y_e^U \rangle, s) = f_e(\langle x_e^U, y_e^U \rangle, s + 1)$, where $(x_e^U, y_e^U)$ is the witness of $R$ at the end of stage $s$.

The construction. At stage $s$ we define approximations to $f^S(\_ s)$ and $\gamma^S(\_ s)$ for $S \in \{U, V\}$ ($U[s]$ and $V[s]$ will be the equivalence relations having $f^U(\_ s)$ and $f^V(\_ s)$ as characteristic functions, respectively), and the approximations to the various parameters, including $r_{R,S}$ and $r_{R,S}^-$. We will often omit to mention the stage to which a given parameter is referred, if this is clear from the context. Unless otherwise specified at each stage each parameter keeps the same values as at the previous stage. It will be clear
from the construction that at each stage \( s \geq 1 \), \( U[s] \) and \( V[s] \) are equivalence relations with only finite equivalence classes and such that almost all equivalence classes are singletons.

**Stage 0.** Initialize all \( Q \)-requirements; no \( P \)-requirement is inactive; for \( S \in \{U, V\} \) define \( f^S(x, 0) := 0 \) and \( \gamma^S(x, 0) := a \) for all \( x \). Define \( S[0] := \emptyset \). 

**Stage 1.** For \( S \in \{U, V\} \) define \( S[1] := \text{Id} \), with suitable definitions of \( f^S(\_1, 1) \) and \( \gamma^S(\_1, 1) \) (similar to the definitions of \( f \) and \( \gamma \) at stage 1 in the proof of Theorem 3.2).

**Stage \( s + 1 \geq 2 \).** Consider the highest priority requirement \( R \) that requires attention. (Notice that there is always such a requirement since at each stage almost all \( Q \)-requirements are initialized). Action:

1. If \( R \) is initialized, then \( R = P^S_e \) for some \( e \) and \( S \in \{U, V\} \). Assume \( S = U \): the other case is similar, and is treated by interchanging the roles of \( U \) and \( V \). Choose a new fresh witness \( (x^U_e, y^U_e) \) for \( R \), i.e. \( (x^U_e, y^U_e) = (2i, 2i + 1) \) where \( i \) is bigger than all numbers so far used in the construction: we may as well suppose that still \( f_e(\langle x^U_e, y^U_e \rangle, s + 1) = 1 \), but \( f^U(\langle x^U_e, y^U_e \rangle), s) = 0 \), and \( \gamma^U(\langle x^U_e, y^U_e \rangle, s + 1) = \gamma^U(\langle x^U_e, y^U_e \rangle, s) = a \). Let \( r_{R,UV} \) be the least string extending \( r_{R,UV} \), such that \( r_{R,UV}(\langle x^U_e, y^U_e \rangle) \downarrow \), and \( r_{R,UV} \subseteq U[s] \); let \( r_{R,V} := r_{R,UV}. \) Let \( U[s + 1] := U[s] \), and \( V[s + 1] := V[s] \).

2. Otherwise:
   a. \( R = P^S_e \) for some \( e \) and \( S \in \{U, V\} \). Suppose that \( S = U \), the other case being similar, and treated by interchanging the roles of \( U \) and \( V \). Then pick the least quadruple \( (\sigma, \tau, u, v) \) such that the pairs \( (\sigma, \tau) \) and \( (u, v) \) are as in the definition of requiring attention; declare \( P^S_e \) inactive (and it will remain inactive as long as the requirement is not initialized); define \( r_{R,UV} := \sigma \) and \( r_{R,V} := \tau \) (notice that if eventually \( \tau \) is an initial segment of \( V \) then the numbers \( u, v \) are \( V \)-collapsed for the sake of \( R \)). On pairs \( \langle x, y \rangle \) that are \( V \)-collapsed following this action define \( f^V(\langle x, y \rangle, s + 1) := 1 \) and \( \gamma^V(\langle x, y \rangle, s + 1) := 1 \). Define \( U[s + 1] := U[s] \) and \( V[s + 1] := V[s] \).
   b. \( T = Q^S_e \): assume that \( S = U \), the other case being similar, and treated by interchanging the roles of \( U \) and \( V \). Define \( f^U(\langle x^U_e, y^U_e \rangle, s + 1) = f_e(\langle x^U_e, y^U_e \rangle), s + 1 \) and \( \gamma^U(\langle x^U_e, y^U_e \rangle, s + 1) := \gamma_e(\langle x^U_e, y^U_e \rangle, s + 1) \), so that we diagonalize \( U \) against \( E^U_e \) at witness \( (x^U_e, y^U_e) \). Define \( V[s + 1] := V[s] \) and \( U[s + 1] \) to be the equivalence relation such that \( x^U_U \ U[s + 1] \) \( y^U_U \) if and only if \( x^U_U \ U[s + 1] \) \( y^U_U \) and coinciding with \( U[s] \) on all other pairs. Set \( r_{R,V} := r_{R,V} \), and define \( r_{R,UV} \) to be the least string defined on \( \langle x^U_U, y^U_U \rangle \) and such that \( r_{R,UV} \subseteq r_{R,UV} \cup cU[s + 1] \).

At the end of the stage, initialize all lower priority \( Q \)-requirements.
The verification. A straightforward inductive argument shows again that for every requirement \( R \) there is a least stage \( t_R \) such that no \( R' \) of higher priority than \( R \) nor \( R \) itself requires attention or acts at any \( s \geq t_R \). Hence all parameters for \( R \), including witnesses \( (x_i^S, y_i^S) \) and the restraints \( r_{R,S}, \bar{r}_{R,S} \), for \( S \in \{U,V\} \), reach a limit.

An argument similar to Lemma 3.4 enables us to conclude that all \( U \) - and \( V \)-equivalence classes are finite and each \( R \) is satisfied. Let us check this in the particular case \( R = P^U_e \). First of all notice that whenever we \( V \)-collapse two numbers \( u, v \) for the sake of \( R \), then the \( V \)-classes of these two numbers will never be separated again: indeed, no future choice of a string \( \sigma = r_{R',V} \), for some \( P \)-requirement \( R' = P^V_i \), can do this when choosing \( \sigma \) so that \( u', v' \in W_\sigma^e \), for some pair \( u', v' \), because such a \( \sigma \) is chosen so that \( T_\sigma \) is the same equivalence relation as at the previous stage and thus it does not introduce any new change in the corresponding characteristic function; on the other hand no \( Q \)-requirement can separate the \( V \)-classes of \( u, v \) because by the analogue of Lemma 3.4, \( Q \)-requirements may only move pairs of numbers of different parity. Now, if \( W_e^U \) is infinite then by the finiteness of the \( V \)-equivalence classes, it enumerates a distinct pair \( u, v \) of the same parity which are not restrained from being \( V \)-collapsed by higher priority requirements (which request not to modify the finitely many \( V \)-equivalence classes they use). Then there certainly are \( \sigma, \tau \) and a stage \( t \) such that \( R \) is never initialized after \( t \), \( \sigma \) is an initial segment of the characteristic function of \( U \) and \( u, v \in W_e^U \) at any stage \( s \geq t \), \( \tau\langle u, v \rangle = 1 \) and \( \tau \) is \((R,V)\)-compatible at any stage \( s \geq t \). Then at any such stage \( s \geq t \) the pairs \( (\sigma, \tau) \) and \( (u, v) \) are eligible to make \( P_e \) require attention if \( P_e \) is still active. In this case the action requested by the construction at such a stage makes \( u, v \in W_e^U \) and \( u \neq v \), achieving that \( W_e^U \) is not an infinite transversal for \( V \).

An argument similar to Lemma 3.4 enables us also to conclude that \( U, V \in \Sigma_a^{-1} \) and that the pairs \( \langle f^U, \gamma^U \rangle \) and \( \langle f^V, \gamma^V \rangle \) are \( \Sigma_a^{-1} \)-approximations to \( U, V \), respectively.

Finally, the case when \( \mathcal{X} = \Pi_a^{-1} \) for some notation \( a \) with \( |a|_\mathcal{O} > 1 \) is treated exactly as in Theorem 3.2. \( \square \)

As anticipated by Remark 3.3, Theorem 3.2 immediately follows from Theorem 4.6 and Proposition 4.3.

Our goal now is to prove that no pair of mutually dark equivalence relations can have infimum. To show this, we make use of the operation \( R \mapsto R \oplus \text{Id}_1 \), that has been greatly exploited in [3]. This operation can be viewed as an inverse of the operation on equivalence relations obtained by collapsing two equivalence classes, and leading from an equivalence relation \( R \) to \( R_{\text{coll}(x,y)} \). In fact, if \( R \) is an equivalence relation and \( z \) is a number such that \( [z]_R \) is not a singleton, then define \( R_{\langle z \rangle} \) to be the equivalence relation

\[ x \sim_{R_{\langle z \rangle}} y \iff x = y \lor [x \sim R y \land z \notin \{x, y\}] \]
So we see that in getting $R[z]$ instead of collapsing two equivalence classes we do exactly the opposite, i.e. splitting an equivalence class into two classes. We have:

**Lemma 4.7.** For every $z$ such that $[z]_R$ is not a singleton, $R \oplus \text{Id}_1 =_c R[z]$.

*Proof.* To show $R[z] \leq_c R \oplus \text{Id}_1$, consider the computable function $f$ where

$$f(x) = \begin{cases} 1, & \text{if } x = z, \\ 2x, & \text{if } x \neq z. \end{cases}$$

To show $R \oplus \text{Id}_1 \leq_c R[z]$, pick $y \neq z$ in the equivalence class of $z$, and consider the computable function $g$,

$$g(x) = \begin{cases} \frac{y}{2}, & \text{if } x \text{ even and } \frac{y}{2} \neq z, \\ y, & \text{if } x \text{ even and } \frac{y}{2} = z, \\ z, & \text{if } x \text{ is odd}. \end{cases}$$

□

The following lemma has been proved in [3] for ceers (see Observation 4.2 and Lemma 4.6 of [3]), but the same proof works whatever equivalence relation $R$ one starts with.

**Lemma 4.8.** If $R$ is dark then $R < R \oplus \text{Id}_1$.

*Proof.* We recall how the proof goes. First of all one shows that if $R$ is dark then $R$ is self-full i.e. any reduction $f : R \leq_c R$ must have range that intersects all equivalence classes: indeed, if $f$ were a reduction missing say the equivalence class of $a$, then the orbit $\operatorname{orb}_f(a)$ would be easily seen to provide a transversal for $R$. Next, one easily shows that if $S$ is a self-full equivalence relation then $S < c S \oplus \text{Id}_1$ (in fact it is shown in [3] that $S$ is self-full if and only if $S < c S \oplus \text{Id}_1$). □

**Lemma 4.9.** If $R, S \in \Sigma_a^{-1}$ and $R|_d S$ then $R, S$ do not have inf in the $\Sigma_a^{-1}$-equivalence relations.

*Proof.* Let $R, S \in \Sigma_a^{-1}$ be such that $R|_d S$, and suppose that $T$ is an infimum of $R, S$ in $\Sigma_a^{-1}$, i.e. $T \leq_c R, S$ and for every $Z$ such that $Z \leq_c R, S$ we have $Z \leq_c T$. It is clear that $T$ is not finite. Let $f, g$ be computable functions reducing $T$ to $R$ and $S$. We claim that $f$ and $g$ do not hit respectively all the $R$-classes and all the $S$-classes, i.e. there exist numbers $y_R, y_S$ such that for every $x$, $f(x) \not\in R y_R$ and $g(x) \not\in S y_S$, respectively. Suppose for instance that for every $y$ there exists $x$ such that $f(x) \in R y$. Then it is easy to define an $R$-computable function $f^*$ reducing $R \leq_c T$: just set $f^*(y) = x$ where $x$ is the least number such that $f(x) \in R y$. It follows that $g \circ f^*$ is an $R$-computable function reducing $R \leq_{\deg f(R)} S$ contradicting that $R|_d S$. In a similar way one shows that the range of $g$ avoids some $S$-classes.
We now derive a contradiction by showing that $T \oplus \text{Id}_1 \leq_c R, S$ and applying Lemma 4.8. We use the existence of $y_R$ to show that a suitable reducing computable function $f^-$ is given by

$$f^-(x) = \begin{cases} f(x), & \text{if } x \text{ even,} \\ y_R, & \text{if } x \text{ odd.} \end{cases}$$

A similar argument shows that $T \oplus \text{Id}_1 \leq_c S$. □

We are now in a position to prove:

**Theorem 4.10.** For $a \in \mathcal{O}$ such that $|a|_\mathcal{O} > 0$, there are two properly $\Sigma^{-1}_a$ equivalence relations without infimum.

**Proof.** By Theorem 4.6 and Lemma 4.5 let $R, S$ be two equivalence relations lying properly in $\Sigma^{-1}_a$ such that $R|_a S$. Then by Lemma 4.9 $R$ and $S$ have no inf. □

Having shown that no pair of mutually dark $c$-degrees can have infimum, it is natural to ask whether one can obtain the same with dark equivalence relations. The next result answers negatively this question: there are infinitely many levels of the Ershov hierarchy which properly contain a pair of dark equivalence relations with infimum. This contrasts to the case of ceers (where no pair of dark ceers have infimum, see [3]) and thus vindicates the idea that mutual darkness is the correct analogous of darkness for $\Delta^0_2$ equivalence relations.

**Theorem 4.11.**

(1) There are dark equivalence relations $R, S \in \Pi^{-1}_2$ such that $R$ and $S$ have an infimum.

(2) For every $a \in \mathcal{O}$ such that $|a|_\mathcal{O} > 0$, there are dark $\Delta^0_2$ equivalence relations $E, F \not\in \Sigma^{-1}_a$ such that $E$ and $F$ have an infimum.

**Proof.** (1) Let $(x_m, y_m)$ be a minimal pair of c.e. $m$-degrees. We choose c.e. sets $X \in x_m$ and $Y \in y_m$. We also choose a dark ceer $Q$.

We will show that the equivalence relations $R := F_X \oplus Q$ and $S := F_Y \oplus Q$ have infimum $T = \text{Id}_2 \oplus Q$, where $F_X, F_Y$ are as in Lemma 2.1. It is clear that $T$ is a lower bound for $R$ and $S$. Furthermore, by Lemma 2.1 both $R$ and $S$ are $\Pi^{-1}_2$ relations. In addition, the darkness of $Q$ ensures that $R$ and $S$ are dark.

Assume that $E$ is a lower bound of $R$ and $S$. Consider a reduction $g: E \leq_c R$. Then exactly one of the following three cases holds:

(a) range($g$) does not contain even numbers. Then the function $g_1: x \mapsto [g(x)/2]$ is a reduction from $E$ to $Q$, and we have $E \leq_c Q \leq_c T$.

(b) There is only one class $[w]_E$ such that $g([w]_E) \subseteq 2\omega$. Then the set $[w]_E$ is computable, and the function

$$g_2(x) := \begin{cases} 0, & \text{if } x \in w, \\ g(x), & \text{otherwise;} \end{cases}$$

gives a reduction from $E$ to $\text{Id}_1 \oplus Q$. Thus, $E \leq_c \text{Id}_1 \oplus Q \leq_c T$. 

(2) For every $a \in \mathcal{O}$ such that $|a|_\mathcal{O} > 0$, there are dark $\Delta^0_2$ equivalence relations $E, F \not\in \Sigma^{-1}_a$ such that $E$ and $F$ have an infimum.
(c) There are two different classes \([u]_E\) and \([v]_E\) such that \(g([u]_E \cup [v]_E) \subseteq 2\omega\). Note that if \(x_Eu\) and \(x_Ev\), then \(g(x)\) must be an odd number.

We distinguish two cases. If the class \([u]_E\) is computable, then it is easy to show that \(E \leq_c \text{Id}_2 \oplus Q\). Assume that \([u]_E\) is non-computable. Without loss of generality, suppose that \([u]_E\) is a co-c.e. set and \([v]_E\) is c.e. Hence, \([u]_E \leq_m X\). Recall that \(E \leq_c S\), and the relation \(S\) contains only one non-computable co-c.e. class, namely, the \(S\)-class \(\{2z : z \in Y\}\). Thus, we deduce that \([u]_E \leq_m Y\). Hence, the choice of the sets \(X\) and \(Y\) implies that the set \([u]_E\) must be computable (as its complement would be \(m\)-reducible to both \(X\) and \(Y\), and thus would be computable), which gives a contradiction.

In each of the cases above, we showed that \(E \leq_c T\), therefore, \(T\) is the greatest lower bound of \(R\) and \(S\).

(2) The proof of the second part is similar to the first one, modulo the following key modification: One needs to choose \(\Delta^0_2\) sets \(X\) and \(Y\) such that \(X, Y \notin \Sigma^{-1}_a\) and the \(m\)-degrees \(\text{deg}_m(X)\) and \(\text{deg}_m(Y)\) form a minimal pair. The existence of such sets is guaranteed by the following more general theorem: we prove that, in any \(\Sigma\)-level of the Ershov hierarchy that corresponds to a successor ordinal (i.e., having notation \(2^a\) for some \(a\)), there are \(T\)-degrees that form a minimal pair and do not contain any set of a lower \(\Sigma\)-level. Note also that any minimal pair with respect to \(\leq_T\) is also a minimal pair with respect to \(\leq_m\).

**Theorem 4.12.** For every notation \(a \in \mathcal{O}\), there are \(\Sigma_a^{-1}\) sets \(X, Y\) such that \(\text{deg}_T(X)\) and \(\text{deg}_T(Y)\) form a minimal pair and do not contain \(\Sigma_a^{-1}\) sets.

**Proof.** This theorem is a combination of the two following results. The first one is Selivanov’s result [24] about properness of every level in the Ershov hierarchy relative to Turing reducibility. The second one is Yates’ construction of a minimal pair of c.e. Turing degrees (see, e.g., [25]). Below we sketch how these two constructions can be combined together.

We satisfy the following infinite sequence of requirements (recall that, by Posner’s trick, we can consider the same index in an \(N\)-requirement, see [25]):

\[
N_e : \Phi^X_e = \Phi^Y_e = f \text{ is total } \Rightarrow f \text{ is computable,}
\]

\[
Q^X_e : X \neq \Psi^E_e \lor E_e \neq \Theta^X_e,
\]

\[
Q^Y_e : Y \neq \Psi^E_e \lor E_e \neq \Theta^Y_e,
\]

where \(\{\Phi_e\}_{e \in \omega}\) is an effective list of all Turing functionals, and \(\{\Psi_e, \Theta_e, E_e\}_{e \in \omega}\) is an effective list of all possible triples consisting of a pair of Turing functionals and a \(\Sigma_a^{-1}\) set. As before, we consider \(\langle f_e, \gamma_e \rangle\) as a \(\Sigma_a^{-1}\)-approximation to \(E_e\). We also build pairs \(\langle f^X, \gamma^X \rangle\) and \(\langle f^Y, \gamma^Y \rangle\) in order to get \(X\) and \(Y\).
Strategies for the requirements and their interactions. In the following we freely adopt language and terminology (length-agreement functions, tree of strategies, use functions, etc.: in particular a small Greek letter denotes the use function of a Turing functional denoted by the corresponding capital Greek letter) which belong to the jargon of the (infinite) priority method of proof: for details the reader is referred to [25].

A $Q$-requirement in isolation can be satisfied using Cooper’s idea in [6], as adapted by Selivanov [24] to the infinite levels of the Ershov hierarchy. Without loss of generality, we consider the strategy for $Q^X_e$, also we assume that each functional is nondecreasing by stage and increasing by argument. For the sake of convenience consider the following length-agreement function:

$$l(X, e, s) = \mu z (\forall x \leq z \ (X(x)[s] = \Psi^X_e(x)[s] \land \Theta^X_e [\psi_e(x)[s] = E_e \uparrow \psi_e(x)[s])).$$

Thus the strategy for $Q^X_e$ works as follows:

1. Choose a “big” witness $x_e = x$ at stage $s_0$, thus $f^X(x, s_0) = 0$ and $\gamma^X(x, s_0) = 2^a$.
2. Wait for a stage $s_1 > s_0$ such that $x \leq l(X, e, s_1)$.
3. “Put” $x$ into $X$, namely define $f^X(x, s_1 + 1) := 1$ and $\gamma^X(x, s_1 + 1) := a$.
4. Wait for a stage $s_2 > s_1$ such that $x \leq l(X, e, s_2)$.
5. Thus at stage $s_2$ we have that $f_e(z, s_1) \neq f_e(z, s_2)$ and $a \supseteq \gamma_e(z, s_1) > \gamma_e(z, s_2)$ for some element $z < \psi_e(x)[s_1]$. Moreover, from this stage on we have (in case $X$ changes only at $x$) that if $x \leq l(X, e, s)$ then $f^X(x, s) = 0$ if and only if $f_e(z, s) = f_e(z, s_1)$. This means that by putting and extracting $x$ we force $z$ to go in and out from $E_e$.
6. Thus, we define $f^X(x, s_2 + 1) := 0$ and $\gamma^X(x, s_2 + 1) := \gamma_e(z, s_2)$.
7. At later stages $s$, if we see that $x \leq l(X, e, s)$ then define $f^X(x, s + 1) := 1 - f^X(x, s)$ and $\gamma^X(x, s + 1) := \gamma_e(z, s)$. Clearly, if later $f_e(x, t) \neq f_e(x, s)$ for some $t > s$ then $\gamma_e(z, t) < \gamma_e(z, s)$. Thus, at stage $t$, if $x \leq l(X, e, t)$ then we can act the same as at stage $s$ and define (in particular) $\gamma^X(x, t + 1) = \gamma_e(z, t) < \gamma^X(x, s + 1)$.

Notice:

- If $Q^X_e$ can keep $X$ restrained below $\theta_e(\psi_e(x))$ then it is enough for the win.
- The function $\gamma^X(x, s)$ always has the possibility to be defined as notation of a smaller ordinal unless $\gamma_e(z, s) = 1$ (note that when $\gamma_e(z, s)$ turns into 1 the function $\gamma^X(x, s)$ has the possibility to have a last change, thus after this change for any $t > s$ we never see $x \not< l(X, e, t)$ and the strategy becomes satisfied).

Therefore, each $Q^X_e$-strategy changes $X(x)$ finitely many times and wins (if some initial part of $X$ is restrained). The restraint can easily be achieved by initialization of lower priority strategies. The strategy for $Q^X_e$ works in
the same way. Thus, each \(Q\)-strategy is a finitary strategy and has only one outcome \(fin\) on the tree of strategies.

An \(N\)-requirement in isolation is satisfied by waiting for an expansionary stages and restraining either \(\Phi^X_e\) or \(\Phi^Y_e\). The definition of an \(e\)-expansionary stage is as usual. Namely, let the length-agreement function be defined as follows:

\[
l(e, s) = \mu z (\forall u \leq z \ \Phi^X_e(u)[s] \Downarrow = \Phi^Y_e(u)[s] \Downarrow),
\]

and define a stage \(s\) to be \(e\)-expansionary if \(l(e, s) > l(e, t)\) for all \(t < s\). The goal of a strategy \(N_\alpha\) is to build a computable function: thus for a given \(u\) it waits for the first \(e\)-expansionary stage which covers \(u\). At this stage \(s\) the values of \(\Phi^X_e(u)[s] \Downarrow\) and \(\Phi^Y_e(u)[s]\) are the same as \(\Phi^X_e(u)\) and \(\Phi^Y_e(u)\) (unless \(N\) is initialized). Thus, each \(N\)-strategy has two outcomes \(\omega < fin\) on the tree of strategies, where it is satisfied vacuously below outcome \(fin\) and build a computable function below outcome \(\omega\).

The tree of strategy is a subtree of \(\{\omega < fin\}^{<\omega}\) with the usual ordering of nodes. At level \(k = 2e\) we put copies of the strategy \(N_\alpha\), at level \(k = 4e + 1\) we put copies of \(Q^X_e\), and at level \(k = 4e + 3\) we put copies of \(Q^Y_e\).

Similar to the construction of a minimal pair we analyze the most problematic case of interaction between strategies, namely the work of an \(N\)-strategy with several \(Q\)-strategies below its infinite outcome. So, let \(\eta \prec \omega \subset \alpha_1 \subset \alpha_2 \subset \cdots \subset \alpha_k\). Assume that each \(Q\)-strategy \(\alpha_i\) has current witness \(x_i\). Then it holds that \(x_i < \theta_1(\psi_1(x_i)) < x_{i+1} < \theta_{i+1}(\psi_{i+1}(x_{i+1}))\) for \(1 \leq i < k\). Now, if \(\alpha_i\) acts at stage \(s\) (in particular, either \(f^X(x_i, s)\) or \(f^Y(x_i, s)\) is changed) then \(x_{i+1}\) and all greater witnesses are canceled. Also we can visit any of these nodes \(\alpha_j\), where \(j < i\), only when we get the next \(\eta\)-expansionary stage \(t > s\), which means that \(\Phi^X_e(u)[s] \Downarrow = \Phi^Y_e(u)[s] \Downarrow = \Phi^X_e(u)[t] \Downarrow = \Phi^Y_e(u)[t] \Downarrow\) for any \(u < l(e, s)\). Therefore, if some \(\alpha_i\), where \(j < i\), acts at stage \(s\) then \(\eta\) continues to win, moreover \(\alpha_i\) is initialized and \(\alpha_j\) continues to win too since \(\theta_j(\psi_j(x_j))\) was smaller than \(x_i\) (note also that it does not matter whether \(\alpha_j\) works with \(X\)- or \(Y\)-side).

Below we sketch construction and verification, which can easily be expanded to more formal versions.

The construction. At stage \(s + 1\) we construct a computable approximation (with the help of substages) of the true path on the tree of strategies. Starting from the root node we perform actions relative to the visited node and decide its outcome, then we visit the node below the outcome and continue until we reach the node of length \(s\). When proceeding to the next stage, we initialize all nodes to the right to, or below, the visited one.

If we work with an \(N\)-strategy \(\eta\) at substage \(t + 1\) then we check whether the stage \(s + 1\) is \(\eta\)-expansionary. If it is so then \(\eta\) has outcome \(\omega\), otherwise \(\eta\) has outcome \(fin\).

If we work with a \(Q^X\)-strategy (the case of a \(Q^Y\)-strategy is totally similar) \(\alpha\) at substage \(t + 1\) then we assign a big witness \(x_\alpha = x\) (bigger then any number mentioned so far) and initialize all nodes below \(\alpha\). If witness \(x\) was
already assigned then check whether \( x \leq l(X, \alpha, s) \). If the answer is “no” then just take outcome \( \text{fin} \); if the answer is “yes” then initialize all nodes below \( \alpha \) and also define \( f^X(x, s + 1) := 1 \) and \( \gamma^X(x, s + 1) := \alpha \); moreover if the answer “yes” already happened at least one time (after assigning \( x \)) then there is the least \( z \) such that \( f_{\alpha}(z, s_1) \neq f_{\alpha}(z, s_0) \) and \( \gamma_{\alpha}(z, s_1) <_{\sigma} \gamma_{\alpha}(z, s_0) \leq_{\sigma} \alpha \), where \( s_0 + 1 \) is a stage such that \( \gamma^X(x, s_0 + 1) = \alpha \) and \( \gamma^X(x, s_0) = 2^a \) (namely, it is the stage when we initiated the attack using \( x \)) and \( s_1 + 1 \) is the next stage with answer “yes”, then define \( f^X(x, s + 1) := 1 - f^X(x, s) \) and \( \gamma^X(x, s + 1) := \gamma_{\alpha}(z, s) \), and initialize all strategies below \( \alpha \). In all of the cases the outcome is \( \text{fin} \).

The verification. The true path \( TP \), defined as the leftmost path on the tree of strategies visited infinitely often, clearly exists. It remains to show that each requirement is satisfied by a strategy on the true path. However, most of the arguments have been already presented in the previous discussions. Also, by induction it is easy to see that each strategy is initialized and initializes other strategies only finitely many times.

If \( \eta \in TP \) is an \( N \)-strategy then it clearly satisfies the corresponding requirement. Namely, waiting for \( \eta \)-expansionary stages allows to correctly see the value of the computation (also we assume that it happens after stage \( s_0 \) after which \( \eta \) is not initialized). If \( \alpha \in TP \) is a \( Q^X \)-strategy, then let \( s_0 \) be a stage after which \( \alpha \) is not initialized. Henceforth, after assigning the witness \( x \) the strategy \( \alpha \) either sees \( x > l(X, \alpha, s) \), or several times it sees \( x \leq l(X, \alpha, s) \) (which immediately forces \( f^X(x, s) \) to be changed by the construction). As previously argued, the case \( x \leq l(X, \alpha, s) \) can happen only finitely many times (we always have \( \gamma_{\alpha}(z, s) < \gamma^X(x, s) \) which allows at least one more change for \( \gamma^X(x, s) \)). \( \square \)

Going back to the proof of item (2) of Theorem 4.11, we can now reason as in (1) by using the sets \( X, Y \) constructed in the previous theorem. \( \square \)

5. The problem of the existence of suprema

In this section we consider the problem of when a given pair of \( \Delta^0_2 \) equivalence relations has a supremum. The problem is somehow more delicate than that the one concerning infima, discussed in the previous section. This is because a priori the existence of a supremum depends on the level of the Ershov hierarchy that we choose to consider: E.g., consider \( R, S \in \Sigma^{-1}_{a} \) and \( a <_{\sigma} b \). Since \( R \oplus S \in \Sigma^{-1}_{a} \) is an upper bound of \( \{R, S\} \), if \( T \) is a supremum of \( R \) and \( S \) at the \( \Sigma^{-1}_{b} \) level, then \( T \in \Sigma^{-1}_{a} \) as well and \( T \) is the supremum at the \( \Sigma^{-1}_{a} \) level. On the other hand, \( R \) and \( S \) can have sup inside \( \Sigma^{-1}_{a} \), but not have sup inside \( \Sigma^{-1}_{b} \). Therefore, we split the problem in two parts: we first provide a necessary condition for the nonexistence of suprema in \( \Delta^0_2 \), and then we restrict the focus to the \( \Sigma^{-1}_{a} \) equivalence relations.

5.1. Nonexistence of suprema in \( \Delta^0_2 \). The next theorem shows that mutual darkness forbids the existence of suprema in \( \Delta^0_2 \).
Theorem 5.1. If $R, S \in \Delta^0_2$ are mutually dark, then they have no sup in $\Delta^0_2$.

Proof. Towards a contradiction, assume that $T \in \Delta^0_2$ is the supremum of $R, S$. We build $U \in \Delta^0_2$ such that $U$ is an upper bound of $R, S$ and avoids the upper cone of $T$. That is to say, we build $U$ satisfying the following requirements

$$
P_e : \varphi_e \text{ does not reduce } T \text{ to } U,
Q^R : R \leq_c U,
Q^S : S \leq_c U.
$$

Strategy for the requirements. Call the $R$-part (resp. $S$-part) of $R \oplus S$ the one consisting of all even (odd) numbers. Our idea is to construct $U \supseteq R \oplus S$ by injectively merging equivalence classes of the $S$-part of $R \oplus S$ with classes of $R$-part of $R \oplus S$ and by these actions meeting the above requirements. Eventually, each equivalence class of $U$ will consist of the union of exactly two equivalence classes of $R \oplus S$, one belonging to its $R$-part and the other to its $S$-part.

The strategy for meeting a single $P_e$-requirement is straightforward. We look for a pair of distinct numbers $u, v$ such that $\varphi_e(u) \downarrow x_e, \varphi_e(v) \downarrow y_e$ and $x_e, y_e$ have different parity. When found, we distinguish two cases:

1. If $u < T v$, we do nothing and keep $[x_e]_U$ and $[y_e]_U$ separate;
2. If $u \geq T v$, we merge $[x_e]_U$ and $[y_e]_U$ and keep them together.

The strategy prevents $\varphi_e$ from being a reduction of $T$ to $U$. Indeed, if $\varphi_e$ is total and fails to converge on elements with different parity, then range$(\varphi_e)$ must be all contained in either the $R$-part or the $S$-part of $R \oplus S$. Without loss of generality assume range$(\varphi_e)$ is a subset of the $S$-part of $R \oplus S$. If so, one can easily construct from $\varphi_e$ a computable $f$ reducing $T$ to $S$. But since $R \leq_c T$, we would have $R \leq_c S$, contradicting the fact that $R$ and $S$ are incomparable.

To deal with $Q$-requirements, we let $U$ be initially equal to $R \oplus S$. So at first stage of the construction we have that $R \leq_c U$ via $\lambda x.2x$ and $S \leq_c U$ via $\lambda x.2x + 1$. We claim that this is not injured by the subsequent action of any $P$-requirement. To see why, consider for instance $R$. $R$ is obviously reducible to $R \oplus S$ via $\lambda x.2x$. Now let $U$ be obtained from $R \oplus S$ by merging a class of its $R$-part (say, $[2k]_{R \oplus S}$) with a class of its $S$-part (say, $[2j + 1]_{R \oplus S}$). Then $R \leq_c U$, since no equivalence classes in the range of $\lambda x.2x$ have been collapsed. A similar reasoning can be made for $S$. Hence if we allow $P_e$ to merge only equivalence classes with different parity, we obtain that the $Q$-requirements are automatically satisfied.

Interaction between strategies. To combine all strategies, we have to address the following difficulty. When $P_e$ wants to collapse a given pair of equivalence classes we need to be careful that this does not imply collapsing also, by
transitivity, equivalence classes of the same parity, because if this happens we might injure a $Q$-requirement. Suppose for instance that $P_j$ wants to collapse $[2k]_U$ and $[2j+1]_U$ but $P_e$ already collapsed $[2k]_U$ and $[2i+1]_U$. If we let $P_j$ be free to act, then by transitivity it would collapse two equivalence classes of the same parity, i.e., $[2j+1]_U$ and $[2i+1]_U$. To avoid this, we define the following priority ordering of the requirements

$$P_0 < P_1 < \ldots P_e < \ldots$$

Next, $P_e$ looks for numbers $u, v$ such that $\varphi_e(u)$ and $\varphi_e(v)$ have different parity and come from fresh equivalence classes of $R \oplus S$, i.e., neither $u$ nor $v$ belongs to equivalence classes already collapsed in the construction. A similar condition seems $\Sigma^0_2$. $P_e$ asks whether there exist $u, v$ not being in the union of finitely many $\Delta^0_2$ sets (i.e., the equivalence classes already collapsed). Nonetheless, by making use of the fact that $R$ and $S$ are mutually dark we will prove that $0'$ can decide such condition (see Lemma 5.2).

The construction. We build $U$ in stages, i.e., $U = \bigcup_{k \in \omega} U[k]$. During the construction we keep track of the equivalence classes that we collapse by putting a witness them in a set $Z$.

Stage 0. $U[0] = R \oplus S$ and $Z = \emptyset$.

Stage $s + 1 = 2e$. We deal with $P_e$. In doing so, we execute the following algorithm (which is computable in $0'$): List all pairs of distinct numbers $(u, v)$ until one of the following cases happens

(1) $\varphi_e(u) \downarrow = x_e, \varphi_e(v) \downarrow = y_e$, and
(a) either $u T v \Leftrightarrow x_e U y_e,$
(b) or $x_e$ and $y_e$ have different parity and $\{x_e, y_e\} \cap Z = \emptyset$;
(2) there is $\varphi_e(x) \uparrow$.

Lemma 5.2 proves that the algorithm always terminate. If it terminates with outcome (1.b), let $U[s+1] = U[s]_{\text{coll}(x_e, y_e)}$ and put $[x_e]_R \oplus S$ and $[y_e]_R \oplus S$ in $Z$; if it terminates with outcome (1.a) or (2), do nothing.

Stage $s + 1 = 2e + 1$. We ensure that eventually any $U$-class will be the merging of an $R$-class and a $S$-class. To do so, let $u_e$ (resp. $v_e$) be the least even (odd) number not in $Z$. Let $U[s + 1] = U[s]_{\text{coll}(u_e, v_e)}$ and put $[u_e]_R \oplus S$ and $[v_e]_R \oplus S$ in $Z$.

The verification. The verification is based on the following lemma.

Lemma 5.2. For all $P_e$, the algorithm defined at stage $2e$ terminates.

Proof. Assume that there is $P_e$ for which the algorithm does not terminate. This means that $\varphi_e$ is total (otherwise, the algorithm at some point would outcome (2)) and $\varphi_e$ reduces $T$ to $U$ (otherwise, at some point the algorithm would outcome (1.a)). Moreover, $\varphi_e$ can not hit infinitely many equivalence classes of both the $R$-part and the $S$-part of $R \oplus S$. Otherwise, the algorithm would eventually find a pair of fresh equivalence classes with different parity.
Without loss of generality, assume that \( \varphi_e \) hits only finitely many classes in the \( R \)-part of \( R \oplus S \) and let \( A = \{a_0, \ldots, a_n\} \) be a transversal of such classes and let \( B = \{b_0, \ldots, b_n\} \) be a set of odd numbers such that, for all \( 0 \leq i \leq n \), \( a_i U b_i \). The existence of such \( B \) is guaranteed by the fact that each equivalence class of the \( R \)-part of \( R \oplus S \) is merged in \( U \) with an equivalence class of the \( S \)-part of \( R \oplus S \). But then one can define the following \( \deg(R) \)-computable reduction from \( T \) to \( U \) that hits only the \( S \)-part of \( U \),

\[
f(x) = \begin{cases} 
\varphi_e(x) & \varphi_e(x) \text{ is odd}, \\
b_z, \text{ where } z \text{ is such that } xRa_z & \text{otherwise}.
\end{cases}
\]

It follows that \( R \leq \deg(R) S \), contradicting the fact that \( R|_a S \).

We are in the position now to show that all \( P \)-requirements are satisfied. The last lemma guarantees that, given \( P_e \), the corresponding strategy terminates with either disproving that \( \varphi_e \) is a reduction from \( T \) to \( U \) or by providing two equivalence classes that can be collapsed in \( U \) to diagonalize against \( \varphi_e \). The \( Q \)-requirements are also satisfied because we carefully avoid, within the construction, to collapse classes of the same parity.

By modifying the last proof, we can obtain something stronger.

**Theorem 5.3.** If \( R, S \in \Delta^0_2 \) and \( R \) is \( S \)-dark or \( S \) is \( R \)-dark, then \( R, S \) have no sup in \( \Delta^0_2 \).

**Proof Sketch.** Suppose that \( S \) is \( R \)-dark. Then the proof of Proposition 4.5 shows that \( R \not\leq \deg_T(R) S \).

Assume that \( T \) is a \( \Delta^0_2 \) equivalence relation, and \( T = \sup\{R, S\} \). We construct a \( \Delta^0_2 \) equivalence relation \( U \) by employing precisely the same construction as in Theorem 5.1. In order to verify the construction, it is sufficient to re-prove Lemma 5.2 as follows.

Suppose that for some \( e \in \omega \), the algorithm for \( P_e \) does not terminate. Then, arguing as above, we may assume that:

1. The function \( \varphi_e \) is total,
2. \( \varphi_e : T \leq c U \), and
3. \( \varphi_e \) does not hit infinitely many classes of either the \( R \)-part or the \( S \)-part of the relation \( R \oplus S \).

Thus, one of the following two cases holds.

**Case 1.** The function \( \varphi_e \) hits only finitely many classes in the \( R \)-part and infinitely many classes in the \( S \)-part. Then the same argument as in the proof of Lemma 5.2 shows that \( R \leq \deg_T(R) S \), which contradicts the \( R \)-darkness of \( S \).

**Case 2.** Assume that \( \varphi_e \) hits infinitely many classes in the \( R \)-part and only finitely many classes in the \( S \)-part. Then choose a computable function \( h : S \leq c T \), and consider a partial computable function

\[
f(x) := \begin{cases} 
\varphi_e(h(x))/2, & \text{if } \varphi_e(h(x)) \text{ is even}, \\
\uparrow, & \text{otherwise}.
\end{cases}
\]
Since the function $\varphi_e \circ h$ reduces $S$ to $U$, the c.e. set range($f$) intersects infinitely many $R$-classes. Therefore, one can choose an infinite $R$-c.e. set $A$ with the following properties: $A \subseteq \text{dom}(f)$ and $f(x) \neq f(y)$ for distinct $x, y \in A$. Note that the condition $f(x) \neq f(y)$ implies that $\varphi_e(h(x)) \neq \varphi_e(h(y))$, and this, in turn, implies $x \not\sim y$. Hence, $A$ is an $R$-c.e. transversal of $S$, which contradicts the $R$-darkness of $S$.

Therefore, one can re-prove Lemma 5.2 and verify the construction. □

The above result contrasts with the fact that Id and a dark ceer have always sup in the ceers: see [3, Observation 5.1].

5.2. Nonexistence of suprema at the same level of Ershov hierarchy. We turn now to the problem of whether there are equivalence relations $R, S \in \Sigma^{-1}_a$ with no supremum in $\Sigma^{-1}_a$. We know from [3] that this is the case for ceers: in particular, there are light ceers with no sup (in the class of ceers). The next proposition extends this fact to all levels of the Ershov hierarchy, with the exception of co-ceers.

Proposition 5.4. Suppose that $X \in \{\Sigma^{-1}_a, \Pi^{-1}_a : |a|_0 \geq 2\}$. There are light equivalence relations $R$ and $S$ such that both $R$ and $S$ properly belong to $X$, and $R, S$ have no sup in the $X$-equivalence relations.

Proof. Fix a set $A$ properly belonging to the class $X$. Consider two c.e. sets $U$ and $V$ such that $U$ and $V$ are $\leq_m$-incomparable. We define the relations $Q, R,$ and $S$ as follows:

\begin{align*}
Q &:= \text{Id} \cup \{(2y, 2y + 1), (2y + 1, 2y) : y \in A\}, \\
R &:= R_U \oplus Q, \\
S &:= R_V \oplus Q.
\end{align*}

It is easy to show that each of the relations $Q, R, S$ is light and properly belongs to $X$.

Assume that $T$ is the supremum of $\{R, S\}$. Without loss of generality, suppose that $0 \in U \cap V$. Since the relation

\[ E := (R_U \oplus R_V)_{\text{coll}(0, 1)} \oplus Q \]

is an upper bound for $R$ and $S$, we have $T \leq_c E$, and $T$ must be essentially 1-dimensional. Let $[a]_T$ be the unique non-computable $T$-class. The conditions $R \leq_c T$ and $S \leq_c T$ imply that

\[ (2) \quad U \leq_m [a]_T \text{ and } V \leq_m [a]_T. \]

Consider the essentially 2-dimensional relation $F := (R_U \oplus R_V) \oplus Q$. Since $T$ should be reducible to $F$, we have either $[a]_T \leq_m U$ or $[a]_T \leq_m V$. This fact and (2) together contradict the choice of $U$ and $V$. Thus, $R$ and $S$ have no supremum. □

In the previous proof making $R$ and $S$ properly lying in a given class $X$ has as a consequence that $R$ and $S$ are light. Nonetheless, we can build dark (and even mutually dark) equivalence relations with no supremum at the same level of the Ershov hierarchy. The next theorem proves more: we
combine what we know of the nonexistence of infima and suprema to build a pair of equivalence relations that fails to have either.

**Theorem 5.5.** There are mutually dark $\omega$-c.e. equivalence relations with neither inf nor sup in the degrees of $\omega$-c.e. equivalence relations.

**Proof.** If $U, V$ are $\omega$-c.e. equivalence relations which are mutually dark then a simplified version of the argument used in the proof of Lemma 4.9 shows that they have no inf in the degrees of $\omega$-c.e. equivalence relations.

If in addition $U, V$ are essentially 1-dimensional, with one non-computable class $X_U$ for $U$ and $X_V$ for $V$, such that $X_U|_m X_V$ then $U, V$ have no sup either in the $\omega$-c.e. equivalence relations. The argument for showing this is essentially as in the proof of Proposition 5.4. Indeed, assume $0 \in X_U \cap X_V$ and suppose by contradiction that $T$ is such a sup; now, consider the $\omega$-c.e. essentially 1-dimensional equivalence relation $(U \oplus V)_{coll(0,1)}$, which is an upper bound of both $U, V$, thus $T \leq_c (U \oplus V)_{coll(0,1)}$. But then $T$ is essentially 1-dimensional too, and thus has exactly one noncomputable equivalence class, say $X_T$. Since $U, V \leq_c T$ it must be $X_U \leq_m X_T$ and $X_V \leq_m X_T$. On the other hand, as $U \oplus V$ is an upper bound of both $U, V$, we have that $T \leq_m X_U$ or $X_T \leq_m X_V$, giving $X_V \leq_m X_U$ or $X_U \leq_m X_V$, contradiction. \[\square\]

It remains to show that $\omega$-c.e. equivalence relations $U, V$ as the ones used in the proof of Theorem 5.5 exist: this is the goal of the following lemma.

**Lemma 5.6.** There exist essentially 1-dimensional $\omega$-c.e. equivalence relations $U, V$ which are mutually dark and such that all equivalence classes of $U$ and $V$ are finite with the exception of exactly one $U$-equivalence class $X_U$ and one $V$-equivalence class $X_V$ for which we have that $X_U|_m X_V$.

**Proof.** We build equivalence relations $U, V$ so that the equivalence classes $X_U := [0]_U$ and $X_V := [0]_V$ are such that $X_U|_m X_V$, all other classes are finite, and $U, V$ are mutually dark.

**Requirements and strategies.** To achieve our goals, we build $U$ and $V$ to satisfy the following requirements, for every $e \in \omega$:

\[
F_e^V : e \not\in 0 \Rightarrow [e]_V \text{ finite,}
\]

\[
F_e^U : e \not\in 0 \Rightarrow [e]_U \text{ finite,}
\]

\[
P_e^V : W^V_e \text{ is not an infinite transversal for } U,
\]

\[
P_e^U : W^U_e \text{ is not an infinite transversal for } V,
\]

\[
I_{e,U}^V : \varphi_e \text{ does not } m \text{-reduce } [0]_U \text{ to } [0]_V,
\]

\[
I_{e,V}^U : \varphi_e \text{ does not } m \text{-reduce } [0]_V \text{ to } [0]_U.
\]

The priority ordering $<$ of the requirements is given by

\[
\ldots < F_e^V < F_e^U < P_e^V < P_e^U < I_{e,U}^V < I_{e,V}^U < \ldots.
\]
As in the proof of Theorem 4.6 we say that a requirement $R$ has priority position $e$, if $e$ is the position of $R$ in the above ordering: the priority position of $R$ will be denoted by $e_R$.

The strategies for these requirements will turn out to be finitary: each strategy will act only finitely often, and when acting it will modify only a finite amount of $U$ and $V$. The strategies will be similar to the ones in the proof of Theorem 4.6 with the simplification that we do not have to worry about limiting too much the number of changes in the characteristic functions of $U$ and $V$.

More precisely, as in the proof of Theorem 4.6 at any stage of the construction a requirement $R$ will inherit by the higher priority requirements two finite binary strings $r_{R,U}$ and $r_{R,V}$ (these strings are empty if $R$ is the highest priority requirement) which depend of course on the stage, and are initial segments of the current approximations of the characteristic functions of $U$ and $V$, respectively: these strings are the restraints which the strategy for $R$ is bound to preserve. In turn, $R$ will provide its own restraints, i.e. strings $r_{R,U} \supseteq r_{R,U}$ and $r_{R,V} \supseteq r_{R,V}$ which lower priority requirements are bound to preserve.

If $\sigma$ is a finite binary string then we say that $\sigma$ is an equivalence string if the set of pairs $\{ (x, y) : \sigma(\langle x, y \rangle) \downarrow = 1 \} \cup \text{Id}$ is an equivalence relation: call $T_\sigma$ this equivalence relation. Clearly, $T_\sigma$ is an equivalence relation in which all equivalence classes are finite, and almost all of them are singletons.

Strategy for $F^V_e$ and $F^U_e$. If $T \in \{ U, V \}$ then the strategy for $R = F^T_e$ consists in not allowing lower priority requirements to $T$-collapse any number to $e$ if at the given stage $e \notin T$. Outcome: If eventually $e \notin T$ then $[e]_T$ is finite as only higher priority requirements can add numbers to this equivalence class, but each such requirement acts only finitely often. The restraint strings imposed by the requirement are $r_{R,U}$ and $r_{R,V}$ which equal the least equivalence strings of length $\geq e$ which extend $r_{R,U}$ and $r_{R,V}$, respectively.

Strategy for $P^V_e$ and $P^U_e$. Consider the case $R = P^V_e$, the other one being similar. The strategy for $P^V_e$ works within the restraints imposed by $r_{R,U}$ and $r_{R,V}$. If $W^V_e$ hits infinitely many $U$-classes (which is the case if $W^V_e$ is an infinite transversal of $U$) then by finiteness of the restraints we can pick $a, b, c$ with $a \neq b$, such that $a, b$ are not so restrained from $U$-collapsing, and such that we can redefine $V$ respecting higher priority restraints so that $a, b \in W^V_e$. More precisely: $R$ waits for numbers $a, b$ and an equivalence string $\sigma \supseteq r_{R,V}$ such that $a \neq b$, $a, b \in W^\sigma_e$ and $a, b \notin W^\sigma_i$ for every $i \leq e_R$. Action: If and when the wait is over, requirement $R$ $U$-collapses $a, b$, sets $r_{R,V}$ to be the least such equivalence string $\sigma$, and $r_{R,U}$ to be the least equivalence string extending $r_{R,U}$ so that $r_{R,U}(\langle a, b \rangle) = 1$. Outcomes: If the strategy awaits forever, then $W^V_e$ hits only finitely many $U$-classes, and thus is not a transversal for $U$; otherwise the action guarantees that $W^V_e$ is not a transversal for $U$. 
Strategy for $I^U_V$ and $I^V_U$. Let us consider only the case $R = I^U_V$, the other one being similar. The strategy acts a first time by appointing a new witness $x_R$ (being new, it is not in any of the finitely many $U$-classes that are restrained by higher priority requirements, nor is in the current $[0]_U$); waits for $\varphi_e(x_R)$ to converge, meanwhile restraining $x_R$ out of $[0]_U$ (setting $r_{R,U}$ to be the least equivalence string extending $r_{R,U}((-0, x_R)) \downarrow = 0$).

Outcome of the first action: If the strategy waits forever then $\varphi_e$ is not total and thus the requirement is satisfied. If $\varphi_e(x_R)$ converges then $R$ acts a second time: if already $r_{R,V} = r_{R,V}^-$ then it keeps the same $r_{R,U}$, and sets $r_{R,V} = r_{R,V}^-$; otherwise restrains $\varphi_e(x_R) \notin [0]_V$, and $U$-collapses 0 and $x_R$ (setting $r_{R,U}$ to be the least equivalence string extending $r_{R,U}^-$ so that $r_{R,U}((-0, x_R)) \downarrow = 1$ and $r_{R,V}$ to be the least equivalence string extending $r_{R,V}^-$ so that $r_{R,V}((-0, \varphi_e(x_R))) \downarrow = 0$). Outcome of the second action: The outcome is a straightforward diagonalization showing that $\varphi_e$ fails to be a reduction on input $x_R$.

As we see, at each stage each requirement $R$ contributes, through $r_{R,U}$ and $r_{R,V}$, finite initial segments to the characteristic functions of the current approximations to $U$ and $V$, respectively. We will see that eventually these initial segments stabilize in the limit, and if $S$ has lower priority than $R$ then the limit strings proposed by $S$ extend those proposed by $R$: the characteristic functions of the final $U$ and $V$ will be the unions of these limit finite initial segments proposed by the requirements.

When we initialize a requirement $R$ at a stage $s$ we set as undefined its parameters $x_R$ and its restraints $r_{R,U}$ and $r_{R,V}$. An $F$-requirement requires attention at $s + 1$ if it is initialized; a $P$-requirement requires attention at $s + 1$ if it is initialized, or has not as yet acted after its last initialization but is now ready to act, i.e. we have found suitable $a, b, \sigma$. An $I$-requirement requires attention at $s + 1$ if it is initialized, or has not as yet acted after its last initialization but it is now ready to act either by acting a first time, or by acting a second time.

The construction. The construction is in stages. Unless otherwise specified at each stage each parameter keeps the same value as at the previous stage. We will often omit to mention the stage to which a given parameter is referred, if this is clear from the context.

Stage 0. Initialize all requirements, and let $U[0] = V[0] := \text{Id}$.

Stage $s + 1$. Let $R$ be the highest priority requirement requiring attention at $s + 1$: notice that such an $R$ exists since almost all requirements are initialized, and thus requiring attention.

We distinguish the various possible cases for $R$, where $T \in \{U, V\}$.

- $R = F^T_e$: Set $r_{R,U}$ and $r_{R,V}$ to be the least equivalence strings of length $\geq e_R$, which extend $r_{R,U}^-$ and $r_{R,V}^-$, respectively.
- $R = P^T_e$: 

(1) If $R$ is initialized then set $r_{R,U} = r_{R,U}'$ and $r_{R,V} = r_{R,V}'$;
(2) otherwise we find suitable $a, b, \sigma$: act as in the description of the strategy, picking the least such suitable triple and setting new suitable values for $r_{R,U}$ and $r_{R,V}$;

$R = I_e^{U,V}$ or $R = I_e^{V,U}$:

(1) If $R$ is initialized then define a new witness $x_R$, and act as in the description of the strategy by setting new suitable values for $r_{R,U}$ and $r_{R,V}$;
(2) otherwise $\varphi_e(x_R)$ has already converged, so act as in the description of the strategy and setting new suitable values for $r_{R,U}$ and $r_{R,V}$.

Let $U[s + 1] := T_{R,U}$, $V[s + 1] := T_{R,V}$. Initialize all strategies of lower priority than $R$ and go to next stage.

At the end of the construction, $U$ and $V$ are the relations formed by the pairs which appear at co-finitely many stages in the approximations $U[s]$ and $V[s]$.

The verification. We show by induction on the priority ordering that each requirement requires attention (and thus acts) only finitely often and it is eventually satisfied.

Suppose that the claim is true of every requirement $R' < R$, and let $t$ be the least stage after which no $R' < R$ requires attention. It is now immediate to see that after $t$, $R$ requires attention only finitely many times. It requires attention a first time at $t$ because it is still initialized, and then: if $R$ is an $F$-requirement then it will never require attention again; if $R$ is a $P$-requirement then it may require attention at most once more if later finds suitable $a, b$ and $\sigma$; finally if $R$ is an $I$-requirement trying to achieve that $\varphi_e$ is not a reduction, then it may require attention at most once more again if $\varphi_e(x_R)$ converges. This shows that there is a least stage $t_R$ after which neither any $R' < R$ nor $R$ requires attention.

Next, we show that for every $R$, with priority position $e_R$, the number of equivalence classes $[i]_T$, for $i < e_R$ and $T \in \{U, V\}$, does not change after $t_R$, nor does any such equivalence class, except for $[0]_T$, changes after this stage. This is so because no requirement of priority position $j > e_R$ can add numbers to $[i]_T$ if $i < e_R$ and $i \not\in 0$, due to the restraints imposed by the $F$-requirements of priority position $< e_R$: these restraints are respected by the lower priority $P$-requirements as after $t_R$ they may collapse only numbers currently not in these equivalence classes (nor in $[0]_T$ as well), and by the $I$-requirements as by initialization they pick their witnesses not in the current approximations to these equivalence classes. This claim shows also that the $F$-requirements are satisfied.

In the other cases, the last action performed by $R$ at the last stage at which it requires attention achieves satisfaction of $R$, as is clear by the description of the strategies given before the construction. We verify this in more detail only for the $P$-requirements, leaving to the reader the other
cases. Suppose $R = P^U_e$, the case $R = P^V_e$ being similar. Assume that $W^V_e$ is an infinite transversal for $U$. Then since the number of equivalence classes $\{i\}_T$, for $i < e_R$ and $T \in \{U, V\}$, does not change after $t_R$ and is finite, there is a stage $t \geq t_R$ at which $W^\sigma_T$, with $\sigma \subset c_V$, enumerates two distinct numbers $a, b$ not in any of these equivalence classes. But any finite string which is an initial segment of $c_V$ is an equivalence string, so we can certainly find at $t$ an equivalence string $\sigma \supseteq r^\sigma_{R,V}$ with $a, b \in W^\sigma_e$ at $t$, so that $R$'s action (if $R$ is still active) guarantees that $a U b$ and $a, b \in W^V_e$, contradicting that $W^V_e$ is a transversal.

We finally show that each $T \in \{U, V\}$ is $\omega$-c.e. Let $u \in \omega$, and let $R$ be the least $F$-requirement (say $R = F_T^e$) with $e_R > u$. The last time $R$ requires attention it sets a restraint $r_{R,T}$ of length $> u$ which hereinafter will be an initial segment of the approximation to the final characteristic function of $T$, and thus the value $c_T(u)$ will never change again. This shows that the number of possible changes of $c_T(u)$ is bound by the number of times $R$ is initialized, which is bound by the number of times requirements $R' < R$ act. Since such a requirement $R' < R$ can act at most twice after its last initialization, this shows that the number of possible changes of $c_T(u)$ is bound by $2^{e_R}$, where $e_R$ can be effectively computed from $u$. In conclusion $T$ is $\omega$-c.e.. \[\square\]

We conclude the paper with the following open question.

**Question 1.** For which $a \in \mathcal{O}$, there exist equivalence relations properly in $\Sigma^{-1}_a$ with sup in $\Sigma^{-1}_a$?

**Acknowledgements.** Part of the research contained in this paper was carried out while Bazhenov, Yamaleev, and San Mauro were visiting the Department of Mathematics of Nazarbayev University, Astana. These authors wish to thank Nazarbayev University for its hospitality.
